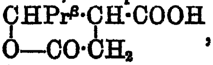
Propylitaconic acid, $COOH\cdot CH_2\cdot C(COOH)\colon CHPr$, crystallises from hot water and ether in prisms, melts at 159°, and is decomposed at about 200—210°, being probably converted into the anhydride. It is almost insoluble in chloroform and carbon bisulphide, and only sparingly soluble in cold water and benzene, but readily in ether, alcohol, and hot water. The *barium* salt, $C_8H_{10}O_4Ba$, contains water of crystallisation, and is more readily soluble in cold than in hot water.

F. S. K.

Isobutaldehyde and Succinic Acid. By R. FITTIG and A. ZANNER (*Annalen*, 255, 86—96; compare Abstr., 1886, 47, 1888, 251).

—*Isopropylparaconic acid*,



$$\begin{array}{l} CHPr^{\beta}\cdot CH\cdot COOH \\ \mid \qquad\quad\;\; \mid \\ O—CO\cdot CH_2 \end{array}$$

, is obtained by heating a mixture of isobutaldehyde, sodium succinate, and acetic anhydride at 110—120° for 40 hours. The acid is isolated as described in the case of ethylparaconic acid. It crystallises from boiling benzene in colourless plates, melts at 68—69°, and is readily soluble in water, ether, and chloroform, but only sparingly in carbon bisulphide, and insoluble in light petroleum. The *barium* salt, $(C_8H_{11}O_4)_2Ba + 3H_2O$, prepared by treating an aqueous solution of the acid with barium carbonate in the cold, crystallises in colourless plates. The *calcium* salt $(+2H_2O)$ crystallises in needles, and is readily soluble in water. The *silver* salt, $C_8H_{11}O_4Ag$, crystallises from boiling water in colourless needles, and does not darken on exposure to light.

Barium isopropylitamalate, $C_8H_{12}O_5Ba + 2H_2O$, is formed when the paraconic acid is boiled with baryta-water; it crystallises in small needles, and is more readily soluble in cold than in hot water. The *silver* salt, $C_8H_{12}O_5Ag_2$, is crystalline, almost insoluble in boiling water, and moderately sensitive to light.

When isopropylparaconic acid is distilled, isoheptolactone (dimethylvalerolactone) and isoheptylenic acid are formed with evolution of carbonic anhydride, whilst some of the acid passes over unchanged; the products can be separated in the usual manner (compare preceding abstract).

Isoheptylenic acid, $CHPr^\beta{:}CH{\cdot}CH_2{\cdot}COOH$, is a colourless oil, boils at 217° (thermometer entirely in vapour), and is volatile with steam; it is specifically lighter than and only sparingly (1 in 110) soluble in cold water, but it is much more readily soluble in hot water. The *barium* salt, $(C_7H_{11}O_2)_2Ba$, prepared in the cold, crystallises in anhydrous needles. The *calcium* salt ($+1\frac{1}{2}H_2O$) crystallises in transparent prisms. The *silver* salt, $C_7H_{11}O_2Ag$, crystallises from boiling water in slender needles, darkens on exposure to light, and decomposes at 100°.

γ-Bromoisoheptylic acid, $CHPr^\beta Br{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$, is formed when the preceding compound is treated with concentrated hydrobromic acid in the cold, but it cannot be obtained in a pure condition.

Isoheptolactone (*dimethylvalerolactone*),  $CHPr^\beta{<}\begin{array}{l}CH_2{\cdot}CH_2\\ O{-}CO\end{array}$, is formed when bromoisoheptylic acid is boiled with water, but it is more easily prepared by warming isoheptylenic acid with dilute (1 : 1) sulphuric acid. It is a colourless oil, boils at 224—225° (uncorr.), and is readily volatile with steam; it dissolves in about 35 parts of cold water, the solution becoming turbid on heating, and then clear again at a higher temperature.

Barium hydroxyisoheptylate, $(C_7H_{13}O_3)_2Ba$, is obtained when the lactone is boiled with baryta-water. The *silver* salt, $C_7H_{13}O_3Ag$, is only sparingly soluble in water. The free acid seems to be less stable than γ-hydroxyheptylic acid. F. S. K.

Valeraldehyde and Succinic Acid. By R. FITTIG and A. SCHNEEGANS (*Annalen*, 255, 97—108; compare Abstr., 1886, 47, 1888, 251).—*Isobutylparaconic acid*,  $CO{<}\begin{array}{l}O{-}CH{\cdot}CH_2Pr^\beta\\ CH_2{\cdot}CH{\cdot}COOH\end{array}$, is prepared by heating a mixture of valeraldehyde, acetic anhydride, and sodium succinate at 110° for 18 to 20 hours. The product is mixed with water, the separated oil extracted with ether and treated with sodium carbonate; unchanged valeraldehyde and condensation-products remain undissolved, whilst the lactonic acid passes into solution and is reprecipitated on the addition of acid. Some of the lactonic acid and unchanged succinic acid remain as sodium salts in the original acetic acid solution; after strongly acidifying with hydrochloric acid and extracting with ether, the two compounds are separated by treatment with chloroform. Isobutylparaconic acid crystallises from cold water in small needles, melts at 124—125°, and sublimes, when carefully heated, in colourless plates. It is readily soluble in alcohol, ether, chloroform, and light petroleum. The *silver* salt, $C_9H_{13}O_4Ag$, is very stable and soluble in hot water. The *calcium* salt, $(C_9H_{13}O_4)_2Ca + 2H_2O$, crystallises in small needles, and is soluble in alcohol and hot water. The *barium* salt $(+3H_2O)$ crystallises in small, well-defined, rhombic prisms, and is readily soluble in alcohol. The *zinc* salt $(+1\frac{1}{2}H_2O)$ crystallises in needles, and is readily soluble in water and alcohol.

The salts of isobutylitamalic acid do not crystallise, and are more sparingly soluble in hot than in cold water, and almost insoluble in alcohol. The *barium* salt, $C_9H_{14}O_5Ba$, prepared by boiling the paraconic acid with baryta-water, and the *calcium* salt are anhydrous. The *silver* salt, $C_9H_{14}O_5Ag_2$, is slowly decomposed by boiling water.

When isobutylparaconic acid is distilled, octolactone, isoctylenic acid, and isobutylitaconic acid are formed, but some of the paraconic acid passes over unchanged. The lactone is isolated in the usual manner, and the isoctylenic acid is separated from the isobutylparaconic acid and isobutylitaconic acid by distillation with steam.

Isoctylenic acid, $CH_2Pr^{\beta}\cdot CH\colon CH\cdot CH_2\cdot COOH$, is a colourless oil, boils at 231—232°, and is specifically lighter than, and almost insoluble in, water. The *silver* salt, $C_8H_{13}O_2Ag$, separates from boiling water in a flocculent condition. The *barium* salt, $(C_8H_{13}O_2)_2Ba$, is more sparingly soluble in hot than in cold water, and only sparingly soluble in alcohol. The *zinc* salt and the *lead* salt are amorphous.

γ-Bromisoctylic acid, $CH_2Pr^{\beta}\cdot CHBr\cdot CH_2\cdot CH_2\cdot COOH$, prepared by treating the unsaturated acid with cold concentrated hydrobromic acid, is a heavy, yellowish oil; it is converted into isoctolactone and isoctylenic acid by dilute sodium carbonate.

Isoctolactone, $CH_2Pr^{\beta}\cdot CH<\begin{matrix}CH_2\cdot CH_2\\ O\text{—}CO\end{matrix}>$, is a colourless liquid, volatile with steam, and only sparingly soluble in cold, but more readily in hot, water; when boiled with baryta-water, it yields the barium salt of hydroxyisoctylic acid as a yellowish, gum-like mass, soluble in hot alcohol, but only sparingly soluble in water.

Isobutylitaconic acid, $CH_2Pr^{\beta}\cdot CH\colon C(COOH)\cdot CH_2\cdot COOH$, is obtained, together with isobutylparaconic acid, when the acid solution which remains after distilling the isoctylenic acid with steam (see above) is extracted with ether. The mixture of acids is treated with water, neutralised with calcium carbonate in the cold, and the filtered solution heated to boiling, whereon *calcium isobutylitaconate*, $C_9H_{12}O_4Ca$, is deposited; the salt is washed with hot water, decomposed with hydrochloric acid, and the itaconic acid recrystallised from boiling water. It melts at 162°, being converted into the anhydride.

F S. K.

Valeraldehyde and Pyrotartaric Acid. By R. FITTIG and F. FEIST (*Annalen*, **255**, 108—125; compare Abstr., 1888, 251, and 1886, 47).—*α*- and *β*-Methylisobutylparaconic acids are obtained as follows:—A mixture of valeraldehyde, sodium pyrotartrate, and acetic anhydride is heated at 110—120° for about 30 hours, then treated with water, the unchanged aldehyde and the acetic acid distilled with steam, the residual solution filtered and extracted with ether. The residue obtained on evaporating the ether is dissolved in sodium carbonate, the alkaline solution shaken with ether, then acidified, and the lactonic acids extracted with ether. A small quantity of the lactonic acids remains, as sodium salts, in the original acetic acid solution, and can be isolated by extracting the strongly acidified solution with ether, evaporating the extract, and dissolving the two lactonic acids in chloroform, in order to free them from pyrotartaric acid. The two methylisobutylparaconic acids obtained in this way can only be separated with difficulty.

α-Methylisobutylparaconic acid,  $CO<\begin{matrix}O\text{——}CH\cdot CH_2Pr^{\beta}\\ CHMe\cdot CH\cdot COOH\end{matrix}$, crystallises from water in plates or prisms, and from benzene in needles, melting at 142°. It is readily soluble in ether, alcohol, chloroform, and hot benzene, but almost insoluble in light petroleum and carbon bisulphide. The *barium* salt, $(C_{10}H_{15}O_4)_2Ba + 2H_2O$, prepared by neutralising a cold aqueous solution of the acid with barium carbonate, crystallises in slender needles, and is readily soluble. The *calcium* salt ($+2H_2O$) is a colourless, semi-crystalline compound. The *silver* salt, $C_{10}H_{15}O_4Ag$, forms small, granular crystals, and is very stable.

Barium methylisobutylitamalate, $C_{10}H_{16}O_5Ba + 2H_2O$, is obtained when the paraconic acid is boiled with baryta-water; it is more readily soluble in cold than in hot water. The *calcium* salt ($+2H_2O$) is almost insoluble in both hot and cold water. The *silver* salt, $C_{10}H_{16}O_5Ag_2$, is very unstable.

When α-methylisobutylparaconic acid is distilled, carbonic anhydride is rapidly evolved; the principal product is isobutylbutylene, but small quantities of methylisobutylbutyrolactone, α-isononylenic acid, and valeraldehyde are also obtained. The distillate is treated with sodium carbonate, the neutral products extracted with ether, and boiled with baryta-water to decompose the lactone, which is thereby converted into *barium hydroxynonylate*, $(C_9H_{17}O_3)_2Ba$. The aldehyde and hydrocarbon are then distilled with steam, and the valeraldehyde separated by shaking with a concentrated solution of sodium hydrogen sulphite; the α-isononylenic acid is isolated from the alkaline solution, after acidifying, by distilling with steam.

Isobutylbutylene (*octylene*), C_8H_{16}, is a colourless liquid boiling at 111·5—112·5°; it combines with bromine yielding the *dibromide*, $C_8H_{16}Br_2$, as a colourless oil.

α-Isononylenic acid, $CH_2Pr^{\beta}\cdot CH{:}CH\cdot CHMe\cdot COOH$, is a colourless oil boiling at 235—240° with partial decomposition. The *calcium* salt, $(C_9H_{15}O_2)_2Ca + 3H_2O$, crystallises in small needles, and is readily soluble in water. The *silver* salt, $C_9H_{15}O_2Ag$, is stable and moderately easily soluble in warm water.

β-Methylisobutylparaconic acid,  $CO<\begin{matrix}O\text{—}CH_2\cdot CH_2Pr^{\beta}\\ CH_2\cdot CMe\cdot COOH\end{matrix}$ (see above), melts at 83°, and shows the same behaviour with solvents as the corresponding α-acid, only it is rather more sparingly soluble. The *barium* salt ($+4H_2O$) is obtained by treating the acid with barium carbonate in cold aqueous solution; it crystallises in prisms, and is very readily soluble. The *calcium* salt $(+2H_2O)$ forms small, feathery crystals. The *silver* salt, $C_{10}H_{15}O_4Ag$, is soluble in hot water

Calcium β-methylisobutylitamalate, $C_{10}H_{16}O_5Ca + H_2O$, prepared by boiling the paraconic acid with lime-water, is insoluble in water. The *barium* salt is anhydrous and almost insoluble in water. The *silver* salt, $C_{10}H_{16}O_5Ag_2$, is sparingly soluble in hot water and very stable.

When β-methylisobutylparaconic acid is distilled, it yields a hydrocarbon boiling at 111·5°, a lactone, and β-isononylenic acid. *Calcium β-isononylenate*, $(C_9H_{15}O_2)_2Ca + 3H_2O$, crystallises in needles, and is rather sparingly soluble in water. The *silver* salt, $C_9H_{15}O_2Ag$, is moderately stable and soluble in warm water. F. S. K.

Œnanthaldehyde and Pyrotartaric Acid. By R. Fittig and R. Rieckelmann (*Annalen*, **255**, 126—142; compare Abstr., 1888, 251).—Two isomeric methylhexylparaconic acids are formed when œnanthaldehyde is heated at 120—130° for 20 hours with sodium pyrotartrate and acetic anhydride. The product is treated with water, the unchanged aldehyde distilled with steam, and the residual solution extracted with ether. The oil obtained in this way is dissolved in sodium carbonate, the slightly alkaline solution shaken with a little calcium chloride solution and, after filtering, extracted with ether to free it from resinous products. The solution is then acidified strongly, the acids extracted with ether, repeatedly evaporated with water to expel acetic acid, and then dissolved in chloroform. On evaporating the chloroform solution, the two paraconic acids are obtained in an oily condition. The α-compound can be obtained in crystals by dissolving the mixture in carbon bisulphide and fractionally precipitating with light petroleum; in order to isolate the β-acid, the acids in the mother liquors are first purified by converting them into calcium salts, and then crystallised from a mixture of ether and light petroleum, the two kinds of crystals being separated mechanically.

α-Methylhexylparaconic acid,  $CO<\begin{matrix}O\text{———}CH\cdot C_6H_{13}\\ CHMe\cdot CH\cdot COOH\end{matrix}$, crystallises from water and carbon bisulphide in colourless plates, and from a mixture of ether and light petroleum in long, slender needles melting at 101°·5. It is very readily soluble in ether, alcohol, chloroform, carbon bisulphide, and benzene, but only very sparingly in water and light petroleum; it is not volatile with steam. The *calcium* salt, $(C_{12}H_{19}O_4)_2Ca + 5H_2O$, is obtained by neutralising an aqueous solution of the acid with calcium carbonate in the cold; it crystallises in needles and is readily soluble in water and alcohol. The *barium* salt $(+3H_2O)$ crystallises in needles and is readily soluble in both alcohol and water. The *silver* salt, $C_{12}H_{19}O_4Ag$, separates from water in colourless needles and is very stable. The *lead*, *copper*, *mercury*, and *ferrous* salts are insoluble in water, but readily soluble in ether.

Calcium methylhexylitamalate, $C_{12}H_{20}O_5Ca + H_2O$, prepared by boiling the lactonic acid with lime-water, is very sparingly soluble in water and insoluble in alcohol. The *barium* salt ($+ 2H_2O$) is very sparingly soluble in cold water. The *silver* salt, $C_{12}H\,{}_0O_5Ag_2$, is insoluble in water and very unstable; the *copper*, *iron*, *lead*, and *mercury* salts are insoluble in ether and alcohol.

The distillation products of α-methylhexylparaconic acid are decylene, œnanthaldehyde, pyrotartaric acid (or its anhydride), and traces of other compounds, but a considerable quantity of the acid passes over unchanged.

Decylene (*hexylbutylene*), $C_{10}H_{20}$, boils at 160—161°, and yields the dibromide, $C_{10}H_{20}Br_2$, as a yellow oil when it is treated with bromine in cold carbon bisulphide solution.

β-Methylhexylparaconic acid, 
$$CO<\begin{matrix}O\text{—}CH{\cdot}C_6H_{13}\\ \quad\ |\\ CH_2{\cdot}CMe{\cdot}COOH\end{matrix}$$

separates from carbon bisulphide in small crystals, and from a mixture of ether and light petroleum in large, cubical forms melting at 83°. It is readily soluble in ether, alcohol, chloroform, and benzene, but only moderately easily in carbon bisulphide and hot water. The *calcium* salt, with $2H_2O$, crystallises in slender needles and is readily soluble in water. The *barium* salt, with $3H_2O$, separates from water in well-defined prismatic crystals. The *silver* salt is moderately easily soluble in water and crystallises from dilute alcohol in slender needles.

Calcium methylhexylitamalate, $C_{12}H_{20}O_6Ca$, is sparingly soluble in hot water. The *barium* salt, with H_2O, separates from hot water, in which it is very sparingly soluble, in slender needles. The *silver* salt, $C_{12}H_{20}O_5Ag_2$, is insoluble in boiling water and is not very stable.

F. S. K.

Synthesis of Fumaric Acid. By E. H. Keiser (*Amer. Chem. J.*, **12**, 99—102).—According to Wislicenus' views of molecular structure, two varieties, an axially- and a plane-symmetrical, of acetylene diiodide should exist, corresponding respectively with fumaric and maleic acids. The author has prepared these by passing acetylene through absolute alcohol containing crystals of iodine until the iodine disappeared. One variety of acetylene diiodide is an unstable liquid, decomposing when heated, and even when distilled with steam. The other is solid, and is much more stable, subliming without decomposition; it is, therefore, probably the axially symmetrical variety. When boiled successively with potassium cyanide and aqueous potash, the latter variety yields a considerable quantity of potassium fumarate. The research is still in progress.

C. F. B.

Dibromotricarballylic Acid. By E. Guinochet (*Compt. rend.*, **110**, 350—352).—Dibromotricarballylic acid is formed, together with the dibromide of monobromaconitic acid (Abstr., 1889, 588) by the action of bromine (4 equivalents) on aconitic acid (1 equivalent) at 115—120°, and is separated from it by means of the solubility of the dibromotricarballylic acid in water. It forms slender, prismatic needles of the composition $C_6H_6Br_2O_6 + \frac{1}{2}H_2O$, very soluble in water, alcohol, and ether, and readily forming supersaturated solutions. Its salts are formed by mixing its solution with a concentrated solution of the particular base until neutral to phenolphthalein, and evaporating rapidly in a vacuum at the ordinary temperature. The *potassium salt*, $C_6H_3Br_2O_6K_3+3H_2O$, is a crystalline powder which decomposes at 130°; the *calcium salt*, $(C_6H_3Br_2O_6)_2Ca_3+4H_2O$, forms a vitreous solid which decomposes at 100° and is very soluble in cold water, forming a solution from which alcohol precipitates the anhydrous salt; the *barium salt*, $(C_6H_3Br_2O_6)_2Ba_3+5H_2O$, is a white, amorphous solid which does not alter at 100°, but decomposes at 115°.

Dibromotricarballylic acid melts below 100° and evolves hydrogen bromide, and on further heating, decomposes. If the fused but not discoloured substance is redissolved in water, it yields a crystalline mass with the properties of the original product. In a vacuum the acid loses weight continually, and the percentage of bromine and the basicity gradually increase. It does not decompose in solution in the cold. In presence of nitric acid, silver nitrate precipitates half the bromine. The aqueous solution decomposes when heated, and if silver nitrate is added, silver bromide is precipitated in quantity varying with the conditions of the experiment.

With sodium amalgam, dibromotricarballylic acid yields ordinary tricarballylic acid. C. H. B.

Guinochet's Isomeric Tricarballylic Acid. By R. Demuth and V. Meyer (*Ber.*, **23**, 529—531).—The tribromotricarballylic acid obtained by Guinochet (Abstr., 1889, 588) by heating aconitic acid with bromine is, in reality, dibromosuccinic acid, and Guinochet's isomeric tricarballylic acid (this vol., p. 238) is succinic acid.

F. S. K.

Action of Sodium and Potassium Ethoxides on Ethyl Tartrate. By E. Mulder (*Rec. Trav. Chim.*, **8**, 361—385).—Sodium was dissolved in pure anhydrous alcohol, and a slight excess of ethyl tartrate added. The mixture was placed in a flask connected with a vessel containing sulphuric acid, and a vacuum was established; at intervals the flask was weighed. The weight finally obtained corresponded with the formation of *ethyl sodiotartrate*, COOEt·CH(ONa)·CH(OH)·COOEt, but it seemed that some compounds of this with one or more molecules of alcohol were first formed. It forms a vitreous mass very soluble in pure alcohol, and insoluble in ether or benzene. It is very deliquescent, but is decomposed by water, alcohol, and ethyl sodium tartrate,

COONa·CH(OH)·CH(OH)·COOEt,

being formed; the latter is at once formed when ethyl tartrate is treated with sodium and ordinary absolute alcohol, which always contains some water.

Ethyl disodiotartrate, $C_2H_2(ONa)_2(COOEt)_2$, was prepared in the same way as the monosodium compound, half the weight of ethyl tartrate being used; it was found advantageous to work in an atmosphere of hydrogen. In its properties this substance resembles the monosodium compound; when it is decomposed by water, normal sodium tartrate is formed. *Mono-* and *di-potassium* compounds have also been prepared, and are still undergoing investigation.

The author has used ethyl chloride or iodide as a means of ascertaining whether a reaction has taken place. Sodium ethoxide dissolved in pure alcohol was added to a slight excess of ethyl tartrate, and then ethyl chloride was added, and the whole sealed up in a tube. If a reaction has taken place, since the ethyl tartrate was in excess, all the ethoxide will have been used up, and nothing will be observed when the ethyl chloride is added. But if no reaction has taken place, the ethyl chloride and sodium ethoxide will react, forming ether and sodium chloride, and the latter, being insoluble in alcohol, will be precipitated. In no case was a precipitate formed, and it was thus shown that the reactions had taken place as described above. In all cases another tube was taken, for the sake of comparison, containing the same quantities of the same substances (except the ethyl tartrate) as the first; this was submitted to the same conditions, and always gave a precipitate of sodium chloride, &c. C. F. B.

Preparation of Levulosecarboxylic Acid. By H. KILIANI and G. DÜLL (*Ber.*, **23**, 449—452).—In order to prepare levulosecarboxylic acid in large quantities for an examination of its behaviour on oxidation, the authors have endeavoured to improve the method previously adopted. An attempt was made to isolate the acid in the form of its phenylhydrazide, according to Fischer and Passmore's method (this vol., p. 152), but even when pure levulosecarboxylic acid was used as the starting point, the phenylhydrazide does not crystallise out until the solution has been evaporated to a syrup and allowed to remain for some time. After recrystallisation from alcohol, it melts at 162°, decomposes at 188°, and gives the characteristic coloration with ferric chloride in aqueous, but not in sulphuric acid solution. No phenylhydrazide could be isolated from the dark-red syrup into which levulosecyanhydrin passes after a time, although this must contain at least 50 per cent. of the ammonium salt of the acid; it was, therefore, necessary to return to the old method, in which, however, certain improvements have been made.

The levulose is obtained according to Hönig's directions (Abstr., 1888, 247) in such a manner as to contain 25—30 per cent. of water; to this an equivalent quantity of 50 per cent. hydrocyanic acid is added, together with a drop of dilute ammonia, and if possible a fragment of ready-formed cyanhydrin. The bottle is tightly stoppered, and allowed to remain in cold water until the whole has completely solidified ($\frac{1}{2}$—1 hour), then stirred with 92 per cent. alcohol, collected, washed with alcohol, and dried in a vacuum over sulphuric acid. The pure and dry cyanhydrin thus obtained may be preserved for months, whereas the impure compound decomposes almost immediately. For its hydrolysis, 10 grams are treated with 20 grams of hydrochloric acid, saturated at the ordinary temperature, and allowed to remain two hours after the separation of ammonium chloride has ceased, then diluted with an equal volume of water, and evaporated on the water-bath to a thin syrup. This is extracted with water, and the solution again evaporated three times, the final syrup dissolved in water, filtered, treated with barium hydroxide, and evaporated. The solution is then saturated with carbonic anhydride, decolorised by animal charcoal, the barium precipitated by dilute sulphuric acid, and the remaining trace of hydrochloric acid by silver oxide. The filtrate on evaporation yields a syrup, which, on stirring and adding a crystal of the ready formed lactone, crystallises completely within a few hours. The levulosecarboxylic lactone thus obtained is sufficiently pure for most purposes, but may be further purified by crystallisation from alcohol. This lactone and also that of dextrosecarboxylic acid yield beautifully crystalline compounds with ammonia, and the former compound gives a polybasic acid on oxidation with nitric acid. H. G. C.

Reduction of the Acids of the Sugar-group. By E. FISCHER (*Ber.*, 23, 930—938).—The method of reducing acids of the sugar-group by means of sodium amalgam (Fischer, Abstr., 1889, 1149; this vol., p. 466) has been extended to a large number of monobasic and to some bibasic acids, with results which are now communicated in a preliminary form. As already pointed out (this vol., p. 471), this reaction is applicable only to those acids which form lactones, since it is the lactone which undergoes reduction; acids like mucic and gluconic acids, which either do not form lactones or only undergo conversion into lactones partially and under special conditions, and salts of the acids, whether lactone-forming or not, are not affected by treatment with sodium amalgam. It is on this account, therefore, that the reduction is carried on in solutions which are kept acid by the frequent addition of small quantities of sulphuric acid. In order to obtain the largest yield of sugar (40—60 per cent.), it is necessary to use the pure, crystallised lactone; when this cannot be obtained, as in the case of gluconic or saccharic acids, the aqueous solution of the acid is concentrated to a syrup and heated on a water-bath or at higher temperatures for many hours, with the object of forming as much lactone as possible. Details of the method adopted for the reduction of the monobasic acids and of the method of purifying the product are given in the paper, but do not differ in any important points from those already communicated (compare this vol., p. 466). Unlike the monobasic acids of the sugar-group, the bibasic acids do not yield sugars, but aldehyde-acids, and consequently a different process is necessary for the isolation and purification of the product; this is described in connection with the reduction of saccharic acid (*vide infra*).

Regarding lactones as "internal" ethereal salts, the author has instituted experiments with the object of ascertaining to what extent it is possible to reduce the ethereal salts of acids of the sugar-group and of other monobasic and bibasic acids which do not form lactones, and finds that ethyl mucate is reduced to an aldehyde-acid by sodium amalgam. The amides of the acids, however, do not undergo reduction by sodium amalgam in acid solution, thus differing from the amides of aromatic acids (compare Guareschi, this Journal, 1875, 569).

Kiliani's method of forming carboxy-acids by treating carbohydrates of the sugar-group with hydrogen cyanide (Abstr., 1886, 219, 438, 526, 869; 1887, 229, 465), combined with the author's method of reducing these acids to the corresponding carbohydrates by means of sodium amalgam, has made it possible to effect the synthesis of sugars containing 7 and 8 atoms of carbon in the molecule (*vide infra*), and the limit to which this process can be carried has not yet been reached. It becomes necessary, therefore, to adopt some system of nomenclature for carbohydrates of this group. The author proposes to employ the terms pentose, heptose, octose, &c., for the sugars, pentitol, heptitol, octitol, &c., for the corresponding alcohols, and heptonic acid, octonic acid, &c., for the acids of the series, according to the number of carbon-atoms in the compounds. A prefix, having reference to the source of the compound, is employed to distinguish the individual substances; thus, the compounds obtained from mannose receive the names mannoheptose, mannoctose, mannoheptitol, mannoctonic acid, &c., those from galactose, galaheptose, &c., those from dextrose, glucoheptose, &c. In view of the fact that an optically inactive and a dextrorotatory modification of levulose have been obtained, and the probability that corresponding compounds of dextrose will soon be prepared (this vol., p. 469), the author proposes to discard these names as misleading, and substitute glucose and fructose for dextrose and levulose respectively. The difficulty which arises from the use of the word glucose as a generic term for the 6-carbon sugars, as well as a synonym for dextrose, can easily be met by adopting the term hexose for this class of sugars.

The following preliminary notes of investigations carried on in conjunction with the author's pupils are communicated:—

Monobasic Acids.—(1.) The reduction of d.-, i.-, and l.-mannonic acids to the corresponding mannoses, and of gluconic acid to d.-glucose (ordinary dextrose) (this vol., p. 466), has already been described.

(2.) Galactonic acid.—The lactone of galactonic acid is present in considerable quantities in the syrup obtained by evaporating an aqueous solution of the acid on a water-bath, and on reduction yields ordinary galactose.

(3.) Mannosecarboxylic acid.—The lactone of this acid, on reduction, yields about 50 per cent. of *mannoheptose*, a dextrorotatory crystalline compound. The *phenylhydrazone* is sparingly soluble in cold water, and melts at 188—190° with decomposition; the *osazone* forms yellow needles, melts at 198—200° with decomposition, and is insoluble in water. On further reduction, mannoheptose is converted into *mannoheptitol*, $C_7H_{16}O_7$, which is identical with perseïtol (Maquenne, Abstr., 1889, 32). On oxidation with dilute nitric acid, mannoheptitol (perseïtol) is reconverted into mannoheptose.

Mannoheptose reacts with hydrogen cyanide, and the resulting *mannoctonic acid* forms a beautifully crystalline *lactone* which melts at 167—170°, and has a specific rotation of $[\alpha]_D = -43{\cdot}58$. On reduction, the lactone yields dextrorotatory *mannoctose*, which is characterised by forming a sparingly soluble *phenylhydrazone*, $C_8H_{16}O_7{\cdot}N_2HPh$, melting at 212—213°.

(4.) Glucosecarboxylic acid.—*Glucoheptose*, obtained from the lactone of this acid by reduction, crystallises from water in beautiful tables which melt at about 190° with decomposition. The *phenylhydrazone* is readily soluble in water; the *osazone* forms golden-yellow needles and melts at 197° with decomposition. On treatment with hydrogen cyanide, glucoheptose yields *glucoctonic acid*, from which a well-crystallised *barium* salt, $(C_8H_{15}O_9)_2Ba$, has been prepared.

(5.) Galactosecarboxylic acid.—The *lactone* of galactosecarboxylic acid is obtained by the prolonged heating of a syrupy aqueous solution of the acid on a water-bath, and forms colourless crystals melting at 149—150°. On reduction it is converted into *galaheptose*, which forms a sparingly soluble *phenylhydrazone* melting at about 199° with decomposition, and an *osazone* melting at about 220° with decomposition. Galaheptose interacts with hydrogen cyanide.

(6.) Rhamnosecarboxylic acid.—A 50 per cent. yield of a *methylhexose*, $OH{\cdot}CMeH{\cdot}[CH{\cdot}OH]_4{\cdot}CHO$, is obtained by the reduction of the lactone of this acid. This carbohydrate crystallises well from methyl alcohol and melts at 180—181°. The *phenylhydrazone* is readily soluble; the *osazone* melts at about 200° with decomposition. On treatment with hydrogen cyanide, it yields a *methylheptonic acid.* The *lactone* of this acid, $C_8H_{14}O_7$, crystallises well, and on reduction is converted into a *methylheptose*, which forms a sparingly soluble *phenylhydrazone.*

(7.) Fructosecarboxylic (levulosecarboxylic) acid and saccharin, on reduction, afford good yields of two carbohydrates containing "branched" carbon-chains.

(8.) Carboxylic acid of Milk-sugar.—Milk-sugar reacts with hydrogen cyanide, forming a *carboxylic acid* which yields an insoluble basic *lead* salt, does not reduce Fehling's solution, and is readily hydrolysed by boiling with dilute sulphuric acid. When evaporated to a syrup and reduced, the acid is converted into a sugar which probably has the formula $C_{13}H_{24}O_{12}$.

Bibasic Acids.—(1.) Saccharic acid.—The lactone of saccharic acid, obtained by heating the aqueous solution of the acid on a water-bath, is converted, on reduction, into an acid which reduces Fehling's solution, and shows a great resemblance to glycuronic acid. This aldehyde-acid is purified by adding neutral lead acetate to the reduction-product rendered slightly acid by acetic acid, whereby sulphuric acid and the regenerated saccharic acid are precipitated; the filtrate is then precipitated by the addition of basic lead acetate, the precipitate decomposed by dilute sulphuric acid, any excess of sulphuric acid being removed by means of baryta, and the filtrate evaporated to a syrup in a vacuum. The aldehyde-acid has not yet been crystallised.

(2.) Mucic acid.—When a 2½ per cent. aqueous solution of ethyl mucate is reduced by sodium amalgam in the usual way, an aldehyde-acid is formed. This can be purified by the method just described, and is a pale-yellow syrup which reduces Fehling's solution, and on oxidation is reconverted into mucic acid. W. P. W.

Constituents of Iceland Moss. By A. HILGER and O. BUCHNER (*Ber.*, 23, 461—464).—The authors have reinvestigated the preparation and properties of lichenstearic and cetraric acids, which were first examined by Knop and Schnedermann (*Annalen*, 55, 164), Herberger (*Annalen*, 21, 137), and Bolley (*Annalen*, 54, 143; 86, 50), and have obtained the following results:—

Lichenstearic acid is best prepared by extracting the powdered flakes of Iceland moss with light petroleum, evaporating the solution, and boiling the residue with water, sodium carbonate being added in such quantity that a portion of the substance remains undissolved. To the filtered solution, an excess of hydrochloric acid is added, the precipitate well pressed and repeatedly crystallised from light petroleum, and the solution decolorised by animal charcoal. It is then further recrystallised several times from boiling alcohol, and is thus obtained as a voluminous, white mass consisting frequently of stellate groups of small prisms, which speedily fall into small, lustrous plates. It melts at 120°, and is soluble in alcohol, chloroform, benzene, and light petroleum, but is almost insoluble in water. Its alkaline salts are the only ones soluble in water, and it is not acted on by acetic chloride. It yields a chloride with phosphoric chloride, and from the analysis of this compound, the free acid, and certain salts, it appears to be a bibasic acid of the formula $C_{43}H_{76}O_{13}$. It is converted on oxidation into carbonic anhydride and capric acid.

Cetraric acid is best obtained by Knop and Schnedermann's process, with the alteration that the precipitate formed by hydrochloric acid is extracted with light petroleum to remove lichenstearic acid, and the colouring matter removed by a mixture of ether and turpentine oil. It decomposes at about 200°, and appears also to be a bibasic acid, the most probable formula being $C_{30}H_{30}O_{12}$. H. G. C.

Chloropyromucic Acids. By H. B. HILL and L. L. JACKSON (*Amer. Chem. J.*, 12, 112—130; compare this vol., p. 482).—*Dichloropyromucic acid* [COOH : Cl_2 = 2 : 4 : 5 or 2 : 3 : 5] was prepared, together with an isomeric acid [2 : 3 : 5], by distilling ethyl pyromucate tetrachloride at 16 mm. pressure. It melts at 197—198°, and sublimes unchanged below its melting point. It dissolves in ether, alcohol, and hot water; 100 parts of water at 19·5° dissolve 0·13 part of the acid. The *barium* and *calcium salts* (both with 4 mols. H_2O) were prepared. Of these, 100 parts of water at 19·5° dissolve 1·58 and 6·85 parts respectively. *Ethyl dichloropyromucate* [2 : 4 : 5 or 2 : 3 : 5] melts at 72—73°, and boils at 122·5° under a pressure of 16 mm. This dichloropyromucic acid is reduced by sodium amalgam to pyromucic acid. With bromine and water, it reacts like the [2 : 3 : 5] acid previously described, giving chlorofumaric acid. When heated over a water-bath with concentrated hydrochloric acid, a substance of the formula $C_4H_3ClO_2$ is formed, according to the equation $C_5H_2Cl_2O_3 + H_2O = C_4H_3ClO_2 + CO_2 + HCl$. This substance is soluble in chloroform and benzene, and slightly in water and light petroleum; when crystallised from this last solvent, it forms slender prisms which melt at 52—53° and sublime rapidly at ordinary temperatures. It reduces silver oxide, and gives a yellow solution with aqueous alkalis. By the action of fuming sulphuric acid on dichloropyromucic acid [2 : 4 : 5 or 2 : 3 : 5], a *dichlorosulphopyromucic acid* is formed, the *barium hydrogen* and *barium* (with 2 mols. H_2O) *salts* of which were prepared. Sufficient data are not available to determine whether this dichloropyromucic acid has the formula [COOH : Cl_2 = 2 : 4 : 5] or [2 : 3 : 5]; the authors incline to the latter view, and look on it as the geometrical isomeride of the [2 : 3 : 5] acid described in a previous paper.

Trichloropyromucic acid [COOH : Cl_3 = 2 : 3 : 4 : 5] was prepared by decomposing the tetrachloride of the [2 : 5] chloropyromucic acid. Ethyl pyromucate was chlorinated at 145° until one hydrogen-atom had been replaced by chlorine; the temperature was then allowed to fall to 120°, and the chlorination continued to saturation. The product (tetrachloride of ethyl chloropyromucate) was treated with alcoholic soda, the sodium salt formed was decomposed with hydrochloric acid, and the acid thus obtained was purified by recrystallising its ammonium salt from water; the yield of acid was only 15 per cent. of the theoretical. Trichloropyromucic acid melts at 172—173°, and dissolves in alcohol, ether, and boiling benzene, and slightly in hot water; 100 parts of water at 19·5° dissolve 0·13 part of it. The *barium* and *calcium salts* (each with 4 mols. H_2O) were prepared: 100 parts of water at 19·5 dissolve 0·27 and 0·64 part of these respectively. The *potassium* and *silver salts* were found to be anhydrous. *Ethyl trichloropyromucate* was prepared by warming an alcoholic solution of the acid with concentrated sulphuric acid; it crystallises in flat prisms melting at 62—63°. *Trichloropyromucamide* was prepared by the action of solid ammonium carbonate on the acid chloride; it crystallises in long, slender needles melting at 160—161°. Trichloropyromucic acid, when treated with bromine and water, gives both *trichlorobromofurfuran* and dichloromaleic acid. When oxidised with nitric acid, it yields dichloromaleic acid.

Dichlorobromopyromucic acid [COOH : Cl_2 : Br = 2 : 3 : 4 : 5] is formed when dichloropyromucic acid [2 : 3 : 4] is exposed to the vapour of bromine at the ordinary temperature. It melts at 185—186°, and dissolves in alcohol, ether, and boiling benzene.

Dibromochloropyromucic acid [COOH : Br_2 : Cl = 2 : 3 : 4 : 5] was prepared by treating ethyl dibromopyromucate [2 : 3 : 4] with chlorine and decomposing the product with alcoholic soda. It melts at 193—194°, and dissolves in alcohol, ether, and boiling benzene.

Dichloronitropyromucic acid [COOH : Cl_2 : NO_2 = 2 : 3 : 4 : 5] was obtained by dissolving dichloropyromucic acid [2 : 3 : 4] in fuming sulphuric acid, isolating the sulphonic acid thus formed, and treating it with a mixture of fuming nitric acid and concentrated sulphuric acid. It melts at 189—190°, and dissolves in alcohol and ether, and in hot benzene or water. C. F. B.

Constitution of Methylpyromucic Acid. By H. B. HILL and W. S. HENDRIXSON (*Ber.*, **23**, 452—453).—The methylfurfuraldehyde described by Hill in a former paper has since been obtained by Maquenne (this vol., p. 33), and Bieler and Tollens (this vol., p. 238), from fucusol, and also by the action of sulphuric acid on rhamnose (isodulcitol); from the last-named formation it would appear to be δ-methylfurfuraldehyde. This supposition has been confirmed by the authors' examination of the methylpyromucic acid obtained by its oxidation, which is resolved by the action of bromine-water into a ketonic acid of the formula $C_5H_6O_3$. Pyromucic acid under similar conditions yields fumaraldehyde. The above ketonic acid appears to be identical with the acetoacrylic acid described by Wolff (Abstr., 1887, 465), which would naturally be formed if the methyl-group occupied the δ-position. The melting point of the acid formed was 122—123°, whereas Wolff gives 125—125·5°, and the hydrazone melts at 157°, agreeing in this and its other properties with the hydrazone of acetoacrylic acid described by Bender (Abstr., 1888, 1188), and Decker (Abstr., 1889, 49). H. G. C.

Stereochemical Studies. By J. Loschmidt (*Monatsh.*, **11**, 28—32).—The author shows how by a combination of six tetrahedral carbon-atoms a formula may be obtained for benzene in which the alternate double and single linkage of the Kekulé formula is maintained, and of which the latter formula appears to be only an abbreviation. H. C.

Nitrothymol-derivatives. By G. Mazzara (*Gazzetta*, **19**, 61—71).—*Paranitro-orthobromothymol*, $C_6HPrMeBr(NO_2)\cdot OH$ [4:1:2:6:3], is prepared by the action of nitric acid (sp. gr. = 1·46) on a solution of bromothymol in glacial acetic acid. It forms yellow crystals, melts at 107—108°, and is very sparingly soluble in water. It is identical with the compound previously described (Abstr., 1886, 1019), melting at 100—101°.

The *potassium*-derivative crystallises in small, yellow needles containing ½ mol. H_2O; on exposure to air they fall into a red powder. The *ethyl ether* forms yellow laminæ which melt at 67—69°.

Paramido-orthobromothymol is prepared by the reduction of the nitrobromothymol; it crystallises from light petroleum in pale-yellow scales, melts at 94—95°, dissolves in hot dilute alcohol and in hot benzene, and is sparingly volatile in steam. It is probably identical with the amidobromothymol previously described (*loc. cit.*), melting at 90°. The *hydrochloride* crystallises from hot alcohol in white needles, and melts at 185° with previous blackening.

Paradiacetamido-orthobromacetylthymol, $C_6HPrMeBr(NAc_2)\cdot OAc$ [4 : 1 : 2 : 6 : 3], is prepared by boiling amidobromothymol with an excess of acetic anhydride for four and a half hours. It forms pinkish-white crystals which have an odour of butyric acid, melts at 136—137°, and is soluble in alcohol and benzene. *Parabenzamido-orthobromothymol*, $C_6HPrMeBr(NHBz)\cdot OH$ [4 : 1 : 2 : 6 : 3], is prepared by heating a mixture of amidobromothymol and benzoic chloride in molecular proportion, at 100—110° for five to six hours. It forms small, reddish nodules which soften at 160°, and melt at 162—164°. It is soluble in alcohol and in benzene. With potash, it forms a greenish-yellow solution, from which it is reprecipitated unchanged by hydrochloric acid.

Dinitrothymol, $C_6HPrMe(NO_2)_2\cdot OH$ [4 : 1 : 2 : 6 : 3], is obtained as a bye-product in the preparation of nitrobromothymol; it may be prepared by the action of nitric acid (sp. gr. 1·46) on nitrobromothymol. It crystallises from light petroleum in needle-shaped prisms; melts at 55°. The *ethyl ether* melts at 52—53°, and is identical with that obtained by Ladenburg and Engelbrecht (Abstr., 1878, 60).

The chlorodinitrocymene melting at 100—101°, prepared by these authors from dinitrothymol, thus contains the two NO_2-groups in the positions 2 : 6, and the dinitro-derivative melting at 80°, obtained by Fileti and Crosa (Abstr., 1889, 494), must consequently have the constitution $[(NO_2)_2 = 5 : 6]$. S. B. A. A.

Aromatic Mercaptans. By R. Leuckart (*J. pr. Chem.* [2], **41**, 179—224).—The author's new method for obtaining aromatic mercaptans consists in acting on the diazo-aromatic compounds with potassium ethylxanthate, and decomposing the compound thus obtained with caustic alkali.

Phenyl ethylxanthate, PhS·CS.OEt, is formed (85 per cent. of theory) when diazobenzene chloride is mixed with potassium ethylxanthate (eq. mols.), and the resulting solid carefully heated; nitrogen is evolved, and the carbonate left as an oil which is purified by dissolving it in ether, washing with alkali and acid, and distilling with steam. When heated with alcoholic potash, it is converted into the potassium compound of thiophenol, from which thiophenol is obtained by the action of an acid; the yield is 70 per cent. of theory. When heated with alcoholic ammonia, it is converted into thiophenol, ethyl alcohol, and ammonium thiocyanate.

Ortho-, *meta-*, and *para-tolyl ethylxanthates* are obtained in like manner, and are also yellowish-red, uncrystallisable oils; with alcoholic potash, they yield ortho-, meta-, and para-thiocresols respectively. Paratolyl bisulphide (Abstr., 1879, 230) melts at 46°, not 43°.

Paratolyl symmetrical dithiocarbonate, $CO(SC_6H_4Me)_2$, is obtained as a bye-product in making paratolyl ethylxanthate in beautiful, colourless needles melting at 90—91°; when heated with alcoholic potash and then acidified with hydrochloric acid, carbonic anhydride and thioparacresol are formed, but no paracresol; this shows that it is the normal salt of the symmetrical dithiocarbonic acid, $CO(SH)_2$, and not of the isomeric acid, OH·CH·SH, a conclusion confirmed by the fact that it can be prepared by the action of carbon oxychloride on thioparacresol.

Metaxylyl ethylxanthate, similarly obtained, is a yellowish-red oil, which yields meta- (?) thioxylol (m. p. 213—214°), with alcoholic potash.

When diazo-orthohydroxybenzene chloride acts on potassium ethylxanthate, hydroxyphenyl mercaptan (b. p. 217°) [OH : SH = 1 : 2] (Abstr., 1883, 989) is obtained. When diazoparahydroxybenzene chloride is used, *monothioquinol ethylxanthate* is formed as a dark, uncrystallisable, sticky substance. *Monothioquinol* is obtained from this compound by heating it with alcoholic potash; the alcohol is distilled off, the residue dissolved in water, filtered, and saturated with carbonic anhydride; the separated oil is extracted with ether, the ether evaporated, and the oil warmed with zinc and sulphuric acid for

4—5 hours; after again separating it with ether, it is distilled under diminished pressure (45 mm.), when it boils without decomposition at 166—168°; it is a colourless liquid, solidifying to a lustrous, white, crystalline mass, which melts at 29—30°. The *lead compound* was obtained.

Monothio-ethylquinol, $OEt\cdot C_6H_4\cdot SH$, is obtained by heating monothioquinol (1·26 grams) with ethyl iodide (1·56 grams) and potassium hydroxide (0·56 gram) in alcohol for three hours; the alcohol is distilled off, the residue dissolved in ether, washed, and distilled; the quinol passes over at 275—277° as a colourless liquid, which solidifies and melts at 40—41°. It gives a yellow precipitate with lead acetate.

Ethylmonothioquinol, $OH\cdot C_6H_4\cdot SEt$, is formed when lead monothioquinol is heated for several hours with ethyl iodide in alcohol. It is a colourless, crystalline solid melting at 40—41°, and boiling at 282—287°; it is not precipitated by lead acetate.

Monothio-acetylquinol, $OAc\cdot C_6H_4\cdot SH$, obtained by treating paracetoxyphenyl bisulphide (see below) with zinc-dust and sulphuric acid at 45°, is a colourless, strongly refractive liquid of faint odour, which boils at 275—280°; its *lead compound* was obtained.

Diacetylmonothioquinol, $OAc\cdot C_6H_4\cdot SAc$, obtained by heating monothioquinol with acetic chloride at 120—130°, forms small, pearly leaflets of faint odour, and melts at 65·5—66°.

Parahydroxyphenyl bisulphide, $S_2(C_6H_4\cdot OH)_2$, is obtained by the action of the air on an ammoniacal alcoholic solution of monothioquinol; it crystallises in slender, pale-yellow needles melting at 150—151°. When heated with acetic chloride, it yields *paracetoxyphenyl bisulphide*, $S_2(C_6H_4\cdot OAc)_2$, which crystallises in pearly leaflets of faint odour, melting at 88—89°.

Metanitrothiophenol, $NO_2\cdot C_6H_4\cdot SH$, is obtained as follows:—Solutions of metanitrodiazobenzene chloride and potassium ethylxanthate are gradually mixed at 70—75°; a yellow diazo-compound separates, but quickly decomposes, evolving nitrogen, and forming a heavy, brown oil; this is dissolved in ether, the solution washed and evaporated, and the oil heated with alcoholic potash. The *potassium compound* of metanitrothiophenol thus obtained is dissolved in water, acetic acid added, and then lead acetate, which gives a dark-yellow precipitate; this is washed with water, suspended in alcohol, and decomposed by hydrogen sulphide. The phenol is a dark-yellow oil, easily oxidised by the air or other agents to *metanitrophenyl bisulphide*, $S_2(C_6H_4\cdot NO_2)_2$, which forms yellowish, well-formed, rhombic crystals, or soft, aggregated needles, melting at 84°; by reduction it yields metamidothiophenol, the *lead compound* of which is described.

Paranitrophenyl bisulphide.—Paranitraniline (2 grams) is diazotised and mixed with a warm solution of potassium ethylxanthate (2·3 grams); a yellowish-red oil separates and is dissolved in ether, washed, and saponified; the bisulphide thus obtained forms beautiful, small crystals melting at 168—170°. With zinc-dust and acetic acid, it yields paranitrothiophenol; but with zinc and sulphuric acid, it yields paramidophenyl bisulphide (see below).

Paramidophenyl ethylxanthate, $EtO\cdot CS\cdot S\cdot C_6H_4\cdot NH_2$, is obtained as an amorphous, brown, soft, wax-like mass when the product of the action of paranitrodiazobenzene chloride on potassium ethylxanthate is dissolved in ammonia and treated with hydrogen sulphide; it is also obtained by the action of hydrogen sulphide on the alcoholic ammoniacal solution of azobenzene ethylxanthate (see below). When it is saponified with alcoholic potash, *paramidothiophenol* is obtained.

Acetylparamidophenyl ethylxanthate, $\mathrm{EtO{\cdot}CS{\cdot}SC_6H_4NHAc}$, is prepared by diazotising acetylparaphenylenediamine, and mixing the diazotised solution with potassium ethylxanthate at 60—70°, washing the precipitate thus formed with strong hydrochloric acid, drying, and recrystallising; it crystallises in thin, pale-yellow leaflets melting at 151°; it is insoluble in water and light petroleum, but soluble in alcohol, ether, glacial acetic acid, and benzene. When it is heated for 20—30 hours with alcoholic potash, the alcohol distilled off, and acetic acid added, paracetamidophenyl bisulphide (Abstr., 1878, 974) is formed; when this is reduced with zinc-dust in acetic acid and precipitated with lead acetate, a lead compound is obtained which, on being decomposed with hydrogen sulphide, yields *acetylparamidothiophenol*, $\mathrm{SH{\cdot}C_6H_4{\cdot}NHAc}$; this crystallises in beautiful leaflets melting at 163°, and soluble in most solvents.

Paramidophenyl bisulphide is identical with Schmidt's pseudodithioaniline (Abstr., 1878, 974); if it is diazotised and the solution mixed with soda, a yellow flocculent precipitate is formed, which melts at 150—151°; if the diazotised solution is mixed with potassium ethyl xanthate, and the product saponified, dithioquinol (m. p. 98°, Abstr., 1877, 81) is produced.

Paraphenylene bisulphide, $\mathrm{C_6H_4S_2}$, is produced by the oxidation of dithioquinol; it blackens without melting at 300°.

Dimethylparamidophenyl ethylxanthate, $\mathrm{EtO{\cdot}CS{\cdot}S{\cdot}C_6H_4{\cdot}NMe_2}$, obtained by diazotising dimethylparaphenylenediamine and mixing the solution with potassium ethylxanthate, is a yellow oil which solidifies and forms yellow crystals melting at 51·5°, and soluble in the usual solvents except water. When it is heated with alkalis, or, better, with alcoholic solution of aniline at 200°, it is converted into tetramethylamidophenyl bisulphide, identical with Merz and Weith's dithiodimethylaniline (Abstr., 1886, 792); this, if treated with tin and hydrochloric acid, yields dimethylamidothiophenol (*loc. cit.*).

Azobenzene ethylxanthate, $\mathrm{EtO{\cdot}CS{\cdot}S{\cdot}C_6H_4{\cdot}N_2Ph}$, is made by diazotising amidoazobenzene sulphate and mixing the solution with potassium ethylxanthate; it forms brilliant, vermilion-red aggregates of crystals melting at 65°.

Azobenzene bisulphide, $\mathrm{S_2(C_6H_4{\cdot}N_2Ph)}$, formed when the last-mentioned compound is saponified with alcoholic potash, crystallises in yellow leaflets melting at 162°.

By saponifying the product of the action of tetrazodiphenyl sulphate (from the diazotising of benzidene sulphate) on potassium ethylxanthate, diphenyl dihydrosulphide (m. p. 176°, Gabriel and Deutsch, Abstr., 1880, 477) is obtained; when methyl chloride is passed into an alcoholic solution of this, containing caustic potash, *diphenyl dithiodimethyl ether*, $\mathrm{C_{12}H_8(SMe)_2}$, is precipitated; it crystallises in soft, pale-yellow leaflets melting at 184°. The corresponding *ethyl compound*, $(C_6H_4\cdot SEt)_2$, obtained in like manner, crystallises in beautiful, silvery leaflets melting at 135°.

Orthoditolyl dihydrosulphide, $C_{12}H_6Me_2(SH)_2$, obtained by a method similar to that for diphenyl dihydrosulphide forms beautiful, yellowish leaflets, melts at 113°, and is soluble in alcohol, ether, benzene, and aqueous potash. By oxidation, it yields a substance which crystallises in needles melting at 118°.

By the action of α-diazonaphthalene chloride on potassium ethylxanthate, α-naphthyl mercaptan is obtained, and α-naphthyl bisulphide, α-naphthyl sulphide, and α-naphthyl sulphone can be prepared from the mercaptan; these substances are already known.

Potassium sulpho-α-naphthyl ethylxanthate, $EtO\cdot CS\cdot SC_{10}H_6{}^{\alpha}\cdot SO_3K$, is obtained by the action of α-diazonaphthalenesulphonic acid (from naphthionic acid and sodium nitrite) on potassium ethylxanthate; it crystallises in small, brownish leaflets. When it is heated with dilute alcoholic potash, the alcohol evaporated, and acetic acid added, a yellow precipitate of *potassium sulphonaphthyl bisulphide* $S_2(C_{10}H_6SO_3K)_2$, is obtained.

By this general method, β-naphthyl bisulphide and β-naphthyl mercaptan were also obtained; they are already known.

Potassium sulpho-β-naphthyl ethylxanthate was also obtained; when it is heated with strong alcoholic potash, the alcohol evaporated, and acetic acid added, a colourless, crystalline mass (which gives *zinc β-thionaphtholsulphonate* with zinc and sulphuric acid), and *potassium sulpho-β-naphthyl bisulphide* are obtained; the free acid and the *lead salt* of the latter were also prepared. A. G. B.

Paraxylidine. By L. Pflug (*Annalen*, **255**, 168—176).—*Formylparaxylidine*, $C_9H_{11}NO$, prepared by boiling xylidine with concentrated formic acid, crystallises from water in long, colourless needles, melts at 111—112°, and turns reddish on keeping. The *benzoyl*-derivative, $C_{15}H_{15}NO$, crystallises from alcohol in colourless needles melting at 140°. The *benzylidine*-derivative, $C_{15}H_{15}N$, crystallises from alcohol in yellowish plates, melts at 101—102°, and is decomposed by boiling acids. The *benzyl*-derivative, $C_{15}H_{17}N$, prepared by reducing the benzylidene-derivative with sodium amalgam in alcoholic solution, is a light-yellow oil, boiling at 320—325°; the *hydrochloride* crystallises in colourless needles, and is readily soluble in water. The *nitrosamine* is a yellow oil, and gives Liebermann's reaction.

Metanitrobenzylidenexylidine, prepared by warming paraxylidine with metanitrobenzaldehyde, crystallises from alcohol in yellow needles, and melts at 126°; it is only sparingly soluble in cold alcohol, ether, and light petroleum, and insoluble in water.

Dianilidoparaxyloquinone, $C_{20}H_{18}N_2O_2$, can be easily obtained from paraxyloquinone; it crystallises from hot alcohol in yellowish-brown needles, melts at 264°, and is more readily soluble than dianilidoquinone.

Methylparaxylidine is prepared by boiling formylxylidine with potash and methyl iodide in methyl alcoholic solution, and heating the product with concentrated hydrochloric acid. It is a yellowish oil, boils at 225—227° (735 mm.), and is readily volatile with steam.

Paramethylxylylnitrosamine, $C_9H_{12}N_2O$, is prepared by treating methylxylidine with sodium nitrite and dilute sulphuric acid in ice-cold aqueous solution; it is a yellow oil.

Paranitrosoparamethylxylidine, $C_9H_{12}N_2O$, is obtained by dissolving the preceding compound in ether, gradually adding alcoholic hydrochloric acid to the well-cooled solution, and decomposing the salt thus produced with ammonia. It crystallises from benzene or alcohol in green needles with a blue reflex, melts at 164°, and gives the same reactions as other nitroso-bases. It is decomposed by boiling soda, yielding methylamine and paranitrosoxylenol.

Methylxylylenediamine [$NHMe : Me_2 : NH_2 = 1 : 2 : 5 : 4$], prepared by reducing the preceding compound with tin and hydrochloric acid, crystallises in almost colourless needles, melts at 83°, and is readily soluble in ether and alcohol, but only sparingly in water. Its salts are colourless, but, like the base itself, they become coloured on exposure to the air. The *hydrochloride* crystallises from alcohol in colourless needles, and in its aqueous solution ferric chloride gives a deep, violet-blue coloration. The *stannochloride* crystallises in colourless needles.

Paranitrosoxylenol [$NOH : Me_2 : O = 1 : 2 : 5 : 4$], crystallises in yellowish prisms, melts at 165°, and is readily soluble in ether and alcohol; it behaves like other nitroso-phenols, and dissolves in ammonia and dilute alkalis yielding red solutions.

Paranitrosoxylidine, $C_8H_{10}N_2O$, obtained by heating nitrosoxylenol with ammonium chloride and ammonium acetate, crystallises from benzene and ether in green needles melting at 169°; it is sparingly soluble in water, and is decomposed by boiling alkalis.

Paraxyloquinonedioxime, $C_8H_{10}N_2O_2$, can be obtained by treating the nitroso-base with hydroxylamine hydrochloride in cold dilute alcoholic solution; it crystallises from boiling alcohol in slender, yellow needles, melts at 254°, and is sparingly soluble in all ordinary solvents except alkalis.

Dinitrosoxylene, $C_8H_8N_2O_2$, prepared by oxidising xyloquinonedioxime with potassium ferricyanide in alkaline solution, is a yellow, sparingly soluble compound melting at about 250°. F. S. K.

Methylorthanisidine. By T. T. Best (*Annalen*, **255**, 176—188).—*Methylorthanisidylnitrosamine*, $OMe{\cdot}C_6H_4{\cdot}NMe{\cdot}NO$, can be obtained by dissolving methylorthanisidine (prepared from orthanisidine by Hepp's method, *Ber.*, **10**, 327) in dilute sulphuric acid, covering the solution with a little ether, and gradually adding an aqueous solution of sodium nitrite, with constant shaking. On evaporating the ethereal solution, the nitrosamine remains as a yellow oil. It gives Liebermann's reaction, and is readily soluble in alcohol and ether, but insoluble in water.

Paranitrosomethylorthanisidine, $OMe{\cdot}C_6H_3(NO){\cdot}NHMe$, is formed when the preceding compound is treated with an alcoholic solution of hydrochloric acid in the cold, and the salt produced decomposed with dilute ammonia. It crystallises in green or steel-blue plates, melts at 110°, and is readily soluble in alcohol, benzene, glacial acetic acid, ether, and methyl alcohol, but only very sparingly in light petroleum and water. The *hydrochloride*, $C_8H_{10}N_2O_2,HCl$, separates from water and alcohol in long, yellowish-green needles or plates, and is very readily soluble in water, only moderately easily in alcohol, and insoluble in ether. It is decomposed by hot dilute soda, giving methylamine and the sodium compound of nitrosoguaiacol. The *sulphate* crystallises in yellow or brown plates, and is moderately easily soluble in water. The *platinochloride*, *picrate*, and *oxalate* are yellow or brown, sparingly soluble compounds.

When paranitrosomethylorthanisidine is warmed with aniline and aniline hydrochloride, it is converted into azophenine (m. p. 241°) (compare Abstr., 1887, 1105).

Paranitroanisylmethylnitrosamine, $OMe\cdot C_6H_2(NO_2)\cdot NMe\cdot NO$, is obtained when methylorthanisidine or methylorthanisidylnitrosamine sulphate is treated with excess of sodium nitrite in dilute sulphuric acid solution; it crystallises from dilute alcohol in long, yellowish needles, melts at 138°, and is soluble in alcohol, but only moderately easily in ether, and insoluble in water. It gives Liebermann's reaction, and, when treated with alcoholic hydrochloric acid, it is converted into paranitromethylanisidine.

Methoxymethylparaphenylenediamine $[NHMe : NH_2 : OMe = 1 : 4 : 6]$ is prepared by reducing paranitrosomethylorthanisidine with tin and concentrated hydrochloric acid and decomposing the resulting crystalline stannochloride with cold soda. It crystallises from light petroleum in long, colourless needles, turns reddish on exposure to the air, and melts at 67—68°; it is readily soluble in water, alcohol, ether, and acids, but rather more sparingly in light petroleum. The *hydrochloride* crystallises from alcohol in colourless needles; its aqueous solution is coloured deep violet or blue on the addition of ferric chloride. The *platinochloride* separates from water in dark-brown crystals.

Paranitrosoguaiacol, $OMe\cdot C_6H_3(NO)\cdot OH$, prepared by boiling paranitrosomethylanisidine hydrochloride with soda, crystallises in needles or prisms, and decomposes at 140—150° with a slight explosion. It is readily soluble in alcohol and ether, but only sparingly in water. When treated with hydroxylamine hydrochloride in alcoholic solution, it is converted into methoxyquinonedioxime (see below). The sodium, potassium, and ammonium derivatives are red, crystalline compounds which decompose with a slight explosion when heated, and are soluble in alcohol.

Paranitrosoanisidine, $OMe\cdot C_6H_3(NO)\cdot NH_2$, is obtained by heating the preceding compound with ammonium acetate and ammonium chloride, with frequent addition of ammonium carbonate. It separates from benzene and ether in green crystals, melts at 107°, and is readily soluble in alcohol, ether, benzene, and acids, but only sparingly in water.

Methoxyquinonedioxime, $OMe\cdot C_6H_3(N\cdot OH)_2$, prepared by treating nitrosoanisidine with hydroxylamine hydrochloride, crystallises from dilute alcohol in small, grey needles, melts at 250° with decomposition, and is soluble in ether and alkalis, but insoluble in water. When treated with a cold alkaline solution of potassium ferricyanide, it is converted into paradinitrosoanisoïl. This compound, $OMe\cdot C_6H(NO)_2$, forms yellow crystals, melts at 94—96° with partial decomposition, and is almost insoluble in all solvents; it is oxidised to paradinitroanisoïl by potassium ferricyanide. F. S. K.

Paramidodiphenylamine. By C. HENCKE (*Annalen*, 255, 188—195).—Paramidodiphenylamine is best prepared by reducing paranitrosodiphenylamine with alcoholic ammonium sulphide. The *benzylidene*-derivative, $C_{19}H_{16}N_2$, crystallises from alcohol and benzene in greenish plates, melts at 107—109°, and is decomposed by dilute acids and alkalis. The *benzyl*-derivative, $C_{19}H_{18}N_2$, prepared by reducing the preceding compound with sodium and alcohol, crystallises in yellowish plates, and melts at 124°. The *paranitrobenzylidene*-derivative crystallises from benzene in red needles, and is sparingly soluble in ether, alcohol, and light petroleum; it melts at 172°. The corresponding *metanitro*-compound forms yellow plates, melts at 123°, and is more readily soluble in ether and alcohol than the para-compound.

Orthohydroxybenzylideneparamidodiphenylamine, prepared from the amido-base and salicylaldehyde, separates from alcohol in dark yellow crystals, and from hot benzene in brown prisms melting at 120°. Cumaldehyde and the amido-base combine together yielding a compound $C_{22}H_{22}N_2$, which crystallises from alcohol in brown prisms melting at 132°. The condensation-product obtained from furfuraldehyde has the composition $C_{17}H_{14}N_2O$; it separates from alcohol in yellow crystals melting at 129°.

Phthalamidodiphenylamine,  $C_6H_4{<}{\substack{CO\\CO}}{>}N\cdot C_6H_4\cdot NHPh$, prepared by heating the amido-base with phthalic acid at 180°, forms green needles, melts at 270°, and is almost insoluble in water, alcohol, ether, benzene, and light petroleum.

The compound $CS(NH\cdot C_6H_4\cdot NHPh)_2$ is obtained when paramidodiphenylamine is boiled with carbon bisulphide in alcoholic solution; it crystallises from dilute alcohol in colourless needles, melts at 180°, and when boiled with mercuric oxide in alcoholic solution is converted into a yellowish-green, crystalline compound which melts at 117° and has the composition $C_{25}H_{18}N_4S$.

Paramidodiphenylamine combines with quinone yielding a dark red, sparingly soluble compound $C_6H_2O_2(NH\cdot C_6H_4\cdot NHPh)_2$ [$(NH\cdot)_2$ = 2 : 3], which melts above 360°.

Phenylquinonediimide, $(C_{12}H_{10}N_2)_n$, is formed when an ethereal solution of paramidodiphenylamine is shaken for a few minutes with finely-divided lead peroxide. It crystallises from methyl alcohol with 3 mols. of the solvent, melts at 208°, and behaves like an indamine. When treated with alcoholic ammonium sulphide at 120°, it is reconverted into the amido-base, and when warmed with aniline and aniline hydrochloride, it yields azophenine and an induline base.

F. S. K.

Phenylparatolylamine. By A. REICHOLD (*Annalen*, 255, 162—168).—*Paranitrosophenyltolylamine*, $C_{13}H_{12}N_2O$, can be easily prepared by dissolving phenylparatolylnitrosamine in alcoholic ether, and adding alcoholic hydrochloric acid to the ice-cold solution. The hydrochloride, which separates from the solution after some time, is washed with alcoholic ether, and decomposed with alcoholic ammonium sulphide, whereon the base is gradually precipitated in blue prisms or plates. It is moderately easily soluble in alcohol, ether, and chloroform, but more sparingly in benzene, from which it separates in green plates, and very sparingly in hot water and light petroleum. It dissolves in glacial acetic acid with a brown coloration, and in concentrated sulphuric acid yielding a red solution which turns violet on warming. It melts at 163°, and dissolves in dilute alkalis, but is reprecipitated by carbonic anhydride. The salts with acids are decomposed by water. The base is decomposed by boiling soda, yielding paratoluidine and nitrosophenol. The *nitroso*-derivative, $C_{13}H_{11}N_3O_2$, crystallises from ether in green plates, melts at 110° with decomposition, and gives Liebermann's reaction. The *acetyl*-derivative, $C_{15}H_{14}N_2O_2$, forms red crystals melting at 103°.

Benzenediazonitrosophenyltolylamine, $C_{19}H_{18}N_4O$, is obtained when paranitrosophenytolylamine hydrochloride is treated with excess of phenylhydrazine hydrochloride in dilute alcoholic solution. It crystallises from warm alcohol in yellow plates. melts at 125° with decomposition, and explodes when heated quickly. It is decomposed by boiling alcoholic hydrochloric acid with evolution of nitrogen, yielding benzene and nitrosophenyltolylamine.

Methylazophenine $[NC_7H_7 : NPh \cdot (NHPh)_2 = 1 : 4 : 2 : 5]$ is formed when the nitroso-base (1 part) is heated at 100° for some hours with aniline (4 parts) and aniline hydrochloride (1 part). The crystalline residue is boiled with dilute alcohol to free it from the induline dye, and then recrystallised from xylene. It forms red plates, melts at 230°, and gives the same reactions as azophenine.

Paramidophenyltolylamine, $C_{13}H_{14}N_2$, prepared by reducing the nitroso-base with alcoholic ammonium sulphide, crystallises in colourless plates, melts at 118°, and is readily soluble in alcohol, ether, and benzene, but more sparingly in light petroleum; it quickly turns violet on exposure to the air. The *sulphate* crystallises in colourless needles, and is only sparingly soluble.

Benzylideneamidophenyltolylamine, $C_{20}H_{18}N_2$, is formed when the amido-base is warmed with benzaldehyde. It crystallises from alcohol in yellow plates, melts at 139°, and turns greenish on exposure to light. It is decomposed by boiling acids, yielding benzaldehyde and the amido-base. The corresponding compound $C_{20}H_{18}N_2O$, obtained in like manner from salicylaldehyde, forms reddish-yellow crystals, melts at 142°, and is moderately easily soluble in alcohol, ether, and benzene.

Paranitrobenzylidenephenyltolylamine, $C_{20}H_{17}N_3O_2$, obtained by boiling an alcoholic solution of the amido-base with paranitrosobenzaldehyde, crystallises in red needles melting at 130°. F. S. K.

Action of Thionyl Chloride on Aromatic Tertiary Amines.

By A. Michaelis and E. Godchaux (*Ber.*, 23, 553—559).—Thiodimethylaniline, $S(C_6H_4{\cdot}NMe_2)_2$, is formed, together with dimethylanilinesulphonic chloride, when dimethylaniline is treated with thionyl chloride (1 mol.) in well-cooled ethereal solution. The ether, which contains the chloride, is decanted, the residual dark, solid product dissolved in dilute hydrochloric acid, the filtered solution rendered strongly alkaline with soda, and distilled with steam to free it from dimethylaniline; the thiodimethylaniline, which remains as a solid, green mass, is then recrystallised from hot alcohol. It forms green needles, melts at 126°, and is readily soluble in ether and hot alcohol (compare Tursini, Abstr., 1884, 1140). The *hydrochloride*, $C_{16}H_{20}N_2S,2HCl$, melts at 176°, is very readily soluble in water, and becomes coloured on exposure to light. The *platinochloride*,

$$C_{16}H_{20}N_2S,H_2PtCl_6 + 2H_2O$$

is yellowish-brown; the *ferrocyanide*, $C_{16}H_{\ 0}N_2S,H_4Fe(CN)_6 + 6H_2O$, is a colourless powder almost insoluble in water.

Dimethylanilinesulphonic acid is obtained when the ethereal solution decanted from the thiodimethylaniline is shaken with dilute hydrochloric acid and then evaporated; it melts at 257°, and is identical with the acid obtained by treating dimethylaniline with fuming sulphuric acid. The *sodium* salt ($+2H_2O$) crystallises from water in long, colourless needles, and is sparingly soluble in soda and insoluble in alcohol.

Thiodiethylaniline can be obtained, together with diethylanilinesulphonic acid, exactly as described in the case of the corresponding dimethyl-base. It crystallises from alcohol in long, colourless needles, melts at 83°, and is readily soluble in ether and hot alcohol. The *hydrochloride*, $C_{20}H_{28}N_2S,2HCl$, crystallises in long, colourless needles, melts at 94°, and is readily soluble in water. The *sulphate*,

$$C_{20}H_{28}N_2S,H_2SO_4,$$

crystallises in needles melting at 83°; the *ferrocyanide* is colourless. The *picrate*, $C_{20}H_{28}N_2S,C_6H_3N_3O_7$, crystallises from alcohol in small, yellow needles melting at 177°.

Diethylanilinesulphonic acid turns brown at 250°, and melts at 270° with decomposition.

Sodium methylbenzylanilinesulphonate, $C_7H_7{\cdot}NMe{\cdot}C_6H_4{\cdot}SO_3Na + 3H_2O$, is obtained when methylbenzylaniline is treated with thionyl chloride in ethereal solution, the product dissolved in hydrochloric acid, and precipitated with soda. It crystallises in plates and melts at 100° in its water of crystallisation, the anhydrous substance melting at 238°; it is readily soluble in water and hot alcohol.

Sodium ethylbenzylanilinesulphonate, $C_7H_7{\cdot}NEt{\cdot}C_6H_4{\cdot}SO_3Na + 3H_2O$, prepared in like manner, melts at 222°.

The action of selenyl chloride on aromatic tertiary amines is being investigated, as is also the behaviour of primary and secondary bases.

F. S. K.

Alkylorthophenylenediamines and their Derivatives. By A. HEMPEL (*J. pr. Chem.* [2], **41**, 161—178).—*Orthonitroethylaniline*, $NO_2{\cdot}C_6H_4{\cdot}NHEt$, is best obtained by heating ethyleneorthonitrophenol with ethylamine in alcohol at 140°, evaporating on the water-bath, and distilling the oily residue with steam; the oil is extracted from the distillate by ether, dissolved in strong hydrochloric acid, filtered, and precipitated by water. It is a red oil which does not crystallise, and decomposes at 95° when distilled; it is slightly soluble in warm water and burns with a sooty, luminous flame.

Orthonitromethylaniline, obtained in like manner, is a red oil which crystallises on cooling in red needles melting at 26—28°, and soluble in much cold water.

Ethylorthophenylenediamine, $NH_2 \cdot C_6H_4 \cdot NHEt$, obtained by reducing orthonitroethylaniline with tin in hydrochloric acid, is a colourless, strongly smelling oil, unstable in light and air, and distilling at 248—249°. Its *platinochloride* was obtained.

Ethylazimidobenzene,  $C_6H_4{<}\begin{matrix}\text{NEt}\\ \text{—N}\end{matrix}{>}N$ (compare Abstr., 1888, 273), is obtained by decomposing ethylorthophenylenediamine (10 grams) with the calculated quantity of sodium nitrite in dilute sulphuric acid, filtering, and extracting the filtrate with ether. It is an odorous, yellow oil boiling at 280—281°, soluble in strong, and warm dilute sulphuric acid, and precipitated unchanged by alkalis.

Acetylethylorthophenylenediamine $NHEt \cdot C_6H_4 \cdot NHAc$, is precipitated when ethereal solutions of the calculated quantities of ethylorthophenylenediamine and acetic anhydride are mixed together; it forms white crystals becoming brownish-red on exposure to the air, melts at 104°, and is sparingly soluble in most solvents, but freely soluble in dilute acids and in alcohol.

Ethenylethylorthophenylenediamine,  $C_6H_4{<}\begin{matrix}\text{NEt}\\ \text{—N}\end{matrix}{>}CMe$, is formed (1) by mixing acetic anhydride with ethylorthophenylenediamine; (2) by gently warming ethereal solutions of acetic chloride and ethylorthophenylenediamine together, and then evaporating the ether; (3) by reducing orthonitroacetylethylaniline with tin and hydrochloric acid. It crystallises from alcohol in colourless, rhombic tables, melts at 179—180°, and is soluble in ether, dilute acids, and warm water; its *hydrochloride* forms colourless needles soluble in water.

Orthonitronitroso-ethylaniline, $NO_2 \cdot C_6H_4 \cdot NEt \cdot NO$, is obtained by treating orthonitroethylaniline in strong hydrochloric acid with sodium nitrite; it separates as a yellow oil which solidifies on cooling, and crystallises from dilute alcohol in long, yellow needles melting at 30°. It does not give a nitroso-reaction. The action of nitrous anhydride on orthonitroethylaniline in ether produces 1 : 2 : 4-dinitroethylaniline. *Orthonitronitrosomethylaniline*, prepared in like manner forms a red oil which solidifies in pale-yellow needles melting at 36°.

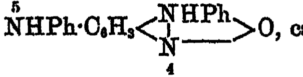
Orthamidophenylethylhydrazine, $NH_2 \cdot C_6H_4 \cdot NEt \cdot NH_2$, is obtained by passing hydrogen sulphide through a solution of orthonitronitrosoethylaniline (10 grams) in absolute alcohol (300 c.c.) mixed with strong ammonia; a *thiosulphate*, $C_8H_{13}N_3,H_2S_2O_3$, separates from the solution, which, after washing with alcohol and carbon bisulphide, forms colourless crystals smelling of garlic and remarkably soluble in water; the filtrate contains a considerable quantity of the free base, which may be separated by evaporating over the water-bath, adding concentrated hydrochloric acid, filtering, and adding excess of aqueous soda. If ammonium sulphide is substituted for ammonia and hydrogen sulphide, the hydrazine compound is formed without the thiosulphate. It is a yellowish-red oil smelling of nicotine, and is easily resinified: it decomposes above 100°, giving a yellow vapour which irritates the eyes; it is soluble in ether, alcohol, and dilute acids; it reduces sulphuric acid, evolving sulphurous anhydride. The *hydrochloride* and *platinochloride* are described. *Orthamidophenylmethylhydrazine*, prepared in like manner, is a red oil having much the same properties as the ethyl compound.

Acetylorthamidophenylethylhydrazine, $NHAc{\cdot}C_6H_4{\cdot}NEt{\cdot}NH_2$, formed by the action of acetic chloride on orthamidophenylethylhydrazine dissolved in ether, crystallises from absolute ether in yellow deliquescent needles, melts at 89—91°, and is soluble in alcohol, ether, and dilute acids. Sulphuric acid decomposes it, evolving sulphurous anhydride and nitrogen, and forming acetylethylorthophenylenediamine (see above); this decomposition indicates the presence of a non-substituted hydrazine-group, and settles the position of the acetyl-group. *Acetylorthamidophenylmethylhydrazine*, prepared in like manner, crystallises in yellow needles melting at 129—131°. When it is heated, it loses nitrogen and water forming ethenylethylorthophenylenediamine (see above).

α-Phenotriazine has been already described by Bischler (this vol., 149); it is also produced by the action of phosphoric anhydride on acetylorthamidophenylmethylhydrazine. The two substances are mixed together, left in a desiccator for some days, and then in the air until all the phosphoric anhydride has been converted into phosphoric acid; the liquid thus obtained is neutralised with sodium carbonate and extracted with ether, which dissolves the α-phenotriazine.

α-Methylphenotetrazine,  $C_6H_4<\begin{matrix}NH-N\\ \quad\ \ \|\\ NMe{\cdot}N\end{matrix}$, is obtained when the calculated quantity of sodium nitrite is added to a strong solution of orthamidophenylmethylhydrazine in dilute hydrochloric acid kept cold. After the action, soda is added, and the mixture shaken with ether, which extracts the tetrazine and, on evaporation, leaves it as a red oil which solidifies on cooling, and forms colourless, pearly leaflets when dried on a plate of gypsum. It melts at 62° and is soluble in ether, benzene, warm alcohol, and warm petroleum; it is precipitated in yellow flocks from its solution in mineral acids. When heated with strong nitric acid at 80—100° and then cooled, it yields yellow prisms and needles of the composition $C_6H_4O_6N_4$, melting at 127°; this substance is still under investigation. A. G. B.

Paranitrosodiphenylmetaphenylenediamine. By O. Fischer and E. Hepp (*Annalen*, 255, 144—147; compare Ikuta, Abstr., 1888, 467).—*Paranitrosodiphenylmetaphenylenediamine*,



$$\overset{5}{N}HPh{\cdot}C_6H_3<\begin{matrix}\overset{1}{N}HPh\\ |\\ \underset{4}{N}\text{———}\end{matrix}>O$$

can be obtained by treating diphenylmetaphenylenediamine with amyl nitrite and hydrochloric acid in alcoholic ethereal solution, and decomposing the salt thus produced with ammonia. It crystallises from benzene in brownish-red prisms with a blue reflex, and is insoluble in alkalis. The *hydrochloride*, $C_{18}H_{15}N_3O,HCl$, crystallises in small, red needles.

Amidodiphenylmetaphenylenediamine $[(NHPh)_2 : NH_2 = 1 : 3 : 4]$, prepared by reducing the preceding compound with tin and hydrochloric acid in alcoholic solution, and decomposing the resulting salt with alkalis, crystallises from a mixture of benzene and light petroleum in almost colourless needles melting at 107°.

Azophenine (Abstr., 1887, 1105) is formed when the nitroso-compound is heated at 110° with aniline and aniline hydrochloride.

Paranitrosomethyldiphenylamine and *paranitrosobenzylaniline* have been prepared from methyldiphenylamine and benzylaniline respectively, and will be described in a later paper.

When nitroso-α-naphthylamine is heated with α-naphthylamine and α-naphthylamine hydrochloride, it is converted into α-β-naphthazine melting at 275° (compare Abstr., 1887, 1114). F. S. K.

Action of Aniline on Benzene Hexachloride. By P. MOHR (*Monatsh.*, 11, 22—27).—When benzene hexachloride (1 mol.) is heated with aniline (4 mols.) in a reflux apparatus, only aniline hydrochloride and trichlorobenzene are formed; but when the hexachloride (1 mol.) is heated with a large excess of aniline (12 mols.) in a sealed tube at 130° for 4—6 hours, a brownish-yellow, crystalline mass, which contains *triphenylamidobenzene*, $C_6H_3(NHPh)_3$, is formed. The new compound crystallises in hexagonal or rhombic, microscopic plates of a golden-yellow colour, which turn brown at 238° and melt at 242°. It is readily soluble in chloroform, benzene, toluene and carbon bisulphide, slightly soluble in ether and light petroleum, but insoluble in water or alcohol. The author supposes it to be formed by the action of trichlorobenzene, produced by the decomposition of the hexachloride, on aniline; this mode of formation explains the very small yield (0·5 per cent. of the hexachloride used) obtained. G. T. M.

Hydroxyazo- and Amidoazo-compounds. By H. GOLDSCHMIDT and Y. ROSELL (*Ber.*, 23, 487—508).—With a view of ascertaining the constitution of certain hydroxyazo- and amidoazo-compounds, the authors have studied the behaviour of several substances of this nature with phenylcarbimide (compare this vol., p. 498) and with benzaldehyde (compare Meldola, Trans., 1890, 328).

Carbanilidohydroxyazobenzene, $C_{19}H_{15}N_3O_2$, is formed when hydroxyazobenzene (1 mol.) is heated at 170° with phenylcarbimide (1 mol.) and a little benzene. It crystallises from benzene in orange needles, melts at 149°, and is readily soluble in alcohol, ether, and benzene, but insoluble in alkalis. It is very readily decomposed by warm alcoholic potash, yielding hydroxyazobenzene, aniline, and carbonic anhydride.

Dicarbanilidohydrazobenzene, NHPh·CO·NPh·NPh·CO·NHPh, is obtained when hydrazobenzene (1 mol.) is heated at 150° with phenylcarbimide (2 mols.) and a little benzene. It melts at 218—220°, is insoluble in all ordinary solvents, and is not decomposed on prolonged boiling with alcoholic potash; it is not acted on by concentrated hydrochloric acid at 150°, but at 200° it is decomposed into aniline, carbonic anhydride, and benzidine hydrochloride. The great difference in the behaviour of these two carbanilido-compounds with alcoholic potash shows a dissimilarity in constitution: as the dicarbanilido-compound has probably the constitution assigned to it above, that of the monocarbanilido-compound is probably represented by the formula $NHPh\cdot CO\cdot O\cdot C_6H_4\cdot N_2Ph$, in which case hydroxyazobenzene would be a true hydroxy-derivative, and not the hydrazone of a quinone.

Carbanilidohydroxyhydrazobenzene, $C_{19}H_{17}N_3O_2$, can be prepared by reducing the corresponding hydroxyazo-compound with zinc-dust in warm glacial acetic acid solution. It crystallises from benzene in colourless needles, melts at 155°, and rapidly oxidises on exposure to the air. It is insoluble in alkalis, but when warmed with alcoholic potash, it is immediately decomposed into aniline and hydroxyhydrazobenzene; the last-named compound is, however, immediately oxidised, and on adding water hydroxyazobenzene is precipitated. This behaviour seems to show that the constitution of the carbanilido-compound is $NHPh\cdot NH\cdot C_6H_4\cdot O\cdot CO\cdot NHPh$.

The compound $NPh{:}N\cdot C_6H_4\cdot O\cdot CO\cdot NH\cdot C_{10}H_7$ is obtained when hydroxyazobenzene is treated with α-naphthylcarbimide as described in the case of the phenyl-derivative. It melts at 149°. The corresponding *hydrazo*-compound, $NHPh\cdot NH\cdot C_6H_4\cdot O\cdot CO\cdot NH\cdot C_{10}H_7$, obtained by treating the azo-compound with zinc-dust and glacial acetic acid, crystallises from benzene in colourless needles, melts at 155°, and is only sparingly soluble in ether.

Carbanilidohydroxyhydrazobenzene (see above) combines with phenylcarbimide yielding a compound $C_{33}H_{27}N_5O_4$, probably *tricarbanilidohydroxyhydrazobenzene*, which separates from alcohol as a colourless, crystalline powder, melts at 215—218°, and is very sparingly soluble in benzene. It dissolves in boiling alcoholic potash yielding a dark-green solution which contains aniline, diphenylcarbamide, an amidophenol, and a phenol-like substance melting at 206—208°.

Carbanilidohydroxyhydrazobenzene combines with acetic anhydride yielding a thick oil. When heated alone at about 150°, it is converted into an isomeride, which crystallises from alcohol in colourless needles melting at 218—220°. This isomeride seems to be unchanged by stannous chloride and hydrochloric acid, but it is decomposed by concentrated hydrochloric acid at 150°, yielding aniline, an amidophenol-like substance, and carbonic anhydride.

Benzeneazoparacresol and benzeneazo-β-naphthol do not combine with phenylcarbimide even at 220°, a fact which, in the authors' opinion, tends to show that both compounds are hydrazones of orthoquinones. This opinion is based on the fact that, although benzylidenehydrazone combines with phenylcarbimide, benzeneazoacetone, which has a constitution somewhat analogous to that of the hydrazone of an orthoquinone, does not do so.

Carbanilidophenoldisazobenzene, $NHPh\cdot CO\cdot O\cdot C_6H_3(N_2Ph)_2$ is formed when phenoldisazobenzene $[OH : (N_2Ph)_2 = 1 : 2 : 4]$ is heated with phenylcarbimide and a little benzene at 170°. It crystallises from hot benzene in small, yellow needles, melts at 133—135°, and is readily soluble in alcohol and ether. When reduced with zinc-dust and glacial acetic acid, it gives a colourless hydrazo-compound.

Amidoazobenzene and benzeneazo-β-naphthylamine do not combine with carbodiphenylimide or with carboparaditolylimide; this fact tends to show that both these azo-compounds are imido- and not amido-derivatives.

Carbanilidoamidoazobenzene (*benzeneazodiphenylcarbamide*),

$$NHPh\cdot CO\cdot NH\cdot C_6H_4\cdot N_2Ph,$$

is obtained when a solution of paramidoazobenzene (1 mol.) is treated with phenylcarbimide in the cold. It crystallises from hot alcohol in golden flakes, melts at 216°, and is almost insoluble in benzene, but readily soluble in hot alcohol. It does not combine with phenylcarbimide, and when reduced with tin and hydrochloric acid, it yields aniline and a colourless, crystalline compound, probably paramidodiphenylcarbamide.

Carbanilidoamidoazotoluene, $C_{21}H_{20}N_4O$, obtained from orthamidoazotoluene in like manner, crystallises in golden needles, melts at 219°, and is almost insoluble in benzene and only moderately easily soluble in hot alcohol. On reduction with stannous chloride and hydrochloric acid, it yields a colourless compound, probably amidotolylphenylcarbamide, which melts at 195°.

Carbanilidobenzeneazo-β-naphthylamine, $C_{23}H_{18}N_4O$, is formed when benzeneazo-β-naphthylamine is heated at 125° with phenylcarbimide and a little benzene. It crystallises from hot alcohol or benzene in orange-red needles melting at 205°. When reduced with stannous chloride and hydrochloric acid in alcoholic solution, it is converted into *amidonaphthylphenylcarbamide*, $NH_2\cdot C_{10}H_6\cdot NH\cdot CO\cdot NHPh$; this compound crystallises in small needles and melts at 290°.

When benzeneazo-β-naphthylamine is heated with phenylcarbimide (2 mols.) and benzene at 150°, the carbanilido-compound (m. p. 205°) described above, diphenylcarbamide, and a yellow, sparingly soluble, crystalline compound of the composition $C_{17}H_{11}N_3O$ are formed. The last-named crystallises from ethyl acetate in yellow needles, melts at 252°, and is only sparingly soluble in benzene; it dissolves in concentrated sulphuric acid with a red coloration, and in hydrochloric acid yielding a yellow solution, from which it is precipitated unchanged on adding ammonia. It is completely decomposed by concentrated hydrochloric acid at 160°, yielding a phenol and β-naphthylamine. The constitution of this compound is probably  $C_{10}H_6{<}\begin{matrix} N\cdot CO \\ | \\ N\cdot NPh \end{matrix}$. Its formation is best explained by assuming that benzeneazo-β-naphthylamine has the constitution $NH{:}C_{10}H_6{:}N\cdot NHPh$. Orthamidoazotoluene is probably analogously constituted.

Benzylideneorthamidoazotoluene, $C_{21}H_{19}N_3$, is obtained when orthamidoazotoluene is treated with excess of benzaldehyde in the cold; it crystallises from alcohol in colourless needles, and melts at 220°.

Benzeneazobenzylidene-β-naphthylamine, $C_{23}H_{17}N_3$, is formed when benzeneazo-β-naphthylamine is heated with benzaldehyde at 140°. It separates from boiling alcohol as a microcrystalline powder, melts at 193°, and is only sparingly soluble in benzene and ether. It is not decomposed by boiling concentrated hydrochloric acid, and when heated therewith at 150°, it is simply converted into the *hydrochloride*, $C_{23}H_{17}N_3,HCl$, which separates from alcohol in colourless crystals melting at 220°. This behaviour seems to show that the constitution of the base is

$C_{10}H_6\begin{cases}NH\cdot CHPh \\ N—NPh\end{cases}$; benzylideneorthamidoazotoluene has probably an analogous constitution. F. S. K.

Inorganic Derivatives of Phenylhydrazine. By A. MICHAELIS and J. RUHL (*Ber.*, **23**, 474—477).—It has been shown by E. Fischer (*Annalen*, **190**, 124) that sulphurous anhydride and phenylhydrazine combine together forming two different additive compounds, N_2H_3Ph,SO_2 and $2N_2H_3Ph,SO_2$. The authors have confirmed these results, and show that the latter compound is readily prepared by saturating an alcoholic solution of phenylhydrazine with sulphurous anhydride, and allowing the clear liquid to evaporate in the air at the ordinary temperature. It crystallises in beautiful, white tablets which sinter together at 70°, blacken without melting at a higher temperature, and are readily soluble in alcohol and water, insoluble in ether and benzene.

If sulphurous anhydride be passed into a cold benzene solution of phenylhydrazine, the additive product N_2H_3Ph,SO_2 separates, but on heating gradually, it loses water, forming *thionylphenylhydrazone*, $NHPh\cdot N\colon SO$. This compound, which may also be directly prepared by heating the benzene solution to 75°, and then passing in sulphurous anhydride, is identical with the compound obtained by the action of thionyl chloride on phenylhydrazine (Abstr., 1889, 1163). To isolate it, that portion which separates on cooling is filtered off, the filtrate shaken with dilute acetic acid until all the phenylhydrazine is removed, the benzene solution evaporated, and the combined portions of the hydrazone recrystallised from boiling alcohol.

If sulphurous anhydride is passed for too long a time, and the solution heated to boiling, the chief product is phenyl bisulphide, S_2Ph_2, which may be readily prepared in this manner, and separated from thionylphenylhydrazone by dilute aqueous soda. The careful separation of phenylhydrazine, mentioned above, is necessitated by the fact that this reacts with thionylphenylhydrazone to form phenyl bisulphide.

Thionylparatolylhydrazone, $C_7H_7\cdot N_2H\colon SO$, is prepared in a similar manner from paratolylhydrazine, and resembles thionylphenylhydrazone in all its properties; by alkalis, it is converted into sodium sulphate and paratolylhydrazine. Orthotolylhydrazine does not react with sulphurous anhydride so readily, and yields an oily compound which has a peculiar aromatic odour, and is decomposed by alkalis in the same way as the para-compound. The secondary hydrazines are without action on sulphurous anhydride.

These results yield additional evidence of the similarity existing between sulphurous acid and the aldehydes. H. G. C.

Phenylammeline and Phenylisocyanuric Acid. By A. Smolka and A. Friedreich (*Monatsh.*, **11**, 1—14; compare Abstr., 1889, 114 and 951).—*Phenylammeline*, $C_3H_4PhN_5O$, may be prepared by heating together molecular proportions of phenylbiguanide hydrochloride and carbamide for half an hour at 150—160°, or by heating together dicyanodiamide and monophenylcarbamide in molecular proportions at 150—160°, but not by the interaction of biguanide hydrochloride and monophenylcarbamide, which gives rise to unsubstituted ammeline and aniline. Phenylammeline forms a white powder insoluble in water, but soluble in dilute mineral and acetic acids and in the alkalis. Boiling alcohol slightly dissolves the substance, which, on cooling the solution, crystallises out in microscopic needles. The hydrochloride, $C_3H_4PhN_5O,HCl$, crystallises in bundles of radiating needles fairly soluble in water, but insoluble in alcohol; the platinochloride is soluble in alcohol but decomposed by water; the sulphate, $C_3H_4PhN_5O,H_2SO_4 + \frac{1}{2}H_2O$, is readily soluble in water, and melts with decomposition at 125—130°.

Phenylisocyanuric acid, $C_3H_2PhN_3O_3$, is formed by heating phenylammeline with concentrated hydrochloric acid in sealed tubes for 4—5 hours at 150°. It crystallises in anhydrous, lustrous needles, is scarcely soluble in cold water, slightly soluble in boiling water and in boiling alcohol, and is dissolved readily by ammonia and the fixed alkalis. It melts with partial sublimation at above 240°, and on heating with concentrated hydrochloric acid at 200° for five hours, it is resolved into aniline, carbonic anhydride, and ammonia. The barium salt crystallises with $3H_2O$; the copper, silver, and sodium salts are described.

The authors, contrary to their earlier views (*loc. cit.*), now conclude that the constitution of ammeline must be represented by a closed chain, and that the formation of phenylammeline and phenylisocyanuric acid, above mentioned, points to their having the constitutions respectively represented by the formulæ

$$\mathrm{NPh}<\genfrac{}{}{0pt}{}{\mathrm{C(NH)\cdot NH}}{\mathrm{CO{-}{-}{-}{-}NH}}>\mathrm{C{:}NH} \text{ and } \mathrm{NPh}<\genfrac{}{}{0pt}{}{\mathrm{CO\cdot NH}}{\mathrm{CO\cdot NH}}>\mathrm{CO}.$$

Dihydroxyphosphinic and Hydroxyphosphinous Acids. By J. Ville (*Compt. rend.*, **110**, 348—350).—The formation of dihydroxyphosphinic acids by the combination of aldehydes with hypophosphorous acid (Abstr., 1889, p. 1134) is accompanied by the formation of hydroxyphosphinous acids. If the mother liquor from dihydroxybenzoylphosphinic acid is mixed with normal lead acetate, a white precipitate is thrown down, and if this is treated with hydrogen sulphide and the filtrate concentrated, the hydroxyphosphinous acid is obtained in thin lamellæ soluble in water, alcohol, and ether. It is a strong acid, decomposing carbonates, and dissolving zinc and iron with evolution of hydrogen. It melts at about 90°, and decomposes at 140° with liberation of benzaldehyde; if more strongly heated, it evolves hydrogen phosphide, and leaves a bulky, carbonaceous residue containing metaphosphoric acid. Hydroxybenzoylphosphinous acid gives the general reactions of phosphorous acid; it has no action on copper sulphate, reduces silver nitrate slowly in the cold and rapidly on heating, and precipitates crystalline mercurous chloride from a solution of mercuric chloride. The acid contains the elements of a molecule of benzaldehyde and a molecule of hypophosphorous acid, and yields a barium salt $(OH\cdot CHPh\cdot PHO\cdot O)_2Ba + \frac{1}{2}H_2O$, crystallising in small nodules which become anhydrous at 105—110°, and an acetyl-derivative, *acetobenzoylphosphinous acid*, $OAc\cdot CHPh\cdot PHO\cdot OH$, a yellowish, resinous compound, easily soluble in ether, alcohol, and chloroform, but insoluble in ether and benzene. This acetyl-derivative is almost insoluble in water, by which it is resolved into acetic acid and hydroxybenzoylphosphinous acid. A similar change is produced more rapidly by potassium hydroxide.

Dihydroxybenzoylphosphinic acid and hydroxybenzoylphosphinous acid are typical of the two series of acids, which may be represented respectively by the generic formulæ $PO(CHR\cdot OH)_2\cdot OH$ and $OH\cdot CHR\cdot PHO\cdot OH$.

The proportion of hydroxyphosphinous acid formed in the reaction increases with the proportion of hypophosphorous acid present.

C. H. B.

Isomeric Dichlorobenzaldehydes, and the Naphthols derived therefrom. By E. Schwechten (*Chem. Centr.*, 1890, i, 217—218; from *Zeit. Naturwiss.*, **62**, 239—268).—With the object of obtaining chlorinated naphthalenes, in which the relative position of the chlorine-atom in the closed chain is known, the author has prepared the four dichloro-derivatives, $C_{10}H_6Cl_2$ [1 : 2; 2 : 3; 1 : 3; and 1 : 4].

The method employed was to first prepare dichlorobenzaldehydes, to convert these by condensation with succinic acid into dichlorophenolparaconic acids, from which the corresponding dichlorophenylisocrotonic acids and dichloro-α-naphthols of definite constitution were obtained.

The dichlorobenzaldehydes were prepared from dichlorotoluenes, which were converted into dichlorobenzyl chlorides, and these into the aldehydes.

The following compounds were prepared. Orthoparadichlorotoluene, $C_6H_3Cl_2Me$ [Me : Cl_2 = 1 : 2 : 4], a colourless liquid boiling at 196—197·5°. Orthodichlorotoluene [Me : Cl_2 = 1 : 3 : 4] boils at 205—208°. *Orthoparadichlorobenzaldehyde*, $C_6H_3Cl_2\cdot CHO$ [CHO : Cl_2 = 1 : 2 : 4], boils at 231—245°, melts at 70—71°, and crystallises in snow-white prisms. *Paradichlorobenzaldehyde* [CHO : Cl_2 = 1 : 2 : 5], melts at 57—58°, crystallises in needles from alcohol; by oxidation it is converted into dichlorobenzoic acid (m. p. 152—153°), and this into dichlorobenzene (m. p. 53—54), which determine its constitution. *Orthodichlorobenzaldehyde* [CHO : Cl_2 = 1 : 3 : 4] melts at 43—44°, and boils at 247—248°. From these dichloroaldehydes the following compounds are obtained by heating with potassium acetate and succinic anhydride at 130—140°. *Orthoparadichlorophenylparaconic acid*, $C_{11}H_8Cl_2O_4$, white lustrous plates melting at 164·5—165·5°. Strong sulphuric acid colours it brown, and it has a bitter taste. *Paradichlorophenylparaconic acid*, $C_{11}H_8Cl_2O_4 + H_2O$, crystallises in white, silky plates, melts at 197—198°, and is turned brown by strong sulphuric acid. *Orthodichlorophenylparaconic acid* melts at 136—137°, crystallises in snow-white needles, and is coloured dark-brown by concentrated sulphuric acid. By careful heating, the dichlorophenylparaconic acids are converted, with separation of carbonic anhydride, into dichlorophenylisocrotonic acids, from which the corresponding dichloro-α-naphthols are formed at a higher temperature. These compounds are: *parachlorophenylisocrotonic acid*, $C_{10}H_9ClO_2$, melting at 108—109°, from which R. Kirchoff's chloronaphthol melting at 123° is obtained; *orthoparadichlorophenylisocrotonic acid*, white prisms, melting at 120—121°, from which the dichloronaphthol [OH : Cl_2 = 1 : 2′ : 4′] melting at 132° is obtained. This crystallises in light-yellow prisms, and yields an intensely purple-coloured liquid with an alkaline solution of 1 : 4-diazonaphthalenesulphonic acid. *Paradichlorophenylisocrotonic acid* melts at 148—149°, crystallises in white prisms, and is converted into *dichloronaphthol* [OH : Cl_2 = 1 : 1′ : 4′], which is crystalline and melts at 114—115°; with 1 : 4-diazonaphthalenesulphonic acid, it yields a deep violet-coloured liquid. *Orthodichlorophenylisocrotonic acid* melts at 63—64°, and crystallises in white needles. From the orthodichlorophenylparaconic acid, the two dichloronaphthols, OH : Cl_2 = 1 : 2′ : 3 and 1 : 1′ · 2′, might be formed, and, indeed, the author obtained two compounds melting respectively at 149—150° and 83—84°, which also differed from each other in solubility, colour reactions, &c. From these naphthols the corresponding dichloronaphthylamines and dichloronaphthalenes were obtained by heating with ammonia at 300°, and diazotising the amines. *Dichloro-naphthylamine* [1 : 2′ : 4′] crystallises in needles which melt at 116—117°; it yields Cleve's 2 : 3-dichloronaphthalene melting at 60—61°. Dichloronaphthylamine [1 : 1′ : 4′] melts at 68—69°.

J. W. L.

Isocinnamic Acid. By C. LIEBERMANN (*Ber.*, 23, 512—516; compare this vol., p. 494).—Pure cinnamic acid is precipitated when isocinnamic acid is dissolved in concentrated sulphuric acid (5—6 parts) at 50°, the solution kept for about 15 minutes, and then poured into water.

Isocinnamic acid is also converted into cinnamic acid when it is boiled for 4—5 hours with iodine (2 parts) in carbon bisulphide solution; even at the ordinary temperature this change takes place, but very much more slowly.

Acetic anhydride at 220° converts isocinnamic acid into an anhydride which behaves like that of cinnamic acid, and yields cinnamic acid when treated with sodium carbonate.

Methyl cinnamate is obtained when a solution of isocinnamic acid in methyl alcohol is saturated with hydrogen chloride and kept for some time.

When isocinnamic acid is heated with water at 260°, it is almost completely converted into cinnamene and cinnamic acid; no compound corresponding with truxillic acid is formed.

Although many of the reactions of isocinnamic acid might be explained by assuming that it is the lactone of β-phenyllactic acid,  $CHPh{\cdot}CH<\genfrac{}{}{0pt}{}{CH_2}{-O-}>CO$, it shows in many respects the distinctive characters of an acid; that it is not identical with the lactone of β-phenyllactic acid was also proved by direct comparison of its barium salt with that of this lactic acid, and by direct comparison of the two acids.

The view that isocinnamic and cinnamic acids are stereochemically isomeric (*loc. cit.*) is also borne out by the results of determinations, made by Ostwald, of the electrical conductivity of isocinnamic acid.

Isocinnamic acid is not formed in the synthetical preparation of cinnamic acid from benzaldehyde. F. S. K.

Phenylparaconic Acid. By R. Fittig and P. Röders (*Annalen*, **255**, 142—144; compare Abstr., 1883, 473).—Phenylparaconic acid separates from water in crystals which have the composition $4C_{11}H_{10}O_4 + H_2O$, melt at 99°, and lose their water at 90—100°. The anhydrous substance melts at 121°, but when it has once been liquefied, it melts at 106°; if a particle of a crystal which melts at 121° is brought into contact with some of the liquefied anhydrous compound (the temperature of which may be as high as 115°), the whole gradually solidifies and does not melt until the temperature rises to 121°; after cooling, it melts again at 106°. F. S. K.

Amido-acids. By O. Rebufatt (*Gazzetta*, **19**, 38—58).—*Plöchl's benzoylimidocoumarin*, $C_{16}H_{11}O_3N$ (m. p. 170°), is obtained when sodium hippurate (30 grams), salicylaldehyde (20 grams), and acetic anhydride (70 grams) are heated for half an hour in a reflux apparatus, the product treated with boiling water, and the precipitate crystallised from benzene (Abstr., 1885, 898).

A compound isomeric with the above is prepared by gently heating the same quantities of the reagents until the hippurate commences to dissolve, withdrawing the source of heat and allowing the reaction to go on by itself. The product is then poured into water, and the yellow mass which separates is pressed between filter-paper, washed with alcohol, dried, powdered, and allowed to digest with a cold 5 per cent. solution of potash for one or two days, so as to dissolve the benzoylimidocoumarin. The insoluble residue is collected, washed, dried, and crystallised from acetone, the crystals are again left for a day or two in a 5 per cent. potash solution, and the undissolved portion is washed, and recrystallised once or twice from toluene and finally from acetone. This isomeride forms thick, yellow prisms with a brilliant lustre, melts at 154—155°, and is readily soluble in chloroform, benzene, and toluene, moderately so in warm acetone, but only sparingly in alcohol and acetic acid.

Contrary to Plöchl's statements, it was found that both these isomerides could be converted into acid compounds. Benzoylimidocoumarin (melting at 170°) dissolves in dilute alkaline solutions in the cold, and is reprecipitated unchanged by acids. A concentrated solution of potash (50 per cent.) dissolves a considerable proportion in the cold, without evolution of ammonia; and if the potash is not in excess, crystalline crusts of a *potassium-derivative*, $C_{16}H_{11}O_3N$ +

2KOH, are deposited after one or two days. This compound is decomposed by water, benzoylimidocoumarin being re-formed. If it is left in the mother liquor, however, until the latter has a distinct ammoniacal odour, on dilution and acidification with hydrochloric acid, an acid compound, $C_{16}H_{13}O_4N$, is precipitated. The isomeride melting at 154° is gradually converted into the same compound by a hot 10 to 20 per cent. solution of potash or by a cold 50 per cent. solution.

The acid thus produced may be purified by washing it with petroleum. It crystallises from dilute alcohol in large, colourless tables which melt at 195° with effervescence. It is readily soluble in alcohol, even when dilute, but only very sparingly in chloroform, it is insoluble in ether; it dissolves in solutions of alkaline carbonates with expulsion of carbonic anhydride. It is gradually converted into benzoylimidocoumarin (m. p. 170°) by the action of acetic chloride in the cold, but if it is very gradually dissolved in boiling acetic chloride, the solvent distilled off, and the residue washed with water and recrystallised from acetone, the isomeride melting at 154° is obtained in a state of great purity.

Another isomeride, or perhaps polymeride, of benzoylimidocoumarin may be obtained by adding acetic chloride (50 grams) to the acid (10 grams), suspended in benzene (100 grams), boiling for seven hours in a reflux apparatus, filtering the benzene solution, then washing it with water, drying over calcium chloride, and fractionally distilling; on cooling the residual solution, it deposits lustrous, orange-yellow scales which, after recrystallisation from alcohol, have the composition $C_{16}H_{11}O_3N$. This substance is very unstable and difficult to purify; it melts at 181—182° with effervescence; when it has once been melted and resolidified, the melting point is lowered to 165°; it is readily soluble in benzene, chloroform, acetone, and acetic acid, forming deep-orange coloured solutions; alcohol converts it into benzoylimidocoumarin (m. p. 170°); when boiled with a solution of sodium carbonate, it produces a characteristic cherry-red coloration and dissolves with effervescence; on acidifying the solution, the acid $C_{16}H_{13}O_4N$ is precipitated. The author considers that the first product of condensation between salicylaldehyde and hippuric acid is the acid $C_{16}H_{13}O_4N$, which is largely converted by the excess of acetic anhydride into a mixture of the three isomeric compounds, the relative proportions of which have been found within certain limits to depend only on the quantity of acetic anhydride present. The isomeride melting at 181° cannot be separated from this mixture, but its presence may be shown by the coloration it imparts to a solution of sodium carbonate.

The "anhydride," $C_{32}H_{24}N_2O_7$ (melting at 160°), obtained by Plöchl by the prolonged action of hippuric acid, salicylaldehyde, and acetic anhydride, has no independent existence; it is merely impure benzoylimidocoumarin (m. p. 170°).

A *bromine-derivative* of benzoylimidocoumarin, $C_{16}H_{11}O_3NBr_2$, is obtained by treating its concentrated chloroform solution with excess of a concentrated solution of bromine in chloroform; the new compound separates out in crimson flakes which give off bromine when exposed to the air. It may be crystallised from a solution of bromine in chloroform. The alkalis convert it into benzoylimidocoumarin.

The isomeride melting at 154° is not attacked by boiling acetic chloride, and forms substitution-derivatives with bromine, but no additive products; by prolonged boiling with alcohol (1 part) and water (3 parts), it is converted into the acid $C_{16}H_{13}O_4N$.

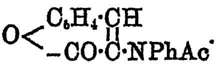
When benzaldehyde and hippuric acid in molecular proportion are treated with excess of acetic anhydride, the product is a mixture of Plöchl's yellow anhydride (m. p. 164), with a little of the substance melting at 225°, regarded by Plöchl as α-benzoylimidocinnamic acid (Abstr., 1884, 1348).

The anhydride is readily soluble in acetone, chloroform, and benzene; it is slowly dissolved in the cold by dilute solutions of the alkalis, and converted into the acid, which again yields the anhydride and an odorous oil on distillation.

After crystallisation from alcohol and acetone, the anhydride has a neutral reaction, melts at 159°, and has the composition $C_{16}H_{11}O_3N$ (not $C_{32}H_{24}O_5N_2$, as stated by Plöchl). It resembles in all respects the yellow isomeride of benzoylimidocoumarin (m. p. 154°), and, like the latter, is formed from the corresponding acid by the abstraction of 1 mol. H_2O.

The condensation of hippuric acid with aldehydes, therefore, results in the formation of unsaturated amido-acids, which, by losing a molecule of water, give rise to a series of yellow compounds, from which the acids are reproduced by the action of alkalis. The constitution of this new class of compounds and of the acids derived from them would be fixed, if the presence of an atom of imide hydrogen in the acid were proved to be necessary for the formation of the yellow compounds. Evidence of this is afforded by the non-formation of any homologous yellow compound by acetylphenylamidoacetic acid, $NPhAc{\cdot}CH_2{\cdot}COOH$.

This acid was prepared by heating phenylglycine (8 grams), acetic anhydride (10 grams), and benzene (100 grams) for seven hours. It crystallises from water in nacreous laminæ, and melts at 190—191°. When the sodium salt of this acid is treated with salicylaldehyde and acetic anhydride, &c., as before, the precipitate thrown down by water crystallises from a mixture of alcohol and ether in small, colourless prisms, melts at 155—156°, and has the composition $C_{17}H_{15}O_3N$. It is insoluble in solutions of the alkaline carbonates, but dissolves in solutions of the hydrates, and is reprecipitated unchanged by acids. This compound is evidently *acetylphenyl-α-amidocoumarin*,



$$O<\begin{matrix}C_6H_4{\cdot}CH \\ \quad\ \ \| \\ -CO{\cdot}C{\cdot}NPhAc\end{matrix}.$$

It appears that the acids formed by the condensation of hippuric acid with salicylic and benzoic aldehydes are likewise amido-acids, namely, benzoylamido-orthocoumaric and -cinnamic acids. The substance regarded by Plöchl as benzoylimidocoumarin is probably benzoylamidocoumarin, as is indicated by the existence of the potash- and bromine-derivatives.

The yellow compounds are respectively the α-benzoyllactimide of cinnamic acid,  $CO<\begin{matrix}NBz\\ |\\ C{:}CHPh\end{matrix}$ (m. p. 159°), and the α-benzoyllactimide of coumaric acid,  $CO<\begin{matrix}NBz\\ |\\ C{\cdot}CH{\cdot}C_6H_4{\cdot}OH\end{matrix}$ (m. p. 154°). S. B. A. A.

Thiocoumarins and their Behaviour towards Hydroxylamine and Phenylhydrazine. By F. ALDRINGEN (*Chem. Centr.*, 1890, i, 119—120).—α-Methylcoumarin, when heated with phosphorus pentasulphide at 120°, is converted into *thio-α-methylcoumarin*,  $C_6H_4<\begin{matrix}O-CS\\ \quad|\\ CH{:}CMe\end{matrix}$, melting at 122°. It is reconverted into α-methylcoumarin by heating with hydrochloric acid, hydrogen sulphide being evolved. With hydroxylamine hydrochloride in alcohol and sodium carbonate, *α-methylcoumaroxime*,  $C_6H_4<\begin{matrix}O-C{:}NOH\\ \quad|\\ CH{:}CMe\end{matrix}$, is formed. The latter is decomposed by boiling with aqueous potash, and does not give a brownish-red coloration with ferric chloride. *α-Methylcoumaroxime acetate* melts at 56°. Phenylhydrazine reacts with thiomethylcoumarin, *α-methylcoumarphenylhydrazide*,  $C_6H_4<\begin{matrix}O-C{:}N{\cdot}NHPh\\ \quad|\\ CH{:}CMe\end{matrix}$, melting at 116°, being formed.

Thio-α-ethylcoumarin, melting at 93—94°, is prepared from ethylcoumarin, as also are *α-ethylcoumaroxime*, melting at 157°; *ethylcoumaroxime acetate*, melting at 61°; and *α-ethylcoumarphenylhydrazide*, melting at 115°. *Thio-α-isopropylcoumarin* melts at 81°, *α-isopropylcoumaroxime* at 170—171°, the *acetate* of the latter at 85°, and the *hydrazide* at 112°.

With umbelliferone and phosphorus pentasulphide, no crystallisable substance could be obtained, but from umbelliferone methyl ether, *thioumbelliferone methyl ether*, melting at 114°, is obtained. *Oximidoumbelliferone methyl ether* melts at 138°, the *phenylhydrazide* at 115°.

J. W. L.

Nitrobenzil and its Isomeric Dioximes. By J. HAUSMANN (*Ber.*, 23, 531—534).—*Nitrobenzil*, $C_{14}H_9NO_4$, is best prepared by gradually adding benzoïn (10 grams) to cold nitric acid of sp. gr. 1·52 (15 c.c.), the temperature being kept below 25°; the solution is kept for about 15 minutes, then poured into cold water, the semisolid precipitate separated and boiled with concentrated nitric acid (75 c.c.) until the whole dissolves. The nitro-compound, which separates from the solution on cooling, is spread on a porous plate and recrystallised from hot alcohol. It forms small, yellow needles or plates, melts at 141—142°, and is readily soluble in ether, chloroform, &c. A nitrobenzil melting at 110° has been previously described by Zinin (*Annalen, suppl. Bd.* 3, 154).

Nitrobenzil-α-dioxime, $C_{14}H_{11}N_3O_4$, separates in colourless crystals when nitrobenzil is warmed for some hours with hydroxylamine hydrochloride (2½ mols.) in alcoholic solution. It melts at 225° with decomposition, and is very sparingly soluble in alcohol, ether, benzene,

&c., but soluble in soda, yielding a deep-yellow solution; it is slowly decomposed by concentrated hydrochloric acid at 100°. The *β-dioxime*, $C_{14}H_{11}N_3O_4$, is formed when an alcoholic solution of the *α*-compound is heated at 160—170° for several hours. It crystallises from a mixture of benzene and chloroform in colourless needles, melts at 185°, and decomposes at a higher temperature; it is very readily soluble in alcohol, dissolves in soda with a yellow coloration, and is slowly decomposed by concentrated hydrochloric acid.

F. S. K.

Xylalphthalide and its Derivatives. By E. HEILMANN (*Chem. Centr.*, 1890, i, 27—28).—By the action of phthalic anhydride on metatoluylacetic acid, the author has prepared *metaxylalphthalide*; when this is warmed on the water-bath with aqueous potash, it is converted into *metamethyldeoxybenzoinorthocarboxylic acid*,

$$C_6H_4Me\cdot CH_2\cdot CO\cdot C_6H_4\cdot COOH,$$

which melts at 111—112°. Hydroxylamine reacts with this acid with formation of the *oximidolactone* of *xylylphenylacetoximeorthocarboxylic acid*,  $CO<^{C_6H_4}_{O\cdot N}>C\cdot CH_2\cdot C_7H_7$, melting at 133—134°.

By protracted heating with alcoholic ammonia under high pressure, the phthalide is converted into *methyldeoxybenzoincarboxylamide*, $C_6H_4Me\cdot CH_2\cdot CO\cdot C_6H_4\cdot CONH_2$, which melts at 125°. This is a very unstable substance, and loses water very readily, *metaxylalphthalimidine*,  $CO<^{C_6H_4}_{NH}>C{:}CH\cdot C_7H_7$, being formed, which melts at 165°. By the action of nitrous anhydride in benzene solution, *nitroxylalphthalimidine*,  $CO<^{C_6H_4}_{NH}>C{:}C(NO_2)\cdot C_7H_7$, is formed, melting at 157—159°.

Nitrous acid reacts with xylalphthalide, producing *xylalphthalnitronitrite*,  $CO<^{C_6H_4}_{—O}>C(NO_2)\cdot CH(NO_2)\cdot C_7H_7$, from which, by the action of alcohol, nitrous acid is liberated and *nitroxylalphthalide*,  $CO<^{C_6H_4}_{—O}>C{:}C(NO_2)\cdot C_7H_7$, is formed. It melts at 144° with decomposition, and reacts with potash forming a salt, which when heated is converted into toluylnitromethane. Nitroxylalphthalide is converted on heating into phthalic anhydride and metatoluyl isocyanate.

From nitroxylalphthalide, by reduction with phosphorus and hydrogen iodide, *isoxylalphthalide*,  $C_6H_4<\begin{matrix}CH\cdot C\cdot C_7H_7\\ CO\cdot O\end{matrix}$, melting at 92—93°, is obtained. Ammonia converts this into *isoxylalphthalimidine*,  $C_6H_4<\begin{matrix}CH{:}C\cdot C_7H_7\\ CO\cdot NH\end{matrix}$, melting at 196°. Phosphorus oxychloride converts this into 3 : 1-*metatoluylchlorisoquinoline*, melting at 43—45°, which, by treatment with hydrogen iodide and phosphorus, is converted into 3-metatoluylisoquinoline melting at 51—52°.

J. W. L.

Derivatives of 1 : 3-Dichloronaphthalene. By P. T. Cleve (*Ber.*, **23**, 954—958).—1 : 3-Dichloronaphthalene, obtained from homonucleal dichloro-α-naphthylamine (Abstr., 1887, 494), boils at 289° (291° corr.) under a pressure of 775 mm. The author states that it occurs in so-called α-dichloronaphthalene, together with 1 : 4-dichloronaphthalene, from which it cannot be separated by crystallisation (compare Armstrong and Wynne, Proc., 1888, 106). When its solution in chloroform is saturated with chlorine at the ordinary temperature, and subsequently mixed with alcohol, a trichloronaphthalene, $C_{10}H_5Cl_3$, is obtained, which crystallises from alcohol in white needles, and is regarded as the 1 : 3 : 4-derivative, since it melts at 92°, the melting point of the trichloronaphthalene prepared from 1 : 3 : 4-dichloronaphthol (Abstr., 1888, 597).

Chloronaphthaquinone, $C_{10}H_5ClO_2$, together with phthalic acid, is obtained when 1 : 3-dichloronaphthalene in acetic acid solution is oxidised with chromic acid. It crystallises in long, golden needles, melts at 115°, and is identical with the chloronaphthaquinone obtained by the oxidation of 1 : 3 : 4-dichloronaphthol (Abstr., 1888, 596). The *oxime*, $C_{10}H_5ClO{:}N{\cdot}OH$, crystallises from alcohol in yellowish needles, melts at 200° with decomposition, and is readily soluble in acetic acid and alcohol; the *sodium* salt, $C_{10}H_5ClO{:}N{\cdot}ONa + 2H_2O$, forms small, yellow needles, and is readily soluble in hot water.

Dilute nitric acid (sp. gr. = 1·2) does not seem to act on 1 : 3-dichloronaphthalene at the ordinary temperature. A mixture of concentrated sulphuric and nitric acids, if the latter is not present in too large quantity, converts it into two isomeric dinitrodichloronaphthalenes; with an excess of nitric acid, however, the chief product is a trinitrodichloronaphthalene.

Dinitrodichloronaphthalene I, $C_{10}H_4Cl_2(NO_2)_2$, is the less soluble of the two dinitro-derivatives in acetic acid. It crystallises from acetic acid with 1 mol. prop. of acetic acid in slender, colourless, radially-grouped needles melting at 150°, and from benzene in short, pale-yellow tables, does not dissolve in aqueous soda, and is not oxidised by chromic acid. *Dinitrodichloronaphthalene II* crystallises in small, white needles, melts at 158°, is sparingly soluble in alcohol, insoluble in aqueous soda, and, like the preceding compound, yields the same trinitrodichloronaphthalene on treatment with a mixture of nitric and sulphuric acids. The trinitrodichloronaphthalene crystallises from acetic acid in pale-yellow, compact needles, melts at 178°, dissolves sparingly in alcohol, and is identical with the product obtained by Widman by nitrating so-called α-dichloronaphthalene.

Amidochlorotrinitronaphthalene, $NH_2{\cdot}C_{10}H_3Cl(NO_2)_3$, obtained by heating trinitrodichloronaphthalene with alcoholic ammonia in a water-bath, crystallises with 1 mol. prop. of alcohol in long, slender, lemon-yellow needles, melts at 252°, and is destitute of basic properties.

Anilidochlorotrinitronaphthalene, $NHPh{\cdot}C_{10}H_3Cl(NO_2)_3$, formed by warming a solution of trinitrodichloronaphthalene in aniline, crystallises in red scales, melts at 230°, and is very sparingly soluble in alcohol and acetic acid.

Trinitrochloronaphthol, $OH \cdot C_{10}H_3Cl(NO_2)_3$, prepared by warming trinitrodichloronaphthalene with aqueous soda and some alcohol, crystallises from acetic acid with 1 mol. prop. of acetic acid in pale-yellow needles, melts at 156° with decomposition, and is readily soluble in alcohol and acetic acid. It has strongly acid properties, and forms crystalline, orange-coloured salts with bases. The *barium* salt crystallises with 1 mol. prop. H_2O in brick-red needles, and is very sparingly soluble in hot water; the *calcium* salt forms thin, rectangular tables; the *potassium*, *silver*, and *lead* salts crystallise in needles, and are sparingly soluble in cold water. W. P. W.

ar.-Tetrahydro-β-naphthol. By E. Bamberger and M. Kitschelt (*Ber.*, **23**, 885—887).—The product obtained by reducing β-naphthol with sodium and boiling amyl alcohol consists chiefly of ac.-tetrahydro-β-naphthol (Bamberger and Lodter, this vol., p. 506). The "aromatic" derivative simultaneously formed is contained partly in the amyl alcohol solution, but chiefly in the alkaline liquor employed in the purification of the "alicyclic" compound, and is separated from the latter by first extracting any "alicyclic" compound with ether, then acidifying, and finally steam-distilling the acid liquid. To obtain the small quantity dissolved in the amyl alcohol, the reduction-product is worked up by the method already described (*loc. cit.*), and the alkaline extract of the fractions boiling at 170—186° and 186—196° under a pressure of 55 mm. is freed from any "alicyclic" derivative by steam-distillation; it is then acidified and the ar.-tetrahydro-β-naphthol separated by steam-distillation. The aqueous distillates of the "aromatic" derivative from both sources are united, saturated with salt, extracted with ether, and then fractionated. The yield from 96 grams of β-naphthol amounts to 8 grams of ar.- and 30 grams of ac.-tetrahydro-β-naphthol.

ar.-Tetrahydro-β-naphthol, $C_{10}H_{11} \cdot OH$ (compare this vol., p. 631), crystallises in lustrous, silvery, flat needles, melts at 58°, boils at 275° (therm. in vapour) under a pressure of 707 mm., and is readily soluble in ether, alcohol, benzene, chloroform, and hot light petroleum, sparingly soluble in hot water. Its odour recalls that of creosote. In its reactions it differs from β-naphthol; thus, its aqueous solution gives a white, flocculent precipitate when treated with bleaching powder, a bluish-green coloration with ferric chloride, changing into brownish-yellow flocks on warming, and a greenish-yellow colour on treatment with chloroform and aqueous soda. Its solution in concentrated sulphuric acid gives, on addition of a small quantity of sodium nitrite, a rose-red colour, which changes to a beautiful reddish-violet on warming. ar.-Tetrahydro-β-naphthol exhibits all the reactions of a phenol, and resembles ar.-tetrahydro-α-naphthol in its properties (Bamberger and Althausse, Abstr., 1888, 960; Bamberger and Bordt, this vol., p. 508). The azo-compound, obtained by combination with diazotised sulphanilic acid, is bordeaux-red in colour.

W. P. W.

2 : 2′-Dihydroxynaphthalene. By A. Clausius (*Ber.*, **23**, 517—529).—2 : 2′-Dihydroxynaphthalene (α-dihydroxynaphthalene of Ebert and Merz, this Journal, 1876, ii, 408) crystallises from water in long, compact needles, from dilute alcohol in slender, white needles, and from acetic acid in scales, and melts at 190° (not at 186°). Its solution in aqueous alkalis becomes brown on exposure to the air. The acetyl-compound melts at 136° (129° according to Weber, Abstr., 1882, 205), and the benzoyl-compound at 139°.

2′ : 1 : 2-*Hydroxynaphthaquinonoxime*,

$$C_{10}H_6O_2{:}N{\cdot}OH\ [OH : N{\cdot}OH : O = 2' : 1 : 2],$$

is obtained by adding the calculated quantity of sodium nitrite to 2 : 2′-dihydroxynaphthalene suspended in dilute hydrochloric acid. It crystallises from alcohol in small, lustrous, brownish-yellow needles, and melts at about 235°. Contrary to expectation, it was not found possible to introduce a second nitroso-group into the molecule by treating the compound with a further quantity of nitrite. On reduction with the calculated quantity of stannous chloride in hydrochloric acid solution, it yields the *hydrochloride* of the corresponding 2′ : 2 : 1-*dihydroxyamidonaphthalene*, $C_{10}H_5(OH)_2{\cdot}NH_2,HCl$, which crystallises from the solution, on addition of an excess of concentrated hydrochloric acid, in small, lustrous, greyish-white needles or scales, which rapidly become blue on exposure to the air. When oxidised in aqueous solution with an excess of dilute aqueous ferric chloride, the amido-derivative is converted into 2′ : 1 : 2-*hydroxynaphthaquinone*, $C_{10}H_5O_2{\cdot}OH\ [OH : O : O = 2' : 1 : 2]$, which could not be obtained in a crystalline form. It is insoluble in ether, chloroform, and benzene, but readily soluble in alcohol and acetic acid, from which it is precipitated in an amorphous form by the addition of water. Alkalis dissolve it forming reddish-brown solutions, and it seems to interact with sodium sulphite, since it is not precipitated from the aqueous solution of the two compounds on the addition of an acid.

1 : 2 : 2′-*Benzeneazodihydroxynaphthalene*,

$$OH{\cdot}C_{10}H_5O{:}N{\cdot}NHPh\ [N_2HPh : O : OH = 1 : 2 : 2'],$$

is prepared by adding the calculated quantity of diazobenzene chloride to an alkaline solution of 2 : 2′-dihydroxynaphthalene. It crystallises in thick, beautiful, greenish-black needles, showing a marked metallic lustre, melts at 220°, and is readily soluble in alkalis, hot alcohol, and benzene. The *acetyl*-derivative, $C_{16}H_{11}ON_2{\cdot}OAc$, crystallises from alcohol in lustrous, steel-blue needles or scales, which appear reddish-yellow by reflected light and melt at 181°. The *ethoxy*-derivative, $C_{16}H_{11}ON_2{\cdot}OEt$, is obtained by dissolving the azo-compound in alcohol, adding the calculated quantity of sodium ethoxide and heating with an excess of ethyl bromide for some time in a reflux apparatus; it crystallises in dark-green, seemingly cubical forms showing a strong metallic lustre, melts at 137°, and is readily soluble in hot alcohol and acetic acid.

1 : 2 : 2′-*β-Naphthaleneazodihydroxynaphthalene*,

$$OH{\cdot}C_{10}H_5O{:}N{\cdot}NHC_{10}H_7,$$

crystallises in greenish needles showing a metallic lustre, and melts at 202°.

1 : 1′ : 2 : 2′-*Dichlorodihydroxynaphthalene*, $C_{10}H_6O_2Cl_2$ [Cl_2 : $(OH)_2$ = 1 : 1′ : 2 : 2′], is formed when chlorine is passed through a cold 10 per cent. solution of 2 : 2′-dihydroxynaphthalene until a considerable separation of colourless needles is obtained. It crystallises from acetic acid in compact needles, melts at 192°, and yields a *diacetyl*-derivative, $C_{10}H_4Cl_2(OAc)_2$, which crystallises in white needles, melts at 195°, and is readily soluble in alcohol and acetic acid.

1 : 3 : 3′ : 1′ : 2 : 2′-*Tetrachlorodihydroxynaphthalene*,

$$C_{10}H_4O_2Cl_4\,[Cl_4 : (OH)_2 = 1 : 3 : 3' : 1' : 2 : 2'],$$

cannot be prepared directly by the action of chlorine on 2 : 2′-dihydroxynaphthalene; it is, however, readily obtained by adding an excess of stannous chloride to a solution of decachloro-2 : 2′-diketohydronaphthalene (*vide infra*). It crystallises from dilute alcohol in long, slender needles, melts at 176°, is readily soluble in alcohol and hot acetic acid, and yields no definite product on oxidation with nitric or chromic acids. The *diacetyl*-derivative, $C_{10}H_3O_2Cl_4(OAc)_2$, crystallises in white needles, melts at 196°, and is readily soluble in alcohol and acetic acid.

Decachloro-2 : 2′-*diketohydronaphthalene*,

$$C_{10}H_2Cl_{10}O_2\,[(Cl_2 : O : Cl_2 : H,Cl)_2 = 1 : 2 : 3 : 4 : 1' : 2' : 3' : 4'],$$

is obtained by passing a slow current of chlorine through a 10 per cent. acetic acid solution of 2 : 2′-dihydroxynaphthalene during 2—3 days. The dichlorodihydroxynaphthalene which at first separates redissolves after some time, and the dark liquid becomes lighter in colour. When completely saturated with chlorine, the liquid is allowed to remain in a closed vessel in the cold for about eight days, then poured off from the crystalline separation, again treated with chlorine and allowed to stand, the process being repeated until no further crystalline separation occurs. It crystallises from a mixture of ether and light petroleum in well-formed, colourless octahedra, melts at 200° with decomposition, and is tolerably sparingly soluble in alcohol, acetic acid, and light petroleum. On treatment with sodium sulphite, it is not reduced, but eliminates hydrogen chloride, forming a compound which melts at [illegible]20°, and has all the properties of a pure substance, but, on analysis, gives numbers which do not agree with any probable formula; the same compound is also formed by the action of potassium acetate.

When 2 : 2′-dihydroxynaphthalene is heated with calcium chloride and aniline at 280—290° for 18 hours, a mixture of dianilidonaphthalene with a small proportion of hydroxyanilidonaphthalene is obtained. The latter, together with any unattacked dihydroxynaphthalene, is extracted from the product by treatment with aqueous soda, and the residue purified by crystallisation from alcohol, and finally from benzene. 2 : 2′-*Dianilidonaphthalene*, $C_{10}H_6(NHPh)_2$, crystallises from benzene in colourless, lustrous scales, and melts at 168°. Its *diacetyl*-derivative, $C_{10}H_6(NAcPh)_2$, forms small, pale-yellow crystals, and melts at 197·5°. The *benzeneazo*-derivative, $PhN_2{\cdot}C_{10}H_5(NHPh)_2$, crystallises from alcohol in small, brownish needles. 2 : 2′-*Hydroxyanilidonaphthalene*, $OH{\cdot}C_{10}H_6{\cdot}NHPh$, crystallises in small, pale-coloured needles, melts at 163°, and is readily soluble in alcohol, benzene, and acetic acid. W. P. W.

β-Nitroso-α-naphthylamine. By A. Harden (*Annalen*, 255, 148—162).—*β-Nitroso-α-naphthylamine*,  $C_{10}H_6<\begin{matrix}NH_2\\|\\N\end{matrix}>O$, is best prepared by heating a finely-divided mixture of β-nitroso-α-naphthol (10 grams), ammonium chloride (20 grams), and ammonium acetate (50 grams) for 30 minutes on the water-bath, with constant stirring, and keeping the mixture alkaline by the frequent addition of small quantities of ammonium carbonate. The whole is then treated with cold water, the solution filtered, and the residue recrystallised from boiling benzene; the yield is 80 per cent. of the nitrosonaphthol employed. It separates from boiling benzene in small, reddish-brown forms, or in short prisms, with a green reflex, and is readily soluble in hot benzene and alcohol, less readily in ether and chloroform, and only sparingly in light petroleum and hot water. It is insoluble in, and is decomposed by, cold alkalis, but it dissolves freely in acids, and, on boiling, nitrosonaphthol separates from the solution. The *hydrochloride*, $C_{10}H_8N_2O,HCl$, prepared by treating the base with an alcoholic solution of hydrochloric acid and precipitating with ether, crystallises in long, red needles, and is very readily soluble in water and alcohol. The *platinochloride*, $(C_{10}H_8N_2O)_2,H_2PtCl_6$, obtained by adding platinic chloride, and then a large quantity of ether, to a concentrated aqueous solution of the base, is a light-red, amorphous compound, sparingly soluble in cold alcohol and water; it is decomposed by boiling water. The *sulphate*, $C_{10}H_8N_2O,H_2SO_4 + H_2O$, separates as a light-red, crystalline precipitate when ether is added to an alcoholic sulphuric acid solution of the base. The compound $C_{10}H_8N_2O,NaOH$ is precipitated in small, light-brown crystals on adding concentrated soda to an alcoholic solution of the base; it is very hygroscopic.

When β-nitroso-α-naphthylamine is treated with hydroxylamine hydrochloride in cold alcoholic solution, it is converted into orthonaphthylenedioxime (m. p. 149°), identical with the compound described by Goldschmidt and Schmid (Abstr., 1884, 1327); on reduction with ammonium sulphide, it is converted into αβ-naphthylenediamine (Griess, Abstr., 1883, 181). Potassium ferricyanide in alkaline solution oxidises the nitroso-base to orthonaphthylenedioxime anhydride (m. p. 78°).

When an alcoholic solution of nitrosonaphthylamine (2 grams) is mixed with an aqueous solution of potassium nitrite (2 grams), hydrochloric acid (1 mol.) gradually added, and the mixture boiled for five minutes and cooled, a potassium derivative separates in colourless plates. This has probably the constitution  $C_{10}H_6<\begin{matrix}N(OH){:}NO{\cdot}NO\\|\\N{\cdot}OK\end{matrix}$. It crystallises from water very slowly in colourless needles containing 1¼ mols. H_2O; the anhydrous compound is stable at 180°, but explodes at 250°. In its dilute solutions, barium, iron, and copper salts produce colourless, amorphous precipitates; the *silver*-derivative is amorphous, insoluble in water and alcohol, and stable in the light. When the potassium salt is treated with boiling concentrated hydrochloric acid, nitrogen is evolved, and, on cooling, nitrosonaphthol separates from the solution. It is also decomposed by cold dilute sulphuric acid, yielding a colourless, amorphous compound which explodes violently at 111°, and is so unstable that it cannot be obtained in a pure condition; if a solution of the potassium salt is warmed with excess of dilute sulphuric acid, the precipitate first produced gradually dissolves, and the filtered solution, on cooling, deposits a crystalline compound which melts at 212—2 5°, and explodes at a slightly higher temperature. This substance has probably the constitution  $C_{10}H_6<\begin{matrix}N(OH)\\ |\\ N\end{matrix}>N$; it crystallises unchanged from boiling hydrochloric acid, dissolves unchanged in concentrated sulphuric acid, and forms salts with alkalis. The *silver* salt, $C_{10}H_6N_3(OH),AgNO_3$, is a colourless, amorphous compound, which explodes at 233°, and is only sparingly soluble in boiling water.

α-Nitroso-β-naphthylamine and β-nitroso-α-naphthylamine both react with phenylhydrazine in the same way, but the products obtained from the β-nitroso-base cannot be obtained in a pure condition.

α-Azoxy-β-naphthylamine, $ON_2{\cdot}(C_{10}H_6{\cdot}NH)_2$, is formed when an alcoholic solution of the α-nitroso-base is kept in the cold for 48 hours with phenylhydrazine and a slight excess of acetic acid. After adding water and shaking for some time, the black, resinous precipitate is separated, spread on a porous plate, and purified by recrystallising from dilute alcohol with addition of animal charcoal. It forms small, red needles, melts at 121—122°, and dissolves freely in concentrated hydrochloric acid, but is reprecipitated on adding water.

α-Phenylorthonaphthylenediamine, $NH_2{\cdot}C_{10}H_6{\cdot}NHPh$, is prepared by gradually adding phenylhydrazine hydrochloride (3·5 grams) to a boiling alcoholic solution of α-nitroso-β-naphthylamine (4 grams), precipitating the salt thus produced with ether, and decomposing it with sodium carbonate. It crystallises from benzene in small, colourless needles, melts at 161°, and is moderately easily soluble in water.

β-Nitroso-α-ethylnaphthylamine,  $C_{10}H_6<\begin{matrix}NHEt\\ |\\ N\end{matrix}>O$, is obtained when β-nitroso-α-naphthol is heated with ethylamine acetate and ethylamine hydrochloride for 20 minutes on the water-bath with frequent addition of ethylamine carbonate; the yield is very small. It crystallises from alcohol in green plates containing 1 mol. H_2O, melts at 95°, and gradually effloresces and turns brown on exposure to the air.

When β-nitroso-α-naphthol is heated with aniline at 100°, β-naphthaquinonedianilide (m. p. 181°) is formed. F. S. K.

ac.- and ar.-Tetrahydro-β-naphthylamine. By E. Bamberger and M. Kitschelt (*Ber.*, 23, 876—884).—It is stated in earlier communications (Abstr., 1888, 599, 712) that the products obtained on reducing β-naphthylamine with sodium and boiling amyl alcohol consist of ac.-tetrahydro-β-naphthylamine and small quantities of dihydronaphthalene and ammonia, a certain proportion of the β-naphthylamine employed escaping reduction. The authors now find that when the proportion of sodium used is raised from 12 to 20 grams for each 15 grams of β-naphthylamine so as to ensure a practically complete reduction of the base, an increase in the yield of ac.-tetrahydro-β-naphthylamine is not obtained, but in its place a corresponding quantity of ar.-tetrahydro-β-naphthylamine is formed. It is probable that the "aromatic" derivative was formed in small quantity in the earlier experiments, but escaped detection through being mixed with the relatively large quantity of unattacked β-naphthylamine; β-naphthylamine, therefore, behaves like its ethyl-derivative (Bamberger and Müller, Abstr, 1889, 888) in yielding a mixture of "alicyclic" and "aromatic" tetrahydro-bases on reduction.

ac.-Tetrahydro-β-naphthylamine is characterised by yielding a well crystallised acetate and a sparingly soluble nitrate. The *acetate*, $C_{10}H_{11}\cdot NH_2,C_2H_4O_2$, crystallises in thick, lustrous, monoclinic prisms $a:b:c = 1\cdot4835:1:1\cdot8018$; $\beta = 78° 24'$. observed faces ∞P, $-\bar{P}\infty$, $+\bar{P}\infty$, and $0P$, melts at 155·5—156°, is sparingly soluble in ether, soluble in alcohol, and still more soluble in water, and effloresces on lengthened exposure to the air. The *nitrate*, $C_{10}H_{11}\cdot NH_2,HNO_3$, is precipitated in white scales when nitric acid or potassium nitrate is added to a solution of a soluble salt of the base. It crystallises from water in satiny tables, melts at 210—212°, decomposes when heated at 220° with explosion yielding a distillate containing water, naphthalene, and a quantity of the nitrate, and is sparingly soluble in cold, readily soluble in hot water. *ac.-Benzylidenetetrahydro-β-naphthylamine*, $C_{10}H_{11}\cdot N{:}CHPh$, obtained by heating ac.-tetrahydro-β-naphthylamine carbonate with benzaldehyde at 100°, crystallises in colourless, lustrous, triclinic prisms, melts at 51·5—52°, is readily soluble in light petroleum, ether, benzene, and hot alcohol, insoluble in water, and is very readily decomposed into its generators on treatment with acids. On oxidation with potassium permanganate, ac.-tetrahydro-β-naphthylamine is known to yield a mixture of hydrocinnamorthocarboxylic acid and phthalic acid. When oxidised with a mixture of potassium dichromate and dilute sulphuric acid, the pure base gives, in addition to phthalic acid, a small yield of α-naphthol and α-naphthaquinone; and since experiment shows that α-naphthol yields but the merest trace of α-naphthaquinone under like conditions, it is evident that these two substances are independent oxidation-products. The formation of these α-derivatives from ac.-tetrahydro-β-naphthylamine is due in all probability to the oxidation of dihydronaphthalene, into which the base decomposes under certain conditions (Abstr., 1888, 712). Oxidation with boiling dilute nitric acid (1 gram of 75 per cent. acid to 7 grams of water) converts the base into a mixture of phthalic acid, naphthalene, and several other compounds which have not been further examined.

ar.-Tetrahydro-β-naphthylamine, $C_{10}H_{11}\cdot NH_2$, occurs to the extent of 3—4 per cent. in the product obtained by the reduction of β-naphthylamine. To separate it, the mixed hydrochlorides (compare Abstr., 1888, 599) are dissolved in water, and the solution rendered alkaline by the careful addition of aqueous soda, is steam-distilled. The distillate, after acidification, is concentrated, then rendered alkaline, and extracted with ether; the ether is removed by evaporation, the residue dissolved in light petroleum, and the base further purified by passing a current of moist carbonic anhydride through the solution in order to convert any trace of the "alicyclic" derivative into its sparingly soluble carbonate, and finally fractionated. It crystallises from light petroleum in lustrous, silvery, flat needles, has an odour recalling that of aniline, melts at 38°, boils at 275—277° (therm. in vapour) under a pressure of 713 mm., and dissolves without difficulty in the ordinary organic solvents. In its reactions it resembles *ar.*-tetrahydro-*α*-naphthylamine (Bamberger and Althausse, Abstr., 1888, 959; Bamberger and Bordt, Abstr., 1889, 715); thus, it is neutral in reaction, forms acid salts with mineral acids, can be diazotised in the usual way, reacts with diazo-compounds forming azo-dyes, &c. On oxidation with potassium permanganate, it yields adipic acid. When its diazo-compound is boiled with dilute sulphuric acid, it is converted into *ar.-tetrahydro-β-naphthol*, $C_{10}H_{11}{\cdot}OH$, which crystallises in silvery, flat needles, melts at 58°, boils at 275°, and is identical with the "aromatic" derivative obtained by reducing *β*-naphthol in the usual way (see p. 627). W. P. W.

Aromatic Carbamide Chlorides. By O. KYM (*Ber.*, **23**, 424—431).—When carbonyl chloride, dissolved in toluene, is added to a benzene solution of phenyl-*β*-naphthylcarbamide, no alteration takes place in the cold for an hour; subsequently, separation of phenyl-*β*-naphthylcarbamide hydrochloride takes place slowly. The reaction proceeds rapidly at 100°, according to the equation $2NHPh{\cdot}C_{10}H_7 + COCl_2 = C_{10}H_7{\cdot}NPH{\cdot}COCl + NHPh{\cdot}C_{10}H_7,HCl$. The hydrochloride is filtered off, the filtrate concentrated, and the greyish, nodular crystals which separate washed with dilute alcohol, and repeatedly crystallised from hot alcohol. These consist of *phenyl-β-naphthylcarbamide chloride*, and form small, lustrous, white plates, melting at 101—102°, and sparingly soluble in cold alcohol and acetic acid, readily in the hot liquids and in benzene.

Asymmetrical phenyl-β-naphthylcarbamide, $C_{10}H_7{\cdot}NPh{\cdot}CO{\cdot}NH_2$, is prepared by acting on the foregoing compound with alcoholic ammonia at 120°. It crystallises in long, white needles melting at 189—190°, and is very slightly soluble in cold alcohol, benzene, and acetic acid, more readily in the hot liquids.

Diphenyl-β-naphthyl carbamide, $CO(NPh{\cdot}C_{10}H_7)_2$, is obtained by heating a solution of phenyl-*β*-naphthylcarbamide chloride in chloroform with aniline (2 mols.). It forms small, white plates melting at 132—133°. It is readily soluble in benzene, less so in acetic acid, and still less in alcohol.

If diphenyl-*β*-naphthylcarbamide be heated with excess of aniline, it is converted into diphenylcarbamide and phenyl-*β*-naphthylamine, a reaction similar to that observed by Michler in the case of triphenylcarbamide (this Journal, 1876, ii, 91). Phenyl-*β*-naphthylamine is also obtained by boiling the above chloride with alcoholic potash.

β-Dinaphthylcarbamide chloride, $N(C_{10}H_7)_2{\cdot}COCl$.—Carbonyl chloride only acts on *β*-dinaphthylamine in benzene solution at a temperature of 130—160° (compare next abstract), the reaction then proceeding just as with phenyl-*β*-naphthylamine. The *β*-dinaphthylamine hydrochloride is filtered off, the filtrate evaporated, and hydrogen chloride passed in to remove the last portions of *β*-dinaphthylamine, the liquid again filtered, and alcohol added to the filtrate. The yellowish substance which separates on cooling is purified by redissolving it in hot benzene and adding alcohol. β-Dinaphthylcarbamide chloride forms white, cauliflower-like aggregates, which melt at 173°, and are very soluble in benzene, readily in hot acetic acid, but almost insoluble in alcohol.

Asymmetrical-β-naphthylcarbamide, $N(C_{10}H_7)_2 \cdot CO \cdot NH_2$, is prepared by acting on the chloride with alcoholic ammonia at 120°. It crystallises in fascicular groups of slender needles which melt at 192—193°, and are sparingly soluble in cold alcohol, acetic acid, and benzene, more readily in the hot liquids.

Phenyl-β-dinaphthylcarbamide, $N(C_{10}H_7)_2 \cdot CO \cdot NHPh$, is prepared by heating aniline and a chloroform solution of β-dinaphthylcarbamide at 130°. It forms fascicular aggregates of long, white needles which melt at 181—182°, and are probably identical with the compound obtained by Gebhardt (Abstr., 1885, 384). By heating with excess of aniline, it is decomposed into β-dinaphthylamine and diphenylcarbamide. β-Dinaphthylcarbamide chloride is also decomposed by alcoholic potash, with formation of β-dinaphthylamine.

Attempts were also made to obtain β-tetranaphthylcarbamide by acting on the chloride with β-dinaphthylamine, but without success (compare next abstract). H. G. C.

β-Dinaphthylcarbamide Chloride. By B. Kühn and N. Landau (*Ber.*, 23, 811—812).—Contrary to the statement of Kym, in the foregoing abstract, the authors find that carbonyl chloride and β-dinaphthylamine react readily at the ordinary temperature, forming β-dinaphthylamine hydrochloride and β-dinaphthylcarbamide chloride. The latter was crystallised from acetic acid and melted at 172—173° (uncorr.). They also find that β-tetranaphthylcarbamide may be readily obtained by mixing β-dinaphthylamine with β-dinaphthylcarbamide chloride in molecular proportion, and heating them to 190—200°, a little zinc-dust being added to the melt. This is then dissolved in benzene, hydrogen chloride passed into the solution, the filtrate evaporated, and the residue crystallised from acetic acid. β-Tetranaphthylcarbamide forms yellowish-brown, prismatic needles, melts at 167—169°, and is sparingly soluble in alcohol and ether, readily in benzene and acetic acid.

Phenyl-β-dinaphthylcarbamide may be obtained, in addition to Kym's method, by digesting a solution of β-dinaphthylcarbamide chloride and aniline in alcohol at the ordinary pressure. The authors found the melting point to be 180° (uncorr.).

β-Dinaphthylcarbamide chloride reacts further with nitroamines, phenoxides, and nitrophenoxides; the authors reserve the further investigation of the products. H. G. C.

1 : 4-Nitronaphthalenesulphonic Acid. By P. T. Cleve (*Ber.*, 23, 958—961).—In addition to the 1 : 4′ and 1 : 1′-nitronaphthalenesulphonic acids, the author finds that the 1 : 4-modification is also formed when naphthalene-α-sulphonic acid is nitrated. To prepare the acid, 1 kilo. of sodium naphthalene-α-sulphonate is gradually added to a mixture of 750 grams of nitric acid (sp. gr. = 1·4) and 500 grams of nitric acid (sp. gr. = 1·5), and the product subsequently diluted with water, neutralised with chalk, and filtered hot. The filtrate, on cooling, deposits abundance of the calcium salt of the 1 : 4′-acid, this is filtered off, the mother liquor concentrated, and a further separation of calcium salt obtained. This is decomposed with sulphuric acid and the solution evaporated to the crystallising point in order to separate a further quantity of the 1 : 4′-acid; the mother liquor is then neutralised with potassium carbonate, the solution concentrated, and the successive fractions of the potassium salt treated with phosphorus pentachloride. The first fractions give almost pure 1 : 4′-nitronaphthalenesulphonic chloride, the later fractions yield mixtures from which the chloride of the 1 : 4-acid can be obtained by crystallisation from benzene and light petroleum. The mother liquor of the calcium salt contains the 1 : 1′-nitronaphthalenesulphonic acid.

1 : 4-*Nitronaphthalenesulphonic acid*, $NO_2{\cdot}C_{10}H_6{\cdot}SO_3H$, is obtained by boiling the chloride with baryta-water, and carefully neutralising the solution of the resulting barium salt with sulphuric acid. It forms a very soluble, yellowish, crystalline mass. The *potassium* salt crystallises in thin, silvery needles, and is sparingly soluble in cold water; the *sodium* salt crystallises, with 1 mol. H_2O, in very soluble, thin needles; the *silver* salt crystallises in tolerably soluble, small, yellow needles; the *calcium* salt crystallises, with 2 mols. H_2O, in silvery scales, and dissolves in 37 parts of water at 17° and in 16 parts at 100°; the *barium* salt crystallises, with 1 mol. H_2O, in small needles, and dissolves in 66 parts of cold and 33 parts of boiling water; the *lead* salt crystallises, with 6 mols. H_2O, in very soluble, granular aggregates. The *ethyl* salt, $NO_2{\cdot}C_{10}H_6{\cdot}SO_3Et$, crystallises from alcohol in large prisms and melts at 93°; the *methyl* salt, $NO_2{\cdot}C_{10}H_6{\cdot}SO_3Me$, crystallises in small needles, melts at 117°, and is sparingly soluble in alcohol. The *chloride*, $NO_2{\cdot}C_{10}H_6{\cdot}SO_2Cl$, crystallises from chloroform or benzene in large, yellowish prisms, and melts at 99°; the *amide*, $NO_2{\cdot}C_{10}H_6{\cdot}SO_2NH_2$, is dimorphous and crystallises in small octahedra or scales melting at 188°. The *bisulphide*, $S_2(C_{10}H_6{\cdot}NO_2)_2$, obtained by boiling a solution of the chloride in acetic acid with hydriodic acid, forms greenish-yellow, very sparingly soluble scales, and melts at 186°.

1 : 4-Nitronaphthalenesulphonic acid yields naphthionic acid on reduction with ammonium sulphide; and 1 : 4-nitronaphthalenesulphonamide, when boiled with acetic acid, hydriodic acid, and phosphorus, and afterwards precipitated by ammonia, is converted into the *amide* of naphthionic acid, $NH_2{\cdot}C_{10}H_6{\cdot}SO_2NH_2$. This crystallises from alcohol in brownish-yellow needles, melts at 206°, and yields a *hydrochloride*, $NH_2{\cdot}C_{10}H_6{\cdot}SO_2NH_2,HCl$, which crystallises in small, colourless, very sparingly soluble needles, and an *acetyl*-derivative, $NHAc{\cdot}C_{10}H_6{\cdot}SO_2NH_2$, which crystallises from alcohol in small, colourless needles, and melts at 241°. W. P. W.

1 : 1′-Chloronaphthalenesulphonic Acid. By P. T. CLEVE (*Ber.*, 23, 962—963).—When potassium 1 : 1′-nitronaphthalenesulphonate is mixed with phosphorus pentachloride, a very vigorous reaction takes place, and the whole mass becomes carbonised. If the conditions are modified by suspending the potassium salt in carbon bisulphide and then adding the pentachloride, the reaction proceeds quietly with the evolution of nitrous fumes, and 1 : 1′-chloronaphthalenesulphonic chloride is formed. After spontaneous evaporation of the carbon bisulphide, the product is extracted with water, and the insoluble chloride crystallised from benzene, chloroform, and acetic acid. The chloride is only slowly hydrolysed by heating with water at 150°, and is for the most part decomposed with the formation of sulphuric acid. *Barium* 1 : 1′-*chloronaphthalenesulphonate*, obtained by boiling the chloride with baryta-water, crystallises, with 2 mols. H_2O, in nacreous scales and is tolerably soluble in water; the *potassium* salt forms readily soluble, colourless prisms; the *silver* salt forms readily soluble, colourless, lustrous prisms. The *ethyl* salt, $C_{10}H_6Cl{\cdot}SO_3Et$, crystallises from alcohol in six-sided, colourless, monoclinic tables, $a : b : c = 1{\cdot}177 : 1 : 1{\cdot}323$; $\beta = 80° 57'$, and melts at 67·5°; the *methyl* salt, $C_{10}H_6Cl{\cdot}SO_3Me$, crystallises from alcohol in colourless, sparingly soluble needles, and melts at 70°. The *chloride*, $C_{10}H_6Cl{\cdot}SO_2Cl$, forms colourless, thin scales, melts at 101°, and is readily soluble in benzene, alcohol, and acetic acid; the *amide*, $C_{10}H_6Cl{\cdot}SO_2NH_2$, crystallises in fairly large, lustrous prisms, melts at 196—197°, and is sparingly soluble in alcohol. The *bisulphide*, $S_2(C_{10}H_6Cl)_2$, crystallises from alcohol in tables and melts at 110°.

W. P. W.

α-Hydroxysulphonaphthoic Acid. By K. König (*Ber.*, **23**, 806—810).—α-Hydroxysulphonaphthoic acid (Abstr., 1889, 719) readily decomposes with the elimination of both the COOH- and SO_3H-groups; thus, α-naphthol is formed in considerable quantity when the acid is either boiled with dilute sulphuric acid or heated with water in a sealed tube. The salts of the acid are more stable; the dry sodium salt, when heated at 180°, yields, for example, the sodium salt of the corresponding α-naphtholsulphonic acid.

When warmed with an excess of dilute sulphuric acid, α-hydroxysulphonaphthoic acid is very readily converted into dinitro-α-naphthol (Martius yellow) with the evolution of carbonic anhydride. An intermediate nitration-product, nitro-α-hydroxynaphthoic acid (Schmitt and Burkard, Abstr., 1888, 59) can be obtained by suspending α-hydroxysulphonaphthoic acid in five times its weight of acetic acid and gradually adding the calculated quantity of nitric acid (sp. gr. = 1·48) diluted with four times its volume of acetic acid, and allowing the mixture to remain in the cold until dissolution is complete; the product is then treated with ice-cold water. The nitro-α-hydroxynaphthoic acid so prepared yields paranitronaphthol when heated with water at 150°, and hence contains the nitro-group in the para- and not in the meta-position relatively to the hydroxyl, as stated by Schmitt and Burkard. Comparison shows that α-hydroxynaphthoic acid is much less readily nitrated than α-hydroxysulphonaphthoic acid, whence the author concludes that the SO_3H-group in the latter is in the para-position with respect to the hydroxyl.

Contrary to expectation, α-hydroxysulphonaphthoic acid readily reacts with diazo-compounds, yielding azo-colours (compare Dahl and Co., Germ. Pat., 51715). This is due, however, to the ready elimination of the COOH-group by the azo-group; the azo-dye obtained by treating the acid with a solution of diazobenzene chloride being identical with benzeneazo-α-naphtholsulphonic acid obtained from Neville and Winther's 1 : 4-naphtholsulphonic acid. It follows, therefore, that α-hydroxysulphonaphthoic acid has the constitution [OH : COOH : SO_3H = 1 : 2 : 4]. W. P. W.

Hydrides of Anthracene and Phenanthrene. By L. Lucas (*Chem. Centr.*, 1890, i, 39).—In the preparation of hexahydroanthracene, Graebe and Liebermann obtained an oily substance, which they did not more closely examine; the author has made this the subject of investigation. When heated with amorphous phosphorus and hydriodic acid (boiling point 127°) at 250°, anthracene is primarily converted into a substance which melts at 87—88°, and which, if subjected to a further digestion, is split up into two substances, a solid and a liquid. The former is *anthracene perhydride*, $C_{14}H_{24}$, melting at 89° and boiling at 277·5°; it sublimes at 100°, and is volatile in steam.

If water is added in the above reaction, *anthracene octohydride*, $C_{14}H_{18}$, and an oily substance are formed. The octohydride melts at 60°, and boils at 295°.

The oily product of both these reactions is the same, *anthracene decahydride*. Its sp. gr. at 20° = 0·9884 (water at 4° = 1); boiling point, 280°. If still more water is used in the reaction, anthracene dihydride is the only product.

When distilled over red-hot pumice, these hydrides are converted into anthracene; at a somewhat lower temperature they remain for the greater part unchanged. If distilled over red-hot zinc-dust, the conversion into anthracene is still more complete. Bromine compounds were not obtained. With fuming nitric acid, the perhydride does not react; when treated with concentrated sulphuric acid and fuming nitric acid, the decahydride, as also the octohydride, forms a yellow precipitate, difficult to manipulate. With concentrated sulphuric acid, the octohydride alone forms a well characterised sulphonic acid; its barium salt has the formula $(C_{14}H_{17}SO_3)_2Ba + H_2O$. With oxidising agents, the perhydride is oxidised to no very well characterised substances; the decahydride is oxidised by chromic mixture to anthraquinone, in addition to which another substance is formed, which was not more fully examined; potassium permanganate oxidises the decahydride to phthalic acid. The octohydride in glacial acetic acid is oxidised by chromic acid to anthraquinone.

Phenanthrene also forms a perhydride, $C_{14}H_{24}$, when heated with amorphous phosphorus and hydriodic acid. Its sp. gr. at 20·5° = 0·9312 (water at 4° = 1); it boils at 268—275°, and melts at about 3°. It is oxidised by chromic acid in glacial acetic acid, the products being indefinite. The same perhydride is obtained from phenanthraquinone, when this is reduced with phosphorus and hydriodic acid. Phenanthrene perhydride is converted into anthracene by distilling over zinc-dust. J. W. L.

Derivatives of Dianthryl. By H. SACHSE (*Chem. Centr.*, 1890, i. 38).—By treating dianthryl dissolved in chloroform with chlorine, *dichlorodianthryl octochloride*, $C_{28}H_{16}Cl_{10}$, is formed, which readily decomposes with separation of hydrogen chloride. When treated with alcoholic potassium hydroxide, the solution of the chloride becomes blood-coloured, and on heating it is converted into the green hexachlorodianthryl, $C_{28}H_{12}Cl_6$. Bromine forms corresponding compounds; the *dibromodianthryl octobromide*, $C_{28}H_{16}Br_{10}$, is somewhat more stable than the chloride, and by the action of alcoholic potash is converted into the *hexabromodianthryl*, $C_{28}H_{12}Br_6$.

Dichlorodianthryl, $C_{28}H_{16}Cl_2$, is prepared from dinitrodianthryl by heating with fuming hydrochloric acid at 180°. Bromine causes the formation of *dibromodianthryl.*

Dianthryl tetrahydride, $C_{28}H_{22}$, is prepared by acting on dianthryl with sodium amalgam; it melts at 248—249°. By bromine it is converted into dibromanthracene. With concentrated sulphuric acid, dianthryl forms a trisulphonic acid. J. W. L.

Massoy Bark Oil. By E. F. R. WOY (*Arch. Pharm.* [3], **28**, 22—48).—This oil is obtained from a plant of the Lauraceæ growing in New Guinea. The crude oil is rather fluid, perfectly clear, and yellow, with an odour resembling that of cloves, and a sharp, burning taste. Its sp. gr. at 10° is 1·0514. Its reaction to litmus is very faintly acid, due to a trace of acetic acid; it contains somewhat over $\frac{1}{2}$ per cent of water, but is free from sulphur and nitrogen. A detailed investigation shows the constituents of the oil to be a new terpene, safrole, eugenol, and small quantities of a creosote-like substance. The new terpene, *massoyene*, $C_{10}H_{16}$, boils at 172°, has a sp. gr. = 0·8619 at 13°, and is dextro-rotatory; it does not agree in character with any terpene hitherto described.

From *safrole* the following four new brominated compounds were obtained:—$CH_2{:}O_2{:}C_6H_3\cdot CH_2\cdot CHBr\cdot CH_2Br$, a liquid boiling at 215° under a pressure of 22 mm.; $CH_2{:}O_2{:}C_6H_2Br\cdot CH_2\cdot CHBr\cdot CH_2Br$, fibrous crystals melting at 54°; $CH_2{:}O_2{:}C_6H_2Br\cdot CH_2\cdot CH{:}CH_2$, a liquid boiling at 185° to 190° under a pressure of 18 mm.;

$$CH_2{:}O_2{:}C_6H_3\cdot CHBr\cdot CHBr\cdot CH_2Br,$$

in small tabular crystals melting at 87°. Further, the pentabromide obtained, although identical with the products described by Schiff, Grimaux, and Knotte, must have the formula

$$CH_2{:}O_2{:}C_6HBr_2\cdot CHBr\cdot CHBr\cdot CH_2Br.$$

Dibromobenzoyleugenol, $CH_2Br\cdot CHBr\cdot CH_2\cdot C_6H_3(OMe)\cdot OBz$, crystallises in lustrous plates and melts at 97°; *eugenol ethyl ether tribromide*, isomeric with that described by Wassermann, forms tufts of slender, silky needles, and melts at 92°. J. T.

Hydroxycamphocarboxylic Acid from Camphocarboxylic Acid. By A. HALLER and MINGUIN (*Compt. rend.*, **110**, 410—412).—Ethyl camphocarboxylate, when heated in sealed tubes at 150° to 200° with a small quantity of sodium dissolved in excess of ethyl alcohol, yields ethyl hydroxycamphocarboxylate, $COOEt\cdot C_8H_{14}\cdot CH_2\cdot COOEt$, identical with the product obtained by the direct etherification of hydroxycamphocarboxylic acid, or by treating the mononitrile, $COOEt\cdot C_8H_{14}\cdot CH_2\cdot CN$, with a solution of hydrogen chloride in alcohol. When treated with excess of aqueous potash, it yields hydroxycamphocarboxylic acid, melting at 228—230° and identical with the acid obtained under other conditions.

It has previously been shown that camphocarboxylic nitrile combines readily with alcohols when heated at 100° with the sodium alkyl oxides. Under these conditions, the closed chain is broken and ethereal salts of hydroxycamphocarboxylic nitrile are formed. The reaction with ethyl camphocarboxylate is similar. It is noteworthy that the presence of cyanogen makes the rupture of the nucleus in

$OC{<}\begin{matrix}CH\cdot CN\\ |\\ C_8H_{14}\end{matrix}$ much easier than in

$OC{<}\begin{matrix}CH\cdot COOEt\\ |\\ C_8H_{14}\end{matrix}$. C. H. B.

Aloïn from Barbados, Curaçao, and Natal Aloes. By E. GROENEWOLD (*Arch. Pharm.* [3], 28, 115—139).—I. *Aloïn from Barbados aloes.*—This was obtained as small, pale-yellow, needle-shaped crystals, slightly soluble in cold water, easily soluble in hot water. In boiling water it rapidly becomes brown. It is more soluble in alcohol than in water, and the solution is more stable. Aloïn is only slightly soluble in ether, chloroform, light petroleum, and benzene. Acetic acid dissolves it readily, and this solution is unaffected by the air. The moist crystals very readily become discoloured, especially when exposed to light. The substance melts at 147°. The results of numerous analyses are best expressed by the formula $C_{23}H_{24}O_{10}$, but the author prefers to adopt $C_{16}H_{16}O_7$, which best accords with the bromine- and acetyl-derivatives. If the latter be accepted, then the air-dried crystals obtained from a concentrated alcoholic solution would be expressed by $C_{16}H_{16}O_7 + 3H_2O$ or $3\frac{1}{2}H_2O$. A bromaloïn, $C_{16}H_{13}Br_3O_7 + 4H_2O$, was obtained by pouring an aqueous solution of aloïn into bromine-water, or by pouring bromine-water into the aloïn solution. The two bromo-compounds agreed, excepting a difference of about 1 per cent. in the water of crystallisation. This variation has also been noticed by E. Schmidt.

Acetyl-derivatives were only obtained with difficulty by the action of acetic anhydride on adding either concentrated sulphuric acid drop by drop, or on adding a drop or two of acetic chloride. In the former case, the product occurred sometimes as white, hard, columnar crystals, $C_{16}H_{10}Ac_6O_7$, and sometimes as beautiful, soft, yellow needles, $C_{16}H_{13}Ac_3O_7 + \frac{1}{2}H_2O$. In the latter case, only the yellow needles were obtained.

II. *Aloïn from Curaçao aloes.*—This appears to be identical with that from Barbados aloes.

III. *Aloïn from Natal aloes*, $C_{24}H_{26}O_{10}$ + Aq (various).—This differs both chemically and physically from the two aloïns just considered. It can readily be obtained in the form of large, well-formed crystals; this, together with its resistance to the action of alkalis, distinguishes it from Barbados aloïn. Halogen substitution-products are not readily obtained. Oxidation with nitric acid yields both oxalic and picric acids. Heated in a capillary tube, the aloïn softens at 180° and melts with decomposition at 210°. The acetyl-derivative appears to be $C_{24}H_{21}Ac_3O_{10}$. Natal aloïn differs from Barbados aloïn in containing a methoxyl-group, as determined both in aloïn, $C_{23}H_{23}(OMe)O_9$, and in acetylaloïn, $C_{23}H_{18}(OMe)Ac_5O_9$. J. T.

Derivatives of Cantharidin. By F. ANDERLINI (*Ber.*, **23**, 485—486; compare Homolka, Abstr., 1886, 723).—Cantharidin is oxidised by prolonged boiling with concentrated nitric acid, but the products cannot be separated from unchanged cantharidin.

Cantharidin phenylhydrazone, $C_{16}H_{16}N_2O_3$, is obtained, together with a compound melting at 130—131°, when cantharidin (1 part) is heated at 135—140° with phenylhydrazine (4 parts) and 50 per cent. acetic acid (2 parts); the two products are separated by crystallisation from benzene. The hydrazone separates from acetone, in which it is readily soluble, in large, rhombic crystals melting at 237—238°; it is insoluble in water, and only sparingly soluble in alcohol and benzene.

The compound melting at 130—131° (see above) has the composition $C_{16}H_{21}N_4O_2$; it separates from benzene and dilute alcohol in colourless crystals, and is readily soluble in boiling water.

A compound of the composition $C_{10}H_{13}NO_3$ is formed when cantharadin is heated at 180° for seven to eight hours with a saturated alcoholic solution of ammonia; it crystallises in small prisms, melts at 200—201°, and is readily soluble in hot water and alcohol, but only sparingly in the cold solvents. F. S. K.

Colouring Matter from Diaptomus analogous to Carrotene. By R. BLANCHARD (*Compt. rend.*, **110**, 292—294).—*Diaptomus bacillifer* was treated with alcohol, and after two months the alcohol, which was only slightly coloured, was decanted off, the organisms triturated with sand, again washed with alcohol, and dried in a vacuum. The bright-red powder thus obtained becomes yellow and finally white when exposed to air even in the dark. The pigment is insoluble in water, ammonia, methyl alcohol, and dilute potash, and only very slightly soluble in hot ethyl alcohol. It dissolves in ether with formation of a red solution, in light petroleum and benzene yielding an orange-brown solution, in chloroform (a rose-red solution), and in carbon bisulphide (a ponceau-red solution). Acids, alkalis, and reducing agents are without action on these solutions.

In order to remove fat, &c., the dried pigment was treated with light petroleum and again dried. The alcohol and the petroleum dissolve some of the pigment and all the fatty and other soluble substances. The residue is exhausted with carbon bisulphide, and the latter, when distilled, leaves a deep carmine-red, oily substance, which, if redissolved in carbon bisulphide and evaporated in a vacuum, solidifies but does not crystallise.

The pigment from *Diaptomus* in some respects resembles the lipochromes, but differs from them in its very slight solubility in alcohol and in the character of its absorption spectrum. Concentrated solutions absorb all rays but the red, and when the solution is diluted the less refrangible rays are transmitted to a greater and greater extent, but no absorption bands are observed. This pigment, in fact, very closely resembles carrotene, and if not identical with it, at any rate belongs to the same group. It is similar in colour, dissolves in the same solvents, behaves similarly with reagents, and shows a similar absorption spectrum. It dissolves, for example, in strong sulphuric acid, forming a deep indigo-blue liquid, and when the solution is poured into water the colour disappears immediately, but no precipitate is formed. Probably there are several carrotenes, just as there are several chlorophylls and hæmoglobins. It follows from these observations (1) that carrotene is common to both animals and plants; (2) that an animal organism is capable of forming a hydrocarbon. *Diaptomus* also furnishes another example of the occurrence of carrotene in the absence of chlorophyll, as in the carrot, tomato, and pumpkin. C. H. B.

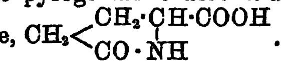
Carrotene and the Green Colouring Matter of Chlorophyll Grains. By H. Immendorff (*Chem. Centr.*, 1890, i, 163—164; *Landw. Jahrb.*, **18**, 507—520).—The author recommends the following method for the separation of carrotene. 500 grams of the leaves are boiled with dilute aqueous soda, the brown-coloured extract poured off, the leaves then washed with water, and pressed as free from the latter as possible. The leaves are next digested with 95—98 per cent. alcohol in glass flasks; if, at the end of 24 hours, one of these flasks with its contents is shaken gently in the sunlight, numberless crystals of metallic lustre of pure carrotene separate After filtering off these, a small quantity of sodium hydroxide is added to the green filtrate, and the alcohol almost entirely distilled off. The residue is then extracted with light petroleum or ether to which a small quantity of alcohol has been added, until no longer coloured. Occasionally this extract deposited a crop of crystals, although, as Husemann has found, this does not always occur. This second colouring matter was not further examined.

Etiolated barley leaves were also examined for carrotene, and it was only found in those leaves which had an orange-colour; in those which were of a pure lemon-yellow colour it could not be detected. By growing plants in a very weak light, leaves which were light-green coloured were obtained in which carrotene was detected.

Carrotene is undoubtedly the yellow colouring matter of chlorophyll grains, and it is also the cause of the autumnal yellow colour of the leaves. J. W. L.

The Colouring Matters of the Cones of Abies excelsa. By L. Macchiati (*Chem. Centr.*, 1890, i, 164; from *Naturwiss. Rundschau.*, **4**, 608).—Alcohol abstracts a yellow colouring matter from the perfectly ripe cones, which gives strong general absorption of the violet end of the spectrum as far as F, and a band between C and E. The alcoholic extract is concentrated, and the residue treated successively with alcohol, ether, and chloroform. The remaining portion is completely soluble in water, to which it imparts a beautiful yellowish-red colour. From this solution, beautiful, triclinic crystals may be obtained, which are now insoluble in alcohol. The substance does not contain nitrogen. If the cones, after extraction with alcohol as above described, are treated with boiling water, the solution is golden-yellow. This colouring matter appears to be amorphous, but not of a tarry nature. J. W. L.

Pyroglutamic Acid. By F. ANDERLINI (*Gazzetta*, **19**, 99—102). —Haitinger (*Monatsh.*, **3**, 228) prepared pyroglutamic acid by heating glutamic acid at 180—190°, and found that pyrroline is formed by the dry distillation of calcium pyroglutamate; the author therefore considers that pyroglutamic acid is a carboxylic derivative of an oxypyrrolidine,



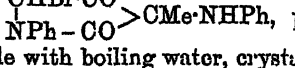
$CH_2{<}\begin{array}{l}CH_2\cdot CH\cdot COOH\\ CO\cdot NH\end{array}$.

The pure acid forms small, colourless, transparent crystals belonging to the monoclinic system $a : b : c = 0{\cdot}8239 : 1 : 0{\cdot}5281$, and exhibiting hemimorphism; it melts at 182—183°. When reduced with sodium and amyl alcohol, a small quantity of an alkaline product with an odour resembling that of pyrollidine is obtained; hydriodic acid and phosphorus yield ammonia and butyric acid in addition. The action of phosphoric chloride, hydrogen chloride, and methyl iodide gave no definite results.

Silver pyroglutamate, $C_5H_6NO_3Ag$, *forms* white crystals which melt at 176—180°, and are slowly coloured by exposure to light; it is soluble in dilute alcohol and in boiling water, but only very sparingly in cold water. S. B. A. A.

Pyridine- and Pyrroline-derivatives from Anilidopyrotartaric Acid. By A. REISSERT (*Ber.*, **23**, 542—553).—*Phenyldiketomethylanilidobromopyrrolidine hydrobromide*, $C_{17}H_{15}N_2O_2Br,HBr$, separates in crystals when the lactone of phenylketohydroxydimethylanilidotetrahydropyridinecarboxylic acid (1 mol.) (compare Abstr., 1889, 694) is dissolved in chloroform, and bromine (1 mol.) gradually added to the well-cooled solution; the mother liquors contain a dibromo-compound which is described below. It crystallises with 1 mol. of chloroform, which is expelled at 100°; it is readily soluble in alcohol but insoluble in water.

The free *base*,



$\begin{array}{l}CHBr\cdot CO\\ NPh-CO\end{array}{>}CMe\cdot NHPh$, prepared by decomposing the hydrobromide with boiling water, crystallises from dilute alcohol in small, colourless needles, melts at 141°, and is readily soluble in benzene, chloroform, alcohol, ether, and glacial acetic acid, but insoluble in water and light petroleum. It dissolves in hot concentrated mineral acids and in alkalis. The *nitroso*-compound, $C_{17}H_{14}N_3O_3Br$, crystallises from alcohol in small needles melting at 199·5°.

Phenyldiketomethylanilidodibromopyrrolidine, $C_{17}H_{14}N_2O_2Br_2$, is obtained when the chloroform mother liquors from the monobromo-compound are evaporated. It crystallises from alcohol in shining plates, and melts at 134°.

Dianilidomethylbromacetoacetic acid,

$$NHPh\cdot CHBr\cdot CO\cdot CMe(NHPh)\cdot COOH,$$

is formed when the monobromo-compound described above is dissolved in hot soda and the resulting sodium salt decomposed with a mineral acid. It crystallises from dilute alcohol and glacial acetic acid in small, colourless needles, melts at 157°, and is readily soluble in alcohol, benzene, ether, and glacial acetic acid; it is reconverted into diketomethylanilidobromopyrrolidine when boiled with concentrated acids. The *sodium* salt crystallises in small needles with 3 mols. H_2O. The acid yields a dinitroso-compound.

Phenylanilidobromomethyl-methylanilidopyrazolone,

$$\mathrm{NPh}<\begin{matrix}\mathrm{N:C\cdot CHBr\cdot NHPh}\\ \mathrm{CO\cdot CMe\cdot NHPh}\end{matrix},$$

is obtained by heating the preceding compound with phenylhydrazine at 140—150°; it is a yellow, semi-crystalline substance, begins to decompose at 70°, and melts completely at 80°.

Phenyldiketomethylanilidodichloropyrrolidine, $C_{17}H_{14}N_2O_2Cl_2$, is formed when the lactone of phenylketohydroxydimethylanilidotetrahydropyridinecarboxylic acid is heated with phosphorus oxychloride and phosphorus pentachloride. It crystallises from alcohol and acetic acid in small plates, melts at 138°, and is readily soluble in benzene and ether.

Dianilidomethyldichloracetic acid, $C_{17}H_{16}N_2O_3Cl_2$, is obtained by boiling the preceding compound with soda and decomposing the product with a mineral acid. It separates from a mixture of chloroform and light petroleum in spherical crystals, melts at 151°, and is readily soluble in benzene, ether, chloroform, and glacial acetic acid, but insoluble in water and light petroleum. F. S. K.

Compounds of Pyridine with Mercury Salts. By A. GROOS (*Arch. Pharm.* [3], **28**, 73—78).—The compound with mercury iodide, $HgI_2,2C_5NH_5$ (Monari, *Jahrsb.*, 1884, 644), is obtained when dry mercurous iodide is dissolved in warm pyridine; it melts at 97° (uncorrected). From a solution in cold pyridine to which alcohol was added, crystals 2 cm. long and 4 mm. thick were obtained. The mercury bromide compound, $HgBr_2,2C_5NH_5$, is prepared like the foregoing compound; beautiful crystals are obtained from its alcoholic solution which melt at 127·5°. These substances dissociate readily, and tables of their vapour-tensions are given as determined at 14°, 35·5°, 78°, 99—100°, and 137°. The compounds re-form as the temperature goes down. Corresponding compounds with mercurous nitrate and sulphate were obtained. The separation of mercury in these reactions shows that mercurous salts are not formed, or at least if formed are not stable. The compounds can also be formed from mercuric salts. J. T.

Metallo-quinolides and Double Salts of Quinoline. By E. BORSBACH (*Ber.*, **23**, 431—440).—Various double salts of quinoline have been described by Hofmann (*Annalen*, **47**), Bromeis (*Annalen*, **52**), Baeyer (*Ber.*, **12**, 2), and especially by Schiff (*Annalen*, **131**), the last of whom introduced the term metallo-quinolides for the compounds obtained by the direct action of quinoline on metallic salts.

The metallo-quinolides were obtained by simply adding quinoline to the metallic salt, the compound separating, as a rule, immediately, but in certain cases only after some time. The double salts may be obtained by dissolving the foregoing compounds in hydrochloric acid, or by adding quinoline hydrochloride to a solution of the metallic salts. All the compounds are stable in the air, and have the characteristic odour of quinoline, which is more intense in the metallo-quinolides; some are decomposed by acids, and others even by water. With few exceptions, quinoline only gives compounds with the halogen compounds of the heavy metals.

The salt $MnCl_2,C_9NH_7,HCl$ is prepared by dissolving manganous chloride in moderately concentrated hydrochloric acid, and adding quinoline. It crystallises from hydrochloric acid in hair-like needles, which have a rose-red colour when dry, and remain unaltered at 250°.

The salt $FeCl_3,C_9NH_7,HCl$ separates as a yellow, crystalline precipitate when concentrated hydrochloric acid is added to a mixture of strong ferric chloride solution and quinoline. It dissolves again on shaking and warming, and then crystallises in small needles, which melt at 150°, and are decomposed by boiling water.

A double salt with ferrous chloride or sulphate could not be obtained.

The salt $CoCl_2,2C_9NH_7$ is formed by adding quinoline to an alcoholic solution of cobalt chloride. It separates as a thick, blue, amorphous precipitate, but is obtained in well-developed triclinic crystals when a dilute alcoholic solution is mixed with a little quinoline, and allowed to evaporate spontaneously. It is decomposed on heating, and also by water and acids.

Copper salts.—The salt $CuCl_2,2C_9NH_7$ is obtained either amorphous or crystalline in exactly the same manner as with the foregoing cobalt salt. In the amorphous state, it has a bluish-grey colour, but when crystalline it is opaque and almost black. It is converted by hot water into a green basic salt, and is also decomposed by acids. The sulphate and nitrate of copper give flocculent precipitates of basic salts with quinoline. The salt $Cu(C_2H_3O_2)_2,C_9NH_7$ separates as an intensely green, crystalline powder on the addition of quinoline to a concentrated neutral solution of cupric acetate. It is readily soluble in alcohol, less in cold water, and is decomposed by boiling water and by acids.

Zinc salts.—The salt $ZnI_2,2C_9NH_7$ is obtained as a white powder when a solution of zinc iodide is precipitated by quinoline. It is slightly soluble in cold and is somewhat decomposed by hot water, and becomes yellow on exposure to light. The compound with zinc bromide has a similar composition, and forms a white, flocculent powder.

Cadmium Salts.—Cadmium chloride gives with quinoline in aqueous or alcoholic solution a thick, white precipitate of the salt $CdCl_2,C_9NH_7$; this is sparingly soluble in water and alcohol, and dissolves in acids forming double salts. The hydrochloric acid double salt has been previously prepared by Williams. The bromide $CdBr_2,C_9NH_7$ is prepared in the same manner, and crystallises from hot alcohol in small white needles, which are decomposed by boiling water and acids. The salt $CdI_2,2C_9NH_7$ differs in composition from the two foregoing compounds, but is also decomposed by hot water. From its solution in hydrochloric acid, the double salt separates after a long time in green, hair-like needles which have a metallic lustre, and are insoluble in water.

Tin Salts.—By the action of quinoline on an alcoholic solution of stannous chloride, a thick, white, amorphous precipitate is obtained which has not a constant composition. It dissolves in dilute acids, and, after a time, the double salt $SnCl_2,C_9NH_7,HCl$ separates in long, thin needles which melt at 127°. Stannic chloride yields a similar double salt, $SnCl_4,2(C_9NH_7,HCl)$, which crystallises in long, lustrous needles. The compound $SnCl_4,2(C_9NH_7,HCl) + H_2O$, described by Schiff, could not be obtained.

Mercury Salts.—The mercuric bromide compound, $HgBr_2,C_9NH_7$, is obtained in the usual manner, and forms a white, voluminous precipitate melting at 204°, and almost insoluble in water and alcohol. The mercuric iodide compound, HgI_2,C_9NH_7, crystallises in pale yellow, lustrous plates, soluble in warm alcohol and in solutions of potassium iodide and ammonium salts. It melts at 168°, and decomposes above this temperature. Of the true double salts, only that with mercuric chloride, $2C_9NH_7,H_2HgCl_4 + 2H_2O$, could be obtained; this separates in monoclinic crystals from a solution of mercury-chloride-quinoline in hydrochloric acid after a long time, and may also be obtained by adding quinoline hydrochloride to a solution of mercuric chloride. It melts at 91°, and decomposes at a higher temperature.

An aqueous solution of lead nitrate is precipitated by quinoline, but the product is simply a basic lead salt of the probable formula $Pb(NO_3)_2,Pb(OH)_2$. Nickel chloride does not act in the same manner as cobalt chloride, but appears not to form a compound, or in any case only a most unstable one.

From a solution of aluminium chloride, quinoline precipitates aluminium hydroxide, which dissolves in concentrated hydrochloric acid. On further addition of the latter, a white, crystalline substance separates, which has the formula, $AlCl_3 + 6H_2O$. H. G. C.

Compounds of Alloxan with Pyrazole Bases. By G. Pellizzari (*Annalen*, **255**, 230—251; compare Abstr., 1889, 517, and 1888, 142).—The compound previously described as formylphenyldimethylpyrazolone (formylantipyrine), obtained by boiling phenyldimethylpyrazolonetartronylimide with concentrated hydrochloric acid or potash, has, in reality, the molecular formula $C_{24}H_{24}N_4O_4$, and is *di-phenyldimethylpyrazoloneacetic acid.* The *platinochloride*, $(C_{24}H_{24}N_4O_4)_2,H_2PtCl_6$, is a reddish-brown powder. The *sulphate*, $C_{24}H_{24}N_4O_4,H_2SO_4$, crystallises in long, silky needles, and is sparingly soluble in cold water. The *barium* salt, $(C_{24}H_{23}N_4O_4)_2Ba$, forms transparent, very deliquescent crystals.

Di-phenyldimethylpyrazoloneacetic acid dissolves in concentrated nitric acid; on boiling the solution, carbonic anhydride and oxides of nitrogen are evolved, and nitrophenyldimethylpyrazolone (m. p. 273°) is formed. The *tetrabromo*-derivative, $C_{24}H_{20}N_4O_4Br_4$, prepared by treating the acid with bromine in glacial acetic acid solution, crystallises in yellow needles, melts at 149—151° with decomposition, and is decomposed by water. The *anilide*, $C_{21}H_{23}N_4O_3$·NHPh, crystallises in colourless needles, melts at 237°, and is very readily soluble in alcohol and acids, but only very sparingly in water, benzene, and ether, and insoluble in cold potash.

Methylenedi-phenyldimethylpyrazolone, $CH_2(C_3N_2Me_2Ph)_2$, is formed when di-phenyldimethylpyrazoloneacetic acid is heated at 240—250° until the evolution of carbonic anhydride is at an end; it can also be obtained by boiling phenyldimethylpyrazolone with formaldehyde and concentrated hydrochloric acid. It separates from alcohol in colourless, monoclinic crystals containing 1 mol. H_2O, $a : b : c = 0{\cdot}83328 : 1 : 0{\cdot}80173$, $\beta = 87° 3' 2''$, and loses its water at 130°, the anhydrous substance melting at 179°. It is readily soluble in water, benzene, glacial acetic acid, and mineral acids, but only sparingly in alcohol and ether, and insoluble in alkalis.

Methylenedi-phenylmethylpyrazolone, $CH_2(C_3N_2HMePh)_2$, can be obtained by boiling methylphenylpyrazolone with formaldehyde and concentrated hydrochloric acid, the hydrochloride separating on cooling in slender, silky needles. The free base is a colourless, amorphous powder, readily soluble in alcohol, benzene, and acetic acid; when heated with methyl iodide at 130° in alcoholic solution, it is converted into methylenedi-phenyldimethylpyrazolone (m. p. 179°).

F. S. K.

Morphine from Papaver rhœas. By O. HESSE (*Arch. Pharm.* [3], 28, 7—9).—Some time ago, Dieterich (*Pharm. Zeit. Russ.*, 27, 269) claimed to have found in the aqueous and alcoholic extracts of the flower leaves of this poppy 0·7 and 0·17 per cent. respectively of morphine. The author has repeated Dieterich's procedure on 300 grams of fresh leaves, but obtained only a few milligrams of glistening crystals, which, however, were not morphine, but appeared to contain some rhœadine. When fresh material is available, the author will pursue the subject.

J. T.

Dextrococaïne. By A. EINHORN and A. MARQUARDT (*Ber.*, 23, 468—474).—According to Einhorn's formula for cocaïne, two asymmetrical carbon-atoms are present in the molecule; if this is correct, similar optical isomerides should exist to those of atropine. Experiments made to convert cocaine directly into an isomeric base have not been attended with success, but similar experiments with ecgonine, one of its decomposition-products, have given the desired result, for this compound and all its derivatives, including cocaïne itself, are converted into dextro-ecgonine by warming with an aqueous solution of potassium hydroxide on the water-bath.

The best material for the preparation of dextro-ecgonine is the mixture of alkaloïds obtained as a bye-product in the preparation of cocaïne, which must be warmed with the aqueous potash for 18—24 hours. Dextro-ecgonine, $C_9H_{15}NO_3$, crystallises in tables which seem to be hemimorphous, and melts at 254°. On heating with acetic acid saturated with hydrogen chloride, it yields the same anhydroecgonine as is obtained from ordinary ecgonine, whence it would appear that the optical activity is due to the asymmetrical carbon-atom in the side chain. The *hydrochloride*, $C_9H_{15}NO_3,HCl$, crystallises from alcohol in monoclinic prisms; an aqueous solution containing 4·4 per cent., in a tube 2 dcm. in length, rotated the plane of polarisation 1·6° to the right. The *aurochloride*, $C_9H_{15}NO_3,HAuCl_4$, forms small, yellow plates which melt with decomposition at 220°. Its *methyl ether*, $C_{10}H_{17}NO_3$, obtained by suspending dextro ecgonine in methyl alcohol, and passing in hydrogen chloride, crystallises from alcohol in prisms melting at 215°.

Dextrococaine is prepared by heating the foregoing methyl ether with benzoic chloride. It is an oil, which gives a beautifully crystalline *hydrochloride*, $C_{17}H_{21}NO_4,HCl$, melting at 205°, whereas ordinary cocaïne hydrochloride melts at 181·5°. A solution of 1·9 per cent. of this salt in dilute alcohol of the same strength as employed by Antrick (Abstr., 1887, 506), in a tube 2 dcm. in length, rotated the plane of polarisation 1·5° to the right. The physiological properties of dextro-cocaine are similar to those of cocaïne, but its action takes place more quickly, and is more transient. H. G. C.

Bye-product from the Commercial Synthesis of Cocaïne. By C. Liebermann and F. Giesel (*Ber.*, **23**, 508—512).—The mother liquors from the cocaïne prepared commercially from ecgonine contain a very small quantity of a compound which is probably *methylcocaine*, $C_{18}H_{23}NO_4$, but which may possibly be an isomeride of cocaïne. This base separates from ether, chloroform, benzene, and light petroleum as an oil; it is also precipitated in an oily condition on the addition of an alkaline carbonate to its solution in acids, but the oil solidifies on keeping, the crystalline compound melting at 46—47°. The *sulphate* crystallises in small plates and is readily soluble in water but only sparingly in alcohol. The *hydrochloride*, $C_{18}H_{23}NO_4,HCl$, is much less readily soluble in cold water than cocaïne hydrochloride, and crystallises from hot alcohol in needles or prisms melting at 209—210°; it produces the same sensation as cocaïne hydrochloride when placed on the tongue. The *nitrate* is precipitated in crystals on adding nitric acid to dilute solutions of the other salts; this reaction serves as a means of distinguishing between, and separating the methyl-derivative from cocaine. It is moderately easily soluble in pure water and crystallises well from boiling water and alcohol. The *platinochloride*, $(C_{18}H_{23}NO_4)_2,H_2PtCl_6$, crystallises from hot water in yellowish needles; the aurochloride, $C_{18}H_{23}NO_4,HAuCl_4$, crystallises from dilute alcohol in needles and melts at 148°.

Methylcocaïne is decomposed by water, although much more slowly than cocaïne, and it is decomposed by boiling hydriodic acid with liberation of methyl iodide (1 mol.); it is only slowly acted on by concentrated hydrochloric acid, but much more quickly by the boiling dilute acid, yielding methyl alcohol, benzoic acid, and methylecgonine hydrochloride.

Benzoylmethylecgonine hydrochloride, $C_{17}H_{21}NO_4,HCl$, the first product of the decomposition of methylcocaine with hydrochloric acid, crystallises from hot water in colourless prisms. The *aurochloride* has the composition $C_{17}H_{21}NO_4,HAuCl_4$. The *nitrate* is sparingly soluble.

Methylecgonine, $C_{10}H_{17}NO_3$, prepared by decomposing the hydrochloride with silver oxide, crystallises from strong methyl alcohol, melts at 264° with decomposition, and is very readily soluble in water, but insoluble in absolute alcohol, and only very sparingly soluble in methyl alcohol. The *hydrochloride*, $C_{10}H_{17}NO_3,HCl$, crystallises in needles and melts at 236°. The *aurochloride*, $C_{10}H_{17}NO_3,HAuCl_4$, crystallises in lemon-yellow needles melting at 220°.

Methylcocaïne and methylecgonine may possibly be identical with the dextro-rotatory cocaine and dextro-rotatory ecgonine described by Einhorn and Marquardt (preceding abstract); experiments will be instituted with the object of testing the correctness of this supposition. F. S. K.

Berberis Alkaloïds. By E. SCHMIDT and W. KERSTEIN (*Arch. Pharm.* [3], 28, 49—73).—Although hydrastine hydrochloride and sulphate are used in medicine, the pure salts have not been described.

Hydrastine hydrochloride, $C_{21}H_{21}NO_6,HCl$, was prepared by dissolving hydrastine in anhydrous and alcohol-free ether, and leading dry hydrogen chloride over the surface of this solution as long as the salt was precipitated. This precipitate, after drying over sulphuric acid, formed a white, microcrystalline powder, easily soluble in water and chloroform. The corresponding hydrobromide was very similar in appearance; it is very soluble in chloroform, but somewhat less soluble in water than the former salt. The hydriodide forms a yellowish-brown, microcrystalline powder, much less soluble in water than the two previous salts. Hydrastine sulphate, $C_{21}H_{21}NO_6,H_2SO_4$, was prepared by adding to the ethereal hydrastine solution ether which had been shaken up with concentrated sulphuric acid. This is added drop by drop, an excess being avoided, as long as a precipitate falls. This salt readily takes up moisture and forms a gummy mass. It was found to contain 3 per cent. more sulphuric acid than the commercial article. Hydrastine aurochloride, $C_{21}H_{21}NO_6,HAuCl_4$, was also prepared, but found, like that prepared by Wilhelm, to yield too little gold by over 0·5 per cent.

This investigation confirms the view that hydrastine contains one methoxyl-group less than narcotine, thus:—Hydrastine, $C_{21}H_{21}NO_6$; narcotine, $OMe{\cdot}C_{21}H_{20}NO_6$. Narcotine, when oxidised with chromic acid, was found to yield opianic acid, $C_{10}H_{10}O_5$, and cotarnine, $C_{12}H_{13}NO_3$, whilst hydrastine has been shown by Schmidt and Wilhelm to give opianic acid and hydrastinine, $C_{11}H_{11}NO_2$. Narcotine, when oxidised by potassium permanganate in alkaline solution, gives hemipinic acid, $C_{10}H_{10}O_6$. Goldschmiedt has shown (Abstr., 1888, 362) that papaverine yields isohemipinic acid. This led to an investigation of the hemipinic acids obtained from narcotine, hydrastine, and berberine, and these acids were found to be chemically identical. Besides hemipinic acid, narcotine gives cotarnine, but to isolate this the oxidation was made with barium permanganate, and after removing the barium with sulphuric acid and the hemipinic acid with ether, cotarnine platinochloride was directly precipitated. The amount obtained, however, bore no relation to the amount of base employed, so that decomposition of the cotarnine first formed takes place. Wanklyn and Chapman found that the whole of the nitrogen of narcotine is evolved as ammonia by treatment with an alkaline permanganate solution. In the present investigation, Kerstein found only traces of ammonium salts in the hydrochloric acid employed to collect anything volatilised, whilst Schmidt, in a footnote, remarks that narcotine, when boiled with excess of alkaline potassium permanganate, evolves a strong odour of methylamine. Although the decomposition of narcotine is not very sharply defined, the primary reaction is doubtless expressed by the equation $C_{22}H_{23}NO_3 + O_2 = C_{10}H_{10}O_6 + C_{12}H_{13}NO_3$, narcotine giving hemipinic acid and cotarnine. By the distillation of narcotine and hydrastine, respectively, in hydrogen, considerable quantities of meconine and trimethylamine were obtained.

Boiling acetic anhydride does not act on hydrastine. Acetic chloride, however, gives a compound which crystallises from alcohol in beautiful, yellowish-green needles, whose solution exhibits a bluish-green fluorescence. Analysis leads to the formula $C_{21}H_{20}AcNO_6$. This is undergoing further investigation. On boiling hydrastine with iodine in alcoholic solution, the following reaction takes place: $C_{21}H_{21}NO_6 + 6I + H_2O = C_{10}H_{10}O_5 + C_{11}H_{10}NO_2I,I_2 + 3HI$. Roser (Abstr., 1888, 1115) obtained a similar reaction for narcotine, and from the triiodide, by treatment with hydrogen sulphide, he obtained the two compounds, iodotarconine methiodide, $C_{11}H_8INO_3,MeI$, and tarconine methiodide, $C_{11}H_9NO_3,MeI$, whilst Kerstein has only succeeded in isolating hydrastonine iodide, $C_{11}H_{10}NO_2I$. Still it does not appear improbable that iodohydrastonine iodide will be obtained under suitable conditions.

Ethylhydrastine, $C_{21}H_{20}EtNO_6$, was prepared by heating hydrastine ethiodide with water, and decomposing with normal potash, when an oily liquid separated, which solidified to a yellowish-green mass. This compound, when recrystallised from alcohol, formed yellowish-green needles melting at 127°; it is easily soluble in mineral acids, alcohol, ether, and chloroform, but not in water. The double chlorides of this compound and platinum, gold, and mercury, also the compound with picric acid, were obtained as amorphous powders.

Phytosterin, $C_{26}H_{44}O + H_2O$, separates from extract of hydrastis root after long standing as a smeary, resinous deposit, along with other compounds. After crystallising from glacial acetic acid, and then from alcohol, phytosterin is removed from solution, after acidifying with hydrochloric acid, by shaking up with ether; fat is removed by saponifying with alcoholic potash and treatment of the dry soap with chloroform. Repeated crystallisation of the residue gives phytosterin as small, brilliant, colourless plates, melting at 133°.

J. T.

Alkaloïds of the Root of Stylophoron diphyllum. By F. Selle (*Arch. Pharm.* [3], 28, 96—109).—The author has exhaustively examined stylophorine, an alkaloïd obtained from the above root, and finds that it is identical with chelidonine, $C_{20}H_{19}NO_5 + H_2O$. Hydrochloric acid under pressure at 150° does not act on this alkaloïd. When heated with aqueous iodine in a glycerol-bath, no methyl iodide was formed, and silver nitrate solution was scarcely rendered turbid. The base therefore contains no methoxyl-group. Chelidonine, although the principal alkaloïd of the root examined, is not the only one; at least two others have been detected, which will be further investigated when more material is available. J. T.

Taxine, the Alkaloïd of the Yew-tree (Taxus baccata). By A. Hilger and F. Brande (*Ber.*, 23, 464—468).—The preparation of this alkaloid was carried out according to the method given by Marmé (*Med. Centr.*, 14, 97). The ethereal solution was extracted by dilute sulphuric acid, the extract precipitated with ammonia, and the yellow precipitate redissolved in ether; the process being repeated until the precipitate with ammonia was quite white. Taxine cannot be obtained in crystals; it is readily soluble in alcohol and ether, less so in chloroform, scarcely at all in water, and insoluble in benzene. It melts at 82° evolving a characteristic aromatic odour, and gives an intense, purple-violet coloration with concentrated sulphuric acid, whilst Frohde's reagent colours it reddish-violet. The slightly acid aqueous solution of the alkaloïd gives precipitates with potassium bismuthoiodide, potassium iodide and iodine, sodium phosphomolybdate, gold chloride, platinic chloride, picric acid, and even fixed alkalis and ammonia. It appears to have the composition $C_{37}H_{52}O_{10}N$.

The salts are soluble in water and difficult to obtain crystalline, only the *hydrochloride*, $C_{37}H_{52}O_{10}N,HCl$, having been prepared in a pure state by passing hydrogen chloride into a solution of the alkaloïd in anhydrous ether. The *platinochloride*, $(C_{37}H_{52}O_{10}N)_2,H_2PtCl_6$, forms a yellow, microcrystalline powder.

Taxine ethiodide, $C_{37}H_{52}O_{10}N,EtI$, is prepared by heating a mixture of the two compounds in molecular proportion at 100° under pressure. It is a crystalline product, which may be purified by dissolving in alcohol, and pouring the solution into water. H. G. C.

Diastatic Ferment of Ungerminated Wheat. By C. J. Lintner (*Bied. Centr.*, 19, 141; compare Abstr., 1888, 497).—Wheat contains a diastatic ferment, which, like malt-diastase, converts starch into maltose; but it differs from malt-diastase in not having the power of dissolving starch paste. Attempts to isolate the ferment failed.

N. H. M.

Physiological Chemistry.

Digestibility of Boiled Milk. By R. W. Raudnitz (*Zeit. physiol. Chem.*, 14, 325—327).—The author corrects and amplifies a reference he had previously made (Abstr., 1889, 1225) to a paper by W. Prausnitz, on the use of milk as a food (*Zeit. Biol.*, 25), pointing out that the calcium salts found in the fæces on a milk diet have a threefold origin: (1) from the food, (2) from the digestive juices, (3) salts separated by the intestine, in which it takes the place of the kidneys as excreting organ. W. D. H.

Action of Dilute Hydrochloric Acid and of Pepsin with Hydrochloric Acid on the Digestible Albumin of Fodders. By A. Siutzer (*Landw. Versuchs-Stat.*, 1890, 107—133).—In pursuance of former investigations, the author has examined the action mentioned above, care being taken that the conditions in all the experiments were alike. All the substances to be tested were passed through a 1-mm. sieve, and then of that which passed through, those portions passing a 0·5-mm. sieve were rejected: the material was soaked in water for 12—14 hours, the water being saturated with chloroform to prevent fermentation: it was found that this antiseptic had no influence on the digestion experiments, to which the fodder was submitted. For every 100 milligrams of nitrogen as digestible albumin, the same quantity of liquid was employed, but the composition of the liquid varied with the different experiments, whilst the temperature was "blood-heat." Hydrochloric acid (0·05—0·10 per cent.), with or without pepsin, dissolved notable quantities of albumin, and it was found advisable to use very dilute solutions, but in large quantities. In the case of bran, about one-third of the albumin soluble in pepsin was also soluble in water; dilute hydrochloric acid showed the greatest activity at a temperature of 40° for 60 min., the strength of solution being 0·03 per cent. of hydrogen chloride. Pepsin and hydrochloric acid together (0·03 per cent. hydrogen chloride) was less active than the acid alone, but if more than 0·03 per cent. of the latter was present, then the mixture became more active than the acid alone.

In the case of wheaten bread, 1·651 per cent. of nitrogen was present as albumin soluble in pepsin, of this but little is soluble in water, and with dilute acids, that containing 0·01 per cent. of hydrogen chloride produced the maximum of solution, which was but little greater than with water alone; the acidified pepsin acted rather better, but slowly, slower than when bran was so treated.

With cotton seed meal containing 5·951 per cent. of nitrogen as albumin soluble in pepsin, a 0·05 per cent. solution of hydrochloric acid dissolved more than half the albumin, and with the addition of pepsin, the solubility increased as soon as the solution contained more than 0·03 per cent. of hydrogen chloride; solution was most rapid at 38—40°, and no difference was noted whether the time was 15 or 30 minutes.

With hay, containing 1·038 per cent. of soluble albuminoïd nitrogen, if the solution contained 0·05—0·2 per cent. of hydrogen chloride, then 100 c.c. of this solution had no more solvent action than 50 c.c.; the most advantageous temperature was 40°, and 30 min. or 60 min. heating produced like results.

Experiments were made as to the preservation of milk with thymol, chloroform, and salicylic acid; thymol was found to be preferable.

E. W. P.

Oxidation in the Blood. By F. Hoppe-Seyler (*Zeit. physiol. Chem.*, 14, 372—376).—S. Handler (Abstr., 1889, 1225) and Yeo (*J. Physiol.*, 6, 93) both state that in solutions of oxyhæmoglobin in sealed tubes, reduction ("self-reduction") does not occur without the presence of septic agencies, and in making this statement suppose that they are at variance with Hoppe-Seyler (*Zeit. physiol. Chem.*, 1, 125), who now writes to say that his words have been misunderstood, that he also considers that the reduction is due to septic agencies, that he always considered this to be the case, and that to his knowledge, he has never employed the expression "self-reduction." Reducing substances do not exist in the circulating blood (*Med. Chem. Untersuch.*, 1, 123); this statement was first made 25 years ago, at a time when nearly all physiologists believed that a good deal of oxidative (metabolic) change occurred in the blood itself, and was the first important step made in the recognition of the true function of the blood as a carrier of indifferent oxygen. W. D. H.

Myohæmatin. By C. A. MacMunn (*Zeit. physiol. Chem.*, **14**, 328—329).—A reply to Hoppe-Seyler's criticisms (Abstr., 1889, 1231), in which the author maintains his original view that myohæmatin is a distinct and special pigment of muscle. In a foot-note, Hoppe-Seyler states that his opinion that the only pigment of muscle is hæmoglobin is also unchanged. W. D. H.

Fat of Bone-Marrow. By P. Mohr (*Zeit. physiol. Chem.*, **14**, 390—394).—C. Eylert (*Wittstein's Vierteljahrschrift f. pract. Pharm.*, 9, 330) described in ox bone-marrow a new fatty acid of the formula $C_{21}H_{42}O_2$, melting at 72·5°, which he called medullic acid; the fatty acids present being palmitic acid, 46; medullic acid, 10; and oleïc acid, 44 per cent. As nothing further has been discovered as to the properties or salts of this acid, it was thought necessary to re-investigate the matter. The fatty acids were separated in the usual way, and the hypothetical acid was found on elementary analysis, and by examining its other properties, melting point, compounds, &c., to be nothing but stearic acid; the acids in the marrow-fat being present in the following proportions: palmitic acid, 22; stearic acid, 10; and oleic acid, 63 per cent. Volatile fatty acids were absent in the fresh marrow. W. D. H.

Amount of Nitrogen in Cow's Milk. By L. F. Nilson (*Bied. Centr.*, **19**, 101—102).—A large number of nitrogen determinations were made in the milk of a cow fed with herring-cake. The maximum percentage of nitrogen was, in 1887, 0·492, the minimum, 0·465; in 1889, the maximum was 0·533, and the minimum 0·509. In the milk of another cow, the maximum was 0·504, and the minimum 0·483 per cent. of nitrogen. The amount of nitrogen in the milk of a cow remains, therefore, almost the same when the feeding is the same.

N. H. M.

Changes in Milk by Udder Tuberculosis. By V. Storch (*Bied. Centr.*, **19**, 105—109).—The author previously showed that the milk from glands attacked by tuberculosis becomes thinner and thinner until it loses entirely the appearance of milk; the change is accompanied by a continuous diminution in the amount of fat and sugar, and the milk gradually becomes alkaline. The relation of the mineral constituents also changes, the calcium phosphate diminishing and the soda increasing in quantity; the minerals of the milk from the healthy glands remain normal. In the advanced stages of the disease, the milk acquires the appearance of blood-serum, which it also resembles in chemical composition.

The following results show the percentage composition (I) of the milk of the diseased glands, (II) of the milk of the healthy glands of the same cow, (III) of normal milk, and (IV) of cow's blood-serum:—

	Water.	Fat.	Total Albuminoids.	Albumin.	Milk-sugar.	Ash.
I.	93·64	0·12	5·22	1·20	—	1·02
II.	74·30	11·79	11·59	2·39	0·40	1·01
III.	88·24	3·18	3·02	0·43	4·78	0·78
IV.	90·77	0·08	8·25	3·89	—	0·76

The percentage composition of the ash was:—

	Ca.	K_2O.	Na_2O.	$MgO + Fe_2O_3$.	P_2O_5.	Cl.
I.	7·52	5·08	42·37	0·79	8·76	44·64
II.	19·24	12·64	21·79	2·10	22·22	27·99
III.	21·93	25·31	9·94	2·87	28·69	13·73
IV.	1·59	3·20	54·85	0·70	3·35	46·87

The last numbers (ash IV) are those obtained by Bunze with bullock's blood-serum.

The milk from the healthy glands behaved like normal milk when heated, whilst that from the diseased glands formed a compact, gelatinous mass when heated at 100°; and very dilute acetic acid gave a precipitate which dissolved in a slight excess of acid.

It is probable that, during the disease, the tissues of the glands are gradually destroyed, and that, as the secretion of milk diminishes, it becomes replaced by blood-serum. The analytical results indicate that the caseïn and most of the fat of milk are derived from the globulin of the blood, and that the milk-albumin and the milk-sugar have also a common origin, to be looked for in the serum-albumin of the blood. N. H. M.

Secretion of Calcium Carbonate by Animals. By R. Irvine and S. T. Woodhead (*Proc. Roy. Soc. Edin.*, **16**, 324—354; compare Abstr., 1889, 429).—Various calcium salts were given to hens, and it was found that the shells of the eggs laid were invariably normal, containing mere traces of phosphate and sulphate. With the exception of carbonate, the most favourable results were obtained with calcium phosphate; it, therefore, appears that all calcium salts are converted into phosphate, and in the secreting surfaces of the oviduct are converted by nascent or combined carbonic anhydride into carbonate. Compounds of strontium and magnesium, although analogous to those of calcium, were incapable of being formed into shells, and the eggs were only covered by strong membrane.

The remaining and principal portion of this paper is physiological, the experiments being conducted on crabs in sea water. As regards the parts of chemical interest, the summary shows that sufficient calcium carbonate for the formation of two shells can be stored up in the crop and gizzard; in the alimentary canal, calcium sulphide and then calcium phosphate or chloride or lime soaps may be formed. The lime is carried as a soluble calcium sodium phosphate, as calcium chloride, or as a soap to the oviduct; it is there secreted along with urea, ammonium carbonate, carbonic anhydride, which latter combining with the lime in presence of urea, we have calcium carbonate deposited in the membranes, and the shell is formed of insoluble carbonate. In certain eggs the carbonate of soda is partially replaced by phosphate, and it is probable that a similar process occurs in marine animals which have the sulphate presented to them in presence of sodium chloride. Crabs, even in presence of sodium chloride, do not assimilate calcium sulphate, and those which throw off their shells in artificial sea water, containing no calcium chloride, do not form a new exo-skeleton of carbonate: as soon, however, as the chloride is added, although the sulphate be withheld, the shell formation may go on. Phosphates of the alkalis and alkaline earths occur in blood and lymph, and they act as carriers of lime, &c., to every point of the body where carbonic anhydride may be given off; thus carbonate is formed, and the phosphoric acid re-enters the circulation.

When alkaline phosphates associated with lime and albumin preponderate in the blood, the lime so separated is in the form of phosphate, as in bone formation; when these are partially replaced by an excess of alkaline carbonates as in marine animals, the lime is secreted as carbonate.

The corals have a secreting layer of cells which produce chitin, chitin infiltrated with calcium carbonate, and almost pure carbonate, with a small quantity of organic cementing material.

The carbonate may be formed by the ammonium carbonate produced by the decomposition of the effete products of animals, as urea, &c., decomposing calcium sulphate with the formation of carbonate.

E. W. P.

Ethyl Carbamate in the Alcoholic Extract of Normal Urine. By M. Jaffé and R. Cohn (*Zeit. physiol. Chem.*, 14, 395—401).—In analyses in which large quantities of urine were employed, an organic substance was found, which was easily soluble in water, alcohol, and ether, but which was different from any hitherto known constituent of urine. The present research was undertaken to determine its nature. After repeatedly treating the alcoholic extract of many litres of urine with various reagents, this substance was obtained in a crystalline form, and its reactions, and the results of elementary analysis, showed that it was identical with ethyl carbamate (urethane), $C_3H_7NO_2$. It was found to be constantly present in the urine of men, dogs, and rabbits, but in especially large quantities in dogs' urine, as much as 5 grams being on one occasion obtained from 7 to 8 litres.

The question then arises, whether this substance is present in the fresh urine, or is formed by the action of the alcohol on certain other constituents of that secretion. On *a priori* grounds, one would be inclined to suppose that it is absent from the normal secretion—first, because it is volatile and so would have passed off in the concentration to which the urine was subjected before it was treated with alcohol, and secondly, because large quantities of a powerful narcotic could hardly be circulating in the healthy organism. This supposition was fully confirmed; if the extraction with alcohol were omitted, no ethyl carbamate was obtainable from the urine, although the same urine, after treatment with alcohol, yielded a large amount. Fresh diabetic urine and the fresh urine of a dog who had received large doses of alcohol by the mouth also yielded no ethyl carbamate.

What constituent of the urine is it, then, which gives rise to ethyl carbamate by the action of alcohol? It appears to be urea, which is acted on in this way—$CON_2H_4 + EtOH = NH_2{\cdot}COOEt + NH_3$. By treating urea with hot alcohol, ethyl carbamate was obtained, together with a small quantity of another nitrogenous, crystalline substance, which was probably a similar compound of allophanic acid. The fact that urea is the source of the ethyl carbamate accounts for the quantity of the latter substance obtainable from dogs' urine, which is very rich in urea, being greater than that obtainable from human or rabbits' urine. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Chromogenic Functions of Bacillus pyocyanicus. By C. Gessard (*Compt. rend.*, **110**, 418—420).—In ordinary cultivation fluids from beef or veal, *Bacillus pyocyanicus* yields a mixture of pyocyanin, which can be separated by agitation with chloroform, and another colouring matter which remains in the aqueous solution and imparts to it a green fluorescence. In egg albumin, the microbe develops no pyocyanin, but the green fluorescent substance is formed, and gradually changes, acquiring the brown colour of faded leaves. Even after repeated cultivations in albumin, however, the bacillus retains its power of producing pyocyanin in suitable media. Albumin which has been completely peptonised yields pure pyocyanin without any trace of the green fluorescence. The existence of both albumins and peptones in the ordinary cultivation fluids explains the production of both colouring matters. The fluorescence disappears on addition of acids, but returns on adding excess of alkali.

B. fluorescens liquefaciens and *B. fluorescens putridus* likewise produce a pigment in cultivation fluids from beef, or in albumin, but develop no colouring matter in solutions of peptones. Many other species seem to behave similarly.

Gelatin yields pyocyanin, like the peptones, but a greenish-yellow or greenish colouring matter is left in the liquid after agitation with chloroform, and gradually becomes red and then red-brown by oxidation. The new pigment can be obtained in a state of purity by adding 1 per cent. of glucose to the gelatin solution.

From these results it follows that one and the same microbe may develop different colouring matters in different media, whilst different species may develop the same colouring matter in the same medium. C. H. B.

Germination of Jerusalem Artichoke. By J. R. Green (*Ann. Agron.*, 15, 569).—During germination the tubers develop a ferment capable of transforming inulin into sugar. The ferment can be extracted from the tubers by glycerol; it is present in very small quantity, and only during germination. It can be artificially formed in the tubers not germinating, by heating them for 24 hours at 35°. Boiling destroys the activity of the ferment; thymol has no influence, so that bacteria are out of the question. It acts on inulin in neutral or very feebly acid solutions; alkalis and strong acids destroy it; it is not identical with dextrose; saliva is without action on inulin. The sugar formed does not crystallise, and reduces less readily than levulose or dextrose; there is produced at the same time an intermediate substance which is more soluble in cold water than inulin, dialyses more easily, and crystallises in pentagonal, rhomboidal, or elongated plates, or in needles arranged in tufts. Whilst inulin is insoluble in 65 per cent. alcohol, the new substance dissolves in alcohol of under 82 per cent. strength.

A good colour reaction for inulin is obtained on placing a microscopic preparation in an alcoholic solution of orcinol and then treating it with concentrated hydrochloric acid, when the inulin takes a bright orange-red colour. The sphero-crystals of inulin disappear during this process, but the place they occupied becomes red or orange. Inulin of commerce gives the same reaction, even in solution. When phloroglucinol is substituted for orcinol, the colour is brown.

J. M. H. M.

Occurrence of Boric Acid in Plants. By E. Bechi (*Bull. Soc. Chim.* [3], 3, 122).—The ash of beech growing in the borax districts of Tuscany contains 1/30,000th of boric acid. T. G. N.

Intercellular Matter. By L. Mangin (*Compt. rend.*, 110, 295—297).—The author uses the term *intercellular matter* to denote the middle layer which connects the cells of soft tissues with one another. Its composition has hitherto not been accurately known.

The author's experiments show that in the Phanerogams and Cryptogams, with the exception of fungi and many algæ, the soft tissues consist of cellules connected by a cement of insoluble pectates. If the tissues are macerated with alcohol containing 20 to 25 per cent. of hydrochloric acid, and then in a solution of a normal potassium or sodium salt with an alkaline reaction, or in very dilute ammonia, or a solution of an organic ammonium salt, the pectic acid dissolves and can be separated from the insoluble tissues and precipitated from solution by the ordinary methods. The microscopic appearance of the tissues after various treatments is described in detail.

C. H. B.

Root Excretions and their Influence on Organic Matter. By H. Molisch (*Ann. Agron.*, 15, 566—567; from *Sitzungsber. Akad. Wiss. Wien*, 46, 84—109; compare Abstr., 1889, 68).—On suspending in water the roots of young seedlings of beans, peas, maize, &c., and adding potassium permanganate to the water, the colour is soon discharged; alcoholic tincture of guaiacum is turned blue; pyrogallol, tannin, gallic acid, and humic substances also are oxidised; solutions of cane-sugar (1 in 1000) are inverted. In many cases the root secretion exudes in droplets; the viscous matter covering the young roots is really a gum and serves to ensure intimate contact between the root-hairs and particles of soil. J. M. H. M.

Composition of Fats of Fodder. By A. STELLWAAG (*Landw. Versuchs-Stat.*, 1890, 135—154).—The greater portion of this paper is occupied by extensive tables, showing the composition and characteristics of the fats of over 20 fodders, as regards the percentage of neutral fats, fatty acids (free and total), lecithin, stearic acid derived from lecithin, phosphorus, and unsaponifiable constituents. The melting points, saponification numbers, and molecular weights of the acids for each fat are also tabulated. E. W. P.

Chemical Composition and the Digestibility of the Proteïds of Various Grasses. By A. EMMERLING and G. LOGES (*Bied. Centr.*, **19**, 114—117).—20 different grasses were grown on the same ground, and each separately analysed. The soil was a loamy sand, containing (air-dry):—water, 1·25; humus, 3·27; nitrogen, 0 121; sulphuric acid, 0·018; phosphoric acid, 0·173; lime, 0·085; potash, 0·027; and magnesia, 0·008 per cent. The grasses were divided into two groups, I, very good, and II, good or of medium food-value. Group I included *Poa pratensis*, *P. nemoralis*, *Agrostis stolonifera*, *Festuca elatior*, *F. pratensis*, *Phleum pratense*, *Avena flavescens*, *A. elatior*, *Lolium perenne*, *Alopecurus pratensis*, *Dactylis glomerata*. The grasses of Group II were *Holcus lanatus*, *Anoxanthum odoratum*, *Poa compressa*, *Festuca ovina*, *Aira cæspitosa*, *Bromus arvensis*, *B. mollis*, and *Cynosurus cristatus*.

The average percentage composition of the grasses of the two groups was as follows (calculated on a percentage of water = 14·30):—

	Crude protein.	Pure protein.	Digestible protein.	Fat.	Carbohydrates.	Crude fibre.	Ash.	Digestibility coefficient of protein.
I.	7·77	5·38	4·70	1·45	36·77	32·66	7·05	60·06
II.	7·87	5·79	4·64	1·29	37·28	30·09	9·16	58·84

The results show that whilst according to a botanical analysis the grasses of Group I would be considered preferable to those of Group II, there is but little difference in the amount of food constituents and in digestibility. On the other hand, it is probable that a comparison of the grasses, if grown on different soils, would show considerable differences in chemical composition, so that hays of the same botanical composition might have different values as food, which can only be determined by chemical analysis. Chemical analysis is thus the simplest and most trustworthy method for determining the value of hay, but a botanical analysis is useful in separating the worthless or injurious grasses. N. H. M.

Lupulin. By E. STOCKBRIDGE (*Bied. Centr.*, **19**, 140—141; from *Agr. Science*, **3**, 29—35).—Hops grown in Japan from European seeds are unsuitable for brewing. The amount of lupulin was only 9·13 and 5·84 per cent. in different years, whilst European hops contain over 12 per cent. Lupulin consists of volatile oil, hop-bitter. and hop resin. The amount of lupulin formed depends largely on the amount of sunshine during the ripening of the hops. In order to neutralise the injurious effects of rain, a manuring of potassium sulphate was applied; this raised the percentage of lupulin 1 per cent., but the amount produced was still only 7·19 per cent.

In analysing hops, it is not generally taken into account that only those portions are of any value for brewing which are soluble in water or alcohol, and that in good hops there is only a slight variation in the relation of substance soluble in alcohol to the substance afterwards dissolved by water. The results of 16 analyses showed this relation to be as 1 : 0·615 to 1 : 0·453; mean, 1 : 0·536. To find the amount of lupulin in a sample of hops it is only necessary to determine this relation and multiply it by 11·34/0·536. The number 11·34 is the average percentage of lupulin in good European hops.
N. H. M.

Constituents of Scopolia atropoïdes. By C. SIEBERT (*Arch. Pharm.* [3], 28, 139—145).—The plant, a native of Germany, yielded a hyoscyamine aurochloride, a very small amount of atropine aurochloride, and still less of a mixture probably of hyoscine and hyoscyamine aurochlorides. A little scopoletin was also extracted, but not sufficient for analysis. The same remark applies to betaïn. Some choline was obtained, and its double chloride was analysed, but whether this substance occurs in the plant, or is produced by the decomposition of the lecithin contained therein, is doubtful. J. T.

Constituents of Anisodus luridus. By C. SIEBERT (*Arch. Pharm.* [3], 28, 145—146).—This plant, belonging to the Solanaceæ, is found in the Himalayas. The plant in flower yielded a not inconsiderable amount of hyoscyamine aurochloride, whilst the plant taken after the ripening of its seeds yielded only a minute quantity of atropine aurochloride and no hyoscyamine aurochloride. The fresh flowering plant gave neither atropine nor hyoscyamine. J. T.

Chemical Composition of Molinia cœrulea (Mönch.) from Königsberg, near Raibl. By G. HATTENSAUR (*Monatsh.*, 11, 19—21).—On the heights near Königsberg, *Molinea cœrulea* grows on a soil containing large quantities of zinc glance and of galena, and the eating of it has been known to cause death to animals.

The air-dried grass contained 16·765 per cent. of water, and yielded 2·245 per cent. of ash having the following composition:—

	SiO_2.	PbO.	CuO.	Fe_2O_3.	MnO.	ZnO.
Calculated on the ash, per cent.	28·656	2·041	0·266	1·419	0·222	0·265
Calculated on the air-dried plant, p. c. ..	0·646	0·046	0·006	0·032	0·005	0·006

	CaO.	MgO.	$\underbrace{K_2O, Na_2O.}$	SO_3.	P_2O_5.	CO_2.
Calculated on the ash, per cent.	1·418	1·322	57·871	2·528	3·194	0·798
Calculated on the air-dried plant, p. c. ..	0·032	0·298	1·027	0·057	0·072	0·018

On proximate analysis, the grass yielded the following percentages:—Crude fibre, 36·367; crude protein (N × 6·25), 6·175; crude fat, 2·070; ash, 2·245; non-nitrogenous extractive matter, 53·143. Substances soluble in water:—Inorganic salts, 1·768; organic constituents, 11·911. G. T. M.

Chemical Composition of Cultivated Strawberries. By W. E. Stone (*Bied. Centr.*, **19**, 117—119; from *Agr. Science*, 1889, 257—261).—The quite ripe fruit was dried in the sun to prevent loss of sap before being analysed; but the sugar and free acids were determined in the fresh substance. The following numbers form the means from analyses of 20 varieties cultivated in America:—

Dry substance.	Free acid.	Glucose.	Glucose after inversion.	Sugar (difference).
9·48	1·37	4·78	5·46	0·58 per cent.

The dry substance contained, per cent.:—

Ash.	Crude fibre.	Extracted by ether.	Albumin.	Non-nitrogenous extract.
6·53	16·35	6·75	10·51	60·79

The predominant acid is malonic acid; tartaric acid could not be detected, and citric acid can only be present in small quantities if at all.

European strawberries contain—water, 87·66; glucose, 6·28; and free acid, 0·93 per cent.; the dry substance containing—protein, 4·63; cellulose, 18·79; and ash, 6·56 per cent. They contain, therefore, more sugar and cellulose and less acid and protein than American strawberries. The relation of acid to sugar is, in wild strawberries, as 1 : 2, in American varieties as 1 : 3·5, and in European as 1 : 9. N. H. M.

Chemistry of Truffles. By A. Chatin (*Compt. rend.*, **110**, 376—382).—The author has analysed truffles grown in the soils of various localities. The proportions of dry solid matter varied from 20·84 to 24·26 per cent.; the proportion of ash in the solid matter varied from 5·62 to 9·88 per cent., and the proportion of nitrogen from 3·98 to 7·16 per cent. The chief constituents of the ash are silica, from 10·0 to 35·25 per cent., phosphoric anhydride, 18·45 to 30·25 per cent., and potassium oxide, 17·40 to 28·34 per cent. Sulphuric acid and calcium are also present in important quantity, and chlorine, iodine, magnesium, sodium, iron, aluminium, and manganese occur in small quantities. C. H. B.

Cultivation of the Leguminosæ. By E. Bréal (*Ann. Agron.*, 15, 529—551; compare Abstr., 1888, 1330, and 1890, 79).—A detailed account of the author's recent experiments on the assimilation of nitrogen by leguminous plants and the relation of the root tubercles to this phenomenon. The roots can be inoculated with bacteria from other plants of the same family, and the plants thus inoculated will assimilate nitrogen from the air. The spores of these bacteria in water survive exposure to the frost of winter without losing their power of growth when inoculated on to roots the following spring. Peas inoculated with the bacteria of lucerne and cultivated in water containing only potassium chloride and calcium phosphate produced plants containing 17 times as much nitrogen as the seeds sown. A pea grown in water in a glass tube of small diameter produced a remarkable development of tubercles, especially near the junction of stem and root; the alternation of wetness and dryness in this situation seemed to favour the development of the tubercles. When peas, the roots of which were inoculated with the bacteria, were grown in three different-sized pots containing increasing weights of river gravel, it was found that the quantity of nitrogen fixed by the plant increased with the quantity of gravel in which it was grown. The gravel itself was not enriched in nitrogen when the quantity taken was small; probably the excessive aëration of the soil in this case is unfavourable to the fixation of nitrogen. Two Spanish beans inoculated with the bacteria of cytisus accumulated 16 times the nitrogen of the seed; the 10 kilos. of gravel in which they were grown contained at the beginning no nitrogen, and in the end 0·0581 per 1000. A plant of lucerne, grown from a piece of root furnished with tubercles, contained, on June 10, 43 times the nitrogen in the root sown; the gravel had increased by $\frac{7}{100}$ its original nitrogen. A second plant of lucerne, planted in October in 4 kilos. of gravel, gave the following year three cuttings containing 80 times the nitrogen in the piece sown; the nitrogen in the soil had more than doubled.

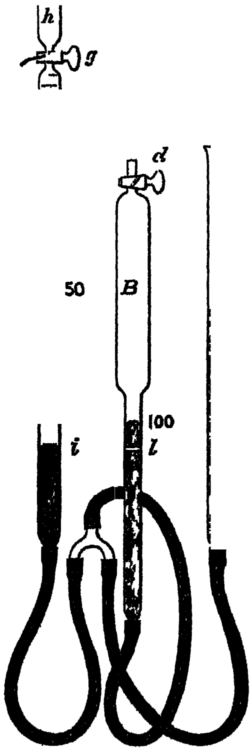
Analytical Chemistry.

The Gasvolumeter. By G. Lunge (*Ber.*, 23, 440—449).—Many methods have already been devised for avoiding all reduction-calculations in gas analyses where the volume of the gases to be measured has to be compared with other gas volumes, but up to the present time no plan has been proposed for effecting the same thing where the gas is obtained from solid or liquid substances. The author has now succeeded in devising an apparatus in which the difficulties of the latter case appear to have been successfully overcome.

The principle on which the method rests is as follows:—The measuring tube for the gas is connected by means of a T-joint and very thick-walled indiarubber tubing with a movable "pressure-tube," and also with a third tube termed the "reduction-tube," in which is placed such a volume of air that, when it is compressed to the division 100, it corresponds with 100 (or 50) c.c. of dry air at 0° and 760 mm. pressure. The liquid employed in the apparatus must in all cases be mercury. When the gas has been collected in the measuring tube, the other tubes are so placed that the mercury in the reduction-tube stands at 100, and also that the top of the mercury in the measuring-tube is level with that in the reduction-tube. The gases in both tubes are then under the same conditions, that is, the volume in each corresponds with that of the dry gas at 0° and 760 mm.

As an example of the detailed application and the method, the apparatus for the estimation of nitrogen in organic substances may be described. In the accompanying figure *A*, *B*, and *C* represent the measuring, reduction, and pressure tubes respectively. The stop-cock *g* is best so constructed that *A* may be connected with the vessel *h*, or either of these with the side tube shown; the tube *A* should further be of exactly 50 c.c. capacity from the stop-cock to just below the side tube *f*. A calculation is then made, once for all,



to find what volume 100 c.c. of dry air at 0° and 760 mm. would occupy under the conditions of temperature and pressure existing at the time of the calculation, due allowance being made for the vapour-tension of the potash solution used in the analysis. A small drop of the latter is passed into *B*, and then the exact quantity of air found by the above calculation admitted and the stop-cock *d* closed.* A volume of air is thus once for all enclosed which, at 0° and 760 mm., must, in the dry state, occupy 100 c.c.

Before commencing an analysis, the tube *C* is raised in order to fill *A* with mercury, and then exactly 50 c.c. of potash solution (sp. gr. 1·36) passed in; after which the analysis is conducted in the usual manner, the tube *C* being lowered to avoid any excessive pressure. When the gas has cooled, the tubes *B* and *C*, which are best held in spring clamps, are raised or lowered until the mercury in *B* stands at the 100th division. In this special case the mercury in *A* and *B* must not be brought to the same level, as allowance has to be made for the column of potash solution *ik*. If, as above suggested, 50 c.c. of solution having a sp. gr. of 1·36 ($\frac{1}{10}$th that of mercury) be taken, it is only necessary to fix a strip of paper, *l*, on the tube *B*, in such a position that the distance from the 100th division to the top of the strip is equal to $\frac{1}{10}$th of the length of the column *ik*, and then to bring the mercury in *A* level with the top of the strip *l*. (In ordinary working, this has proved quite easy of accomplishment, and does not require any previous practice.) The gases in *A* and *B* are then under exactly the same conditions, and the gas to be measured therefore occupies a volume equal to that of the dry gas at normal temperature and pressure.

As soon as the reading has been taken, the stop-cock *g* is so placed that the spent potash can pass off through the side tube, and a fresh quantity of 50 c.c. added, the apparatus being then ready for a further determination. In place of the usual graduation in c.c., the unit of graduation may be made 0·798 c.c., which corresponds with 0·001 gram of nitrogen; in this case, the weight of nitrogen to 0·0001 gram may be directly read off.

In the application of this improvement to such instruments as the nitrometer, &c., where the gases are saturated with moisture, the gas enclosed in the reduction-tube must likewise be saturated, and in the few cases where dry gases are measured, it must be dried over sulphuric acid. In all cases where the gas is collected directly over mercury, the level of the latter in the tubes *A* and *B* must be the same, no such correction being necessary as in the case considered above.

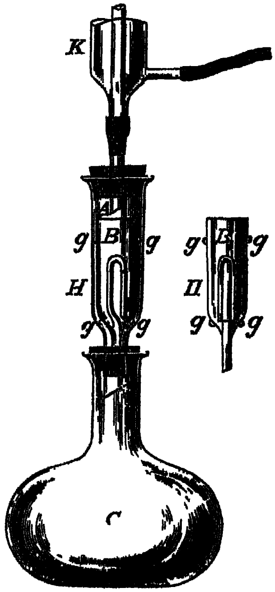
It is, of course, understood that the gases in *A* and *B* must have the same temperature, and when great accuracy is required, these may be surrounded by water, but in the majority of cases this is quite unnecessary.

H. G. C.

---

* This stop-cock may be replaced by a capillary tube, which is fused up when the necessary volume of air has been admitted. An accurately-ground and well greased stop-cock has, however, been found to hold equally well, and has the advantage that, if by chance gas of any kind should pass into *B*, the error may be readily corrected.

New Extraction Apparatus. By O. Knöfler (*Zeit. anal. Chem.*, 28, 671—672).—This apparatus, whilst similar in principle to Soxhlet's, is of much simpler construction. The outer tube, *A*, is fitted tightly into the cork of the flask. The inner tube, *B*, lies loose within *A*, the two being kept apart by the projections *g*,*g*. The syphon may be either a bent tube or a straight tube with a cap. The substance to be extracted is placed on a filter-bed of cotton-wool in the vessel *B*. The complete envelopment of the substance undergoing extraction by the vapour of the solvent maintains the liquid in *B* at its boiling point, and the absence of external tubes renders the apparatus less liable to injury than that of Soxhlet. M. J. S.



Rapid Detection and Estimation of Chlorine in Alkaline Thiocyanates. By C. Mann (*Zeit. anal. Chem.*, 28, 668—669).—On mixing a thiocyanate with excess of copper sulphate and passing hydrogen sulphide, white cuprous thiocyanate is first precipitated. If the gas is stopped as soon as the precipitate begins to become brownish, and a further quantity of copper sulphate is added, the filtrate will be free from thiocyanate but will contain all the chlorine. For 5 grams of thiocyanate there should be used 20 grams of copper sulphate, each dissolved in 100 c.c. of water, with a subsequent addition of 8 grams of copper sulphate in 40 c.c. of water. M. J. S.

Detection of Nitrogen in Organic Compounds. By E. Donath (*Monatsh.*, 11, 15—18).—The author finds that on heating organic compounds with excess of a saturated solution of potassium hydroxide and powdered potassium permanganate, they are invariably partly converted into nitrous or nitric acid, which can be recognised by any of the usual tests. The reaction is exceedingly easy of application and very delicate: 0·03 to 0·05 gram of the nitrogen compound being sufficient in all cases at present tried. A method for quantitatively estimating nitrogen in organic compounds may probably be based on this method of detecting nitrogen. G. T. M.

Phosphorus Trichloride and Oxychloride. By G. Denigès (*J. Pharm.* [5], 21, 216—217).—These two liquids are very similar in many of their properties, and a ready method of distinguishing between them is sometimes useful. If a good pinch of zinc powder is placed in a test-tube and one or two drops of the oxychloride are added (the zinc must be in excess), there is frequently an instantaneous production of flame; in all cases, on the addition of a little water, minute flames of hydrogen phosphide appear. With the trichloride, this reaction is not produced. J. T.

Magnesia in Calcium, Hydrogen, and Sodium Phosphates. By Schlagdenhauffen (*J. Pharm.* [5], 21, 99—102).—The calcium salt, whether in the form of spangles or as large, transparent crystals, is known to contain up to 4 per cent. of calcium sulphate as an impurity. Careful search also reveals the presence of magnesia. The solution of sodium phosphate as usually prepared also contains magnesia in the form of a soluble phosphate. Hence, when the sodium salt is to be used for the precipitation of magnesia, it is necessary to prepare a mixture of the phosphate with ammonium chloride and ammonia, and to let this remain 24 hours before use, to afford time for the ammonium magnesium phosphate to form and settle.

J. T.

Electrolytic Separations. By E. F. Smith and L. K. Frankel (*Amer. Chem. J.*, 12, 104—112).—The solutions electrolysed contained usually rather less than 0·2 gram of each metal, and 4½ grams of potassium cyanide in 200 c.c. of water; the current was usually of such a strength as to give 0·4 c.c. of mixed gases per minute in the water voltameter, and was allowed to pass for 16 hours.

Cadmium from Cobalt.—The separation is quantitative, the cadmium being completely deposited, and quite free from cobalt.

Cadmium from Nickel.—No good results were obtained, the deposited cadmium always containing nickel.

Mercury from Zinc.—The mercury is completely deposited, and contains no zinc.

Mercury from Nickel.—The mercury is completely deposited, and the separation is quantitative.

Mercury from Cobalt.—The results obtained at first were much too low, but when 3 instead of 4½ grams of potassium cyanide were used, the mercury was completely separated.

Silver from Copper.—The silver is completely deposited. Former attempts with a much stronger current had been unsuccessful.

Silver from Zinc.—The silver is completely deposited.

Silver from Nickel.—The silver is completely deposited.

Silver from Cobalt.—The silver separates quantitatively if 3 grams only of potassium cyanide be used; with $4\frac{1}{2}$ grams it is not all deposited.

Copper from Cadmium in presence of Sulphuric Acid.—The separation of the copper was found to be quantitative when 10 or 15 c.c. of sulphuric acid (sp. gr. = 1·09) were present in about 200 c.c. of the solution, and the current gave 0·2 to 0·3 c.c. of mixed gases per minute. With a stronger current, cadmium was deposited along with the copper. C. F. B.

Estimation of Lead in Tin. By PERRON (*J. Pharm.* [5], **21**, 241—242).—An approximate method of estimating lead in tin consists in placing a drop of nitric acid on the tin, evaporating to dryness, and moistening the stain with potassium iodide solution. The intensity of the yellow coloration produced is supposed to give an indication of the amount of lead present in the tin. This is very misleading, as an experiment with Banca tin containing not more than 0·25 per cent. of lead shows, thus :—After evaporating off the acid, add some drops of water, then a little potassium iodide in powder, and quickly remove the excess of water by means of a pipette. A brown tint appears at once, due to the iodide, but after a few moments' agitation, a magnificent, yellow colour appears, which would be variously estimated as indicating 25 to 30 per cent. of lead. The test is somewhat improved by evaporating the stain several times to dryness, water being added each time, moistening with water, and laying a piece of filter-paper over the spot, on the moist part of which the iodide is laid. There is thus obtained a tint without admixture; but in spite of these precautions the depth of colour is always in excess of the lead really present. J. T.

Estimation of Copper by converting the Sulphide into Oxide. By C. HOLTHOF (*Zeit. anal. Chem.*, **28**, 680).—Quantities of about 0·2 gram of precipitated copper sulphide, filtered by suction, placed moist in the porcelain crucible, and ignited strictly according to Bunsen's instructions, are, at a moderate temperature, entirely converted, with incandescence, into oxide. If previously dried, the precipitate is partially converted into sulphate, and even after ignition for an hour at a temperature at which the crucible glaze fuses, traces of sulphate remain undecomposed. M. J. S.

Volumetric Estimation of Copper. By A. ÉTARD and P. LEBEAU (*Compt. rend.*, **110**, 408—410).—The estimation of copper by the action of stannous chloride on a strongly acid solution of cupric chloride is made difficult by the comparatively feeble colour of the cupric solution. Cupric bromide in presence of concentrated hydrobromic acid, however, has a deep purple colour, probably due to a hydrobromide of the cupric bromide (compare Denigès, Abstr., 1889, 747), and if this is gradually mixed with a solution of stannous bromide or chloride in concentrated hydrobromic acid, the disappearance of the colour, owing to the reduction of the cupric salt, gives a sharply defined end reaction.

The solution of the copper salt must be concentrated and mixed with excess of concentrated hydrobromic acid. Care should be taken to avoid unnecessary contact with air during titration, in order that the cuprous bromide may not be reoxidised, but it is not necessary to operate in an atmosphere of carbonic anhydride. A solution of stannous chloride in concentrated hydrochloric acid free from iron may be used instead of the solution in hydrobromic acid. The stannous solution must be titrated from time to time with a standard solution of copper. C. H. B.

Estimation of Mercury. By J. VOLHARD (*Annalen*, 255, 255—256).—See this vol., p. 565.

Separation and Estimation of Tin and Titanium, with special reference to the Analysis of Silicates. By A. HILGER and H. HAAS (*Ber.*, 23, 458—461).—The method of separation of tin and titanium given in this paper depends on the fact that when a mixture of stannic and titanic acids is acted on by hydrogen at a low red heat, only the former is reduced. After allowing the mixture to cool in the atmosphere of hydrogen, the tin may be extracted by boiling the mixture with 20 per cent. hydrochloric acid. The tin in the filtrate is then precipitated by hydrogen sulphide, the precipitate reduced by hydrogen, and oxidised by nitric acid to stannic oxide. The titanic acid is fused with 10 parts of potassium carbonate in a platinum crucible, treated with about 200 c.c. of water, and concentrated sulphuric acid added, drop by drop, until the potassium hydrogen titanate is completely dissolved. The solution is then neutralised with sodium carbonate, 2 grams of concentrated sulphuric acid again added, and the whole diluted to 400 c.c. After boiling for six hours, the titanic acid separates completely, and is collected, washed, ignited, and weighed.

In analysing minerals containing these acids, the finely powdered substance is mixed with water to form a thick paste, dilute sulphuric added until a thin liquid is obtained, and then fuming hydrofluoric acid, to eliminate silicic acid. The evaporated solution is treated with water, neutralised, 2 grams of sulphuric acid added, and the solution diluted to 400 c.c., boiled for six hours, and the precipitated stannic and titanic acids separated as previously described. The titanic acid precipitate sometimes contains iron, which may be removed by a second reduction in hydrogen and extraction with 20 per cent. hydrochloric acid. H. G. C.

Separation of Vanadic and Tungstic Acids. By C. FRIEDHEIM (*Ber.*, 23, 353—357).—Great difficulty is experienced in the separation of vanadic and tungstic acids, especially in the analysis of vanadotungstic acid. Methods have been suggested by Gibbs (Abstr., 1884, 713) and by Rosenheim (Abstr., 1889, 762), neither of which are very convenient or accurate, and the author has therefore devised the following method, which gives satisfactory results. The concentrated solution of the salt is heated in a porcelain dish on the water-bath, a concentrated solution of mercurous nitrate, as neutral as possible, added until the precipitate formed settles down well, and the free acid removed by digestion with mercuric oxide. The precipitate is collected, washed with water containing mercurous nitrate, and then, as far as possible, washed back into the dish, and evaporated until the whole becomes thick. It is next carefully triturated with very concentrated hydrochloric acid, warmed for five minutes on the water-bath, by which means the whole of the vanadium is converted into vanadyl chloride, and almost all the tungstic acid and mercury salts go into solution. The precipitate adhering to the filter-paper is also dissolved in hydrochloric acid and added to the above solution. On the addition of water, tungstic acid separates almost entirely, leaving vanadium and mercury in solution. After remaining for 24 hours, the precipitate is collected, washed with water containing small quantities of hydrochloric acid, dried, and ignited in a porcelain crucible, pure tungstic acid being obtained.

To isolate the vanadium, the solution is heated to 80°, hydrogen sulphide passed in until all the mercury is precipitated, the filtrate evaporated on the water-bath, oxidised with nitric acid, and again evaporated, this operation being repeated at least twice. The hydrated vanadic acid is dissolved in water containing nitric acid, evaporated in a platinum dish, the slight residue in the porcelain dish being dissolved in one or two drops of ammonia and added to the main portion; after evaporation, it is dried at 120° and heated in presence of air, but at first not sufficiently to cause fusion. The reddish-brown, crystalline vanadic acid obtained still contains 0·1 to 0·2 per cent. of tungstic acid, which may be estimated by treating the contents of the dish with dilute sulphuric acid and sulphurous acid, washing the residue with very dilute sulphuric acid and igniting. The vanadium solution may be evaporated, heated to drive off the sulphuric acid, and then ignited as before.

In the filtrate from the mercury salts, the dissolved mercury may be precipitated by hydrogen sulphide and the alkalis determined in the filtrate, the acid sulphate being converted into normal sulphate by Krüss's method (*Ber.*, **20**, 1682).

For the analysis of metatungstates by this method, these must previously be converted into ordinary tungstates by repeated evaporation with ammonia. Lead and silver salts are best decomposed by dilute solutions of chlorides of the alkali metals, and the remaining metallic salts by repeated fusion with sodium potassium carbonate, the aqueous extracts being neutralised with acetic acid and treated as above. The reagents employed must, of course, be pure, as any non-volatile impurity would remain in the vanadic acid, and cause the results to be inaccurate. H. G. C.

Water Analysis. By L. Vignon (*Bull. Soc. Chim.* [3], **3**, 2—4; compare Abstr., 1889, 1035).—Referring to his already published method, the author states that the distilled water used in making the test solutions should be boiled immediately prior to use, as otherwise the results are falsified by the carbonic anhydride dissolved therein (5 c.c. per litre). The precipitation of dissolved carbonates is best attained by ebullition in a porcelain or platinum dish for 15 minutes;

glass vessels should not be employed, since these determine an alkaline reaction. Any loss in volume resulting from this operation should be made up by the addition of previously boiled distilled water. T. G. N.

Estimation of Potassium and Humus in Soils. By J. RAULIN (*Compt. rend.*, **110**, 289—291).—The estimation of potassium is based on the fact that potassium phosphomolybdate is almost insoluble in water, whilst the phosphomolybdates of magnesium, sodium, calcium, iron, and aluminium are more or less soluble. The weight of the phosphomolybdate is 19 times as great as that of the potassium which it contains.

100 grams of ammonium molybdate, dissolved in a small quantity of water, is mixed with a solution of 6·5 grams of ammonium phosphate. Aqua regia is added, and the liquid is heated with successive additions of small quantities of aqua regia until the precipitated phosphomolybdate is completely dissolved. The liquid is then evaporated to dryness at 70°, and the residue treated with 400 c.c. of water and 5 c.c. of nitric acid, and the solution filtered.

A liquid for washing the precipitate is prepared by dissolving in 1000 c.c. of water 20 grams of sodium nitrate, and adding 2 c.c. of nitric acid, 20 c.c of the phosphomolybdic solution, and 1·2 c.c. of a solution of 80 grams of potassium nitrate in 1000 c.c. of water. The liquid is heated, the precipitate allowed to settle, and the clear liquid decanted off.

A quantity of the soil containing about 15 milligrams of potassium oxide is dissolved in the usual way, and the greater part of the calcium, iron, and aluminium is separated. The substances left in solution are converted into nitrates, the liquid concentrated, acidified with nitric acid, mixed with 4·0 c.c. of phosphomolybdic solution for every 10 milligrams of potassium oxide present, and evaporated to dryness at 50°.

The residue is washed with 60 c.c. of the special solution and filtered through a tared filter, a counterpoise filter being washed with an equal volume of the wash-liquid. The precipitate is dried at 50° and weighed; wt. of ppt. × 5·2/100 = wt. of potassium oxide.

Humus in solution can be estimated by means of J. H. Smith's modification of the permanganate process. 10 c.c. of a solution of 16 grams of anhydrous manganese sulphate per litre is mixed with 10 c.c. of a solution of 10 grams of potassium permanganate per litre in a flask holding 250 c.c., and heated until the liquid is colourless and manganese peroxide is precipitated. Now add 100 c.c. of water, and 4 c.c. of a solution of sulphuric acid containing 150 grams of the monohydrate per litre, and then an exactly measured quantity of the humus solution, prepared by treating the soil with sodium hydroxide in the ordinary way. The quantity of humus must not be more than sufficient to reduce half the manganese peroxide present. Boil gently for eight hours in a reflux apparatus. Dissolve the unaltered manganese peroxide in a measured excess of decinormal oxalic acid, and determine the excess of oxalic acid by means of a standard solution of permanganate containing 1 gram per litre. The result gives the quantity of humus in terms of oxalic acid, and from this the proportion of oxygen required for the complete oxidation of the humus can be calculated. The author gives an empirical table for the conversion of the oxalic acid equivalent into the corresponding quantity of humus. C. H. B.

Estimation of Petroleum in Turpentine. By W. M. BURTON (*Amer. Chem. J.*, **12**, 102—104).—A balloon flask of 750 c.c. capacity is connected with a reflux apparatus, and also fitted with a drop funnel; 300 c.c. of fuming nitric acid (sp. gr. 1·4) is placed in the flask, and 100 c.c. of the turpentine to be tested is measured into the funnel. The flask is surrounded with cold water, and the turpentine is allowed to drop slowly into the nitric acid, when a violent action takes place, the turpentine being oxidised to various fatty and aromatic acids which are soluble in water, whilst the petroleum is scarcely affected. When the action is over, the contents of the flask are transferred to a large separating funnel, and treated with successive portions of hot water; the residual petroleum is measured, and represents the amount of the adulteration of the sample. Moderately accurate results may thus be obtained. C. F. B.

Impurities in Commercial Alcohol. By H. BORNTRÄGER (*Zeit. anal. Chem.*, **28**, 670; compare Abstr., 1889, 552).—When a crude spirit, diluted to 30 per cent., is shaken with chloroform, the latter takes up amyl alcohol, acetal, aldehyde, and isobutyl alcohol, but leaves undissolved ethyl alcohol, acetic acid, normal propyl alcohol, and tertiary butyl alcohol, all of which may be present. Normal propyl alcohol is readily soluble in water, and leaves an agreeable fruity odour when rubbed on the hands. Isobutyl alcohol dissolves with difficulty, requiring 10 parts of water; it gives an unpleasant odour of fusel oil to the hands. If present in large proportion in alcohol, it produces a raspberry-red colour when 10 c.c. of the spirit is mixed with 3 drops of concentrated hydrochloric acid and 10 drops of aniline. M. J. S.

Mercury Nitrate as a Test for certain Aromatic Compounds. By P. C. PLUGGE (*Arch. Pharm.* [3], **28**, 9—22).—The author has shown (this Journal, 1873, 533) that mercuric nitrate and the mercurous salt, as well as mixtures of the two salts, in presence of a very small quantity of nitrous acid, gives a red coloration with phenol. E. Millon (*Compt. rend.*, **48**, 40) proposed the mixed salts as a test for albumin. R. Hoffmann (*Annalen*, **11**, 123) proposed the same reagent as a test for tyrosine, but overlooked the necessity of a little nitrous acid. In the paper above cited, the author stated that the reagent was not only a test for phenol, but generally for those aromatic compounds containing a hydroxyl-group in the benzene nucleus. The present paper records the action of the test on 150 compounds, and the work is still in progress. It is, however, at this stage remarked that (1) the benzene-derivatives which do not contain hydroxyl do not give the reaction, or only give it after reactions which introduce derivatives containing hydroxyl;

(2) benzene-derivatives with a hydroxyl-group in the nucleus give the reaction. To this rule there are some exceptions, as the reaction is hindered when one or more of the hydrogen-atoms of phenol are replaced by other elements or by carbon-free radicles (for instance, Cl, Br, I, NO, NO_2, &c.). The reaction holds when the replacing radicle contains carbon.
J. T.

Estimation of the Mineral Matter in Sugar. By J. v. Grobert (*Chem. Centr.*, 1889, ii, 994; from *Neu. Zeit. Rub.-Zuck.-Ind.*, **23**, 181—182).—The author finds that the incineration of sugar may be assisted by the addition of oxalic acid, much in the same way that sulphuric acid assists this process.

The use of oxalic acid removes the objection to that of sulphuric acid, namely, the conversion of all the mineral matter into sulphates. If certain parts of the charred mass appear to glow less than the main portion, a little more oxalic acid may be thrown over these, which assists the combustion.
J. W. L.

Estimation of Wood Fibre in Paper. By R. Godeffroy and M. Coulon (*Zeit. anal. Chem.*, **28**, 738—739).—Wood fibre, when boiled with a dilute solution of auric chloride, precipitates 14·285 parts of gold per 100 of purified, dry wood fibre. Cellulose has no such reducing action. To examine a paper, the weighed sample is treated first with cold, then with boiling water, for the removal of the size, then with a boiling solution of tartaric acid in 80 per cent. alcohol to dissolve out alumina, washed, dried, and extracted with alcohol and ether, and then treated with the gold solution.
M. J. S.

Estimation of Uric Acid in Urine by means of Sodium Hypobromite. By Bayrac (*Compt. rend.*, **110**, 352—353).—Evaporate 50 c.c. of the urine on a water-bath, precipitate the uric acid by addition of 5 or 10 c.c. of hydrochloric acid of 20 per cent., and wash with alcohol in order to remove urea and creatinine. Dissolve the uric acid in a small quantity of sodium hydroxide solution and heat to 90° or 100° with 15 c.c. of a concentrated solution of sodium hypobromite.
C. H. B.

Milk Analysis. By B. F. Davenport (*Analyst*, 1889, 209—210).—For the estimation of total solids and fat, the milk is evaporated in flat-bottomed platinum basins, which for 5 grams of milk have a diameter of 2½ inches at the bottom, thus giving a surface of 1 square inch for the residue from each gram of milk. With a residue of this thickness, the fat can be completely and readily extracted by boiling light petroleum, and its amount is known from the loss. It is recommended that the evaporation should be performed on a water-bath with closed top, as the absence of steam from the neighbourhood of the basins assists the evaporation materially. After weighing the butter-free residue, it is ignited in the same capsule for the determination of ash.
M. J. S.

Description of an Apparatus for drying Fodders containing Drying Oils. By O. Foerster (*Landw. Versuchs-Stat.*, **37**, 57

62).—The percentage of oil obtained from foods containing drying oils is generally too low, because of the oxidation caused by drying the substance at a high temperature. The author has designed a drying apparatus which avoids oxidation, and which is here fully described. It consists of two chambers, the outer one holding water and hermetically sealed above, the only communication with the interior being that necessary for the water supply; the inner chamber is closed by a lid resting on a rim holding Wood's fusible metal, so that this chamber is also hermetically sealed. A pipe passes through the lid and conveys coal gas, which, passing out at the side near the bottom, supplies the burner for heating the water.

There are one or two modifications of this general design which can be used under varying circumstances; drawings are given of the various parts. E. W. P.

New Apparatus for the Analysis of Oils. By F. JEAN (*Chem. Centr.*, 1889, ii, 1070—1071; from *Mon. Sci.*, **34**, 1211—1216).—For the determination of the melting point of fats, the author has constructed an apparatus in which an electric circuit is completed as soon as the fat melts. For this purpose, the fat, in the liquid state, is run into a U-tube and allowed to solidify. While still liquid, two platinum wires connected with the battery are passed one down each limb of the tube until they are opposite to each other. When the fat is solid, a little mercury is poured on to its surface in one limb. The tube is placed in a vessel of water, in which also the thermometer stands. The water is warmed carefully by means of a lamp placed underneath, and as soon as it is sufficiently hot to melt the fat, the mercury falls to the bottom of the U-tube, and connects the ends of the two wires with each other, thereby completing the circuit. In this there is also a bell placed, which indicates the exact moment when the fat melts.

For the determination of the amount of heat developed on mixing oils with sulphuric acid, the author has also constructed an apparatus. It consists of three parts. The innermost is a small, cylindrical bottle, having an internal tube from close to the bottom and reaching through the side near the top. By blowing through a mouth-piece, this bottle may be entirely emptied of its contents, which are thus forced through this internal tube into the next vessel. The latter is a beaker which contains the oil. The third part of the apparatus is a brass jar, in which the second vessel is placed, the space between the two being filled with wadding, as a non-conducting material. When making a determination, 15 c.c. of the oil is placed in the middle vessel, and 5 c.c. of concentrated sulphuric acid in the innermost one. The liquids are then brought to a temperature of 30° and vessels 1 and 2 placed in the brass outer vessel. The acid is now blown out of the innermost into the middle vessel, and the mixing performed by means of a thermometer.

For the determination of the index of refraction, the author has constructed a refractometer, in which the refractive effect of the oil under examination affects the size of the shadow in the field, which shadow is caused by the refractive power of a standard liquid or oil.

A scale is adapted so that the extent of alteration in the size of the shadow-half of the field may be recorded. J. W. L.

Estimation of Quinine in Quinine Tannate. By S. NEUMANN (*Zeit. anal. Chem.*, 28, 663—668).—On examining, by Orillard's method, some specimens of quinine tannate known to contain 25 to 30 per cent. of the alkaloid, only about 7 to 13 per cent. was found. This results partly from the imperfect extraction by alcohol of the quinine contained in the residue of the evaporation with lime, and partly from the solubility of the alkaloïd in the potash employed to throw it down for weighing. The following method is proposed for technical purposes; it gives results which are about 3 per cent. above the truth:—2 grams of the powdered tannate is well shaken in a stoppered cylinder with 20—25 c c. of aqueous potash of specific gravity 1·24. Care must be taken that the tannate does not adhere to the glass. Water is then added to make up to 60—80 c.c., and then 100 c.c. of ether, accurately measured. The cylinder is immediately closed and vigorously shaken. When the two liquids have separated, there must be no solid particles visible in either layer. 50 c.c. of the ethereal layer is taken out with a pipette and evaporated in a weighed beaker, the quinine being finally dried at 100° and weighed. An estimation can be completed in 1½ hours. M. J. S.

Estimation of Chlorophyll in Leaves and in Extracts. By TSCHIRSCH (*Chem. Centr.*, 1889, ii, 996—997; from *Pharm. Centralhalle*, 30, 611—614).—For the estimation of chlorophyll in leaves, a piece of leaf, cut as square as possible, is measured and then extracted with alcohol. The solution is acidified with one drop of hydrochloric acid, diluted to a certain volume, and a portion is then filled into a tube to the depth of 10 mm. In a second such tube, a standard solution of phyllocyanic acid in alcohol is placed, and the absorption spectra of the two solutions are compared by means of the spectroscope described by the author. The thickness of the standard solution is varied until band I appears of the same strength in each spectrum. In the case of the liquid under examination having a thickness of 10 mm., this band should appear faint; if the thickness be increased to 15 mm., it will appear dark in the middle, and band II will be just perceptible.

The standard phyllocyanic acid is prepared from grass by extracting with water and alcohol, and, after evaporating, the residue is warmed with hydrochloric acid. The beautiful, blue solution thus produced is phyllocyanin. It is filtered, the filtrate poured into water, the precipitate thus produced washed with water, and purified by treatment with alcohol, ether, and chloroform. It combines with zinc and copper.

The zinc salt may be used as a means of quantitatively determining the chlorophyll, the zinc precipitate containing 11·07 per cent. of the metal. J. W. L.

General and Physical Chemistry.

Refractive Indices of Saline Solutions. By B. Walter (*Compt. rend.*, **110**, 708—709).—The author's experiments (this vol., p. 202) lead him to the conclusion that the refractive power of salts of the type $M''SO_4$ is 1·5 times as great as that of salts of the type M'_2SO_4, and three times as great as that of salts of the type M'Cl, a result essentially different from that obtained by Doumer (this vol., p. 433). C. H. B.

Anomalous Rotatory Dispersion in Iron, Cobalt, and Nickel. By W. Lobach (*Ann. Phys. Chem.* [2], **39**, 347—360).—Previous researches on the electromagnetic rotation of thin films of iron, &c., were directed principally to the determination of the maximum rotation and its dependence on the strength of the magnetic field. Kundt, in the course of his investigations, noticed that the dispersion in the case of iron was apparently anomalous, and the author, in the present paper, confirms this observation. The prism he employed was a direct-vision Wernicke liquid prism, and sunlight was always used in the experiments. The intensity of the magnetic field was 15,000 c.g.s. units, a strength sufficient to give the maximum rotation for the three metals investigated. The metallic films were deposited on glass plates either chemically or by electrolysis, and their thickness was estimated photometrically from the absorption they produced. They varied from 30×10^{-7} cm. to 100×10^{-7} cm. The results obtained are given below for the different wave-lengths as the simple rotation calculated for 1 cm. thickness—

	Liα.	D.	F.	G.
Iron........	223,000	195,000	145,000	122,000
Cobalt......	185,000	164,000	150,000	143,000
Nickel......	96,300	75,200	64,300	57,000

It is apparent from these values that the rotatory dispersion, not only of iron, but also of cobalt and nickel, is anomalous. J. W.

Dispersive Power of Aqueous Solutions. By P. Barbier and L. Roux (*Compt. rend.*, **110**, 457—460 and 527—532; compare Abstr., 1889, 805).—Examination of solutions of sodium, potassium, and barium chlorides, barium bromide, cadmium iodide, lead nitrate, chloral hydrate, sugar, citric acid, and aniline hydrochloride, with degrees of concentration varying from 8 per cent. to saturated solutions, showed that the dispersive power is a simple function of the concentration, but this does not hold for dilute solutions.

In solutions above a certain concentration, the excess of dispersive power, B, over that of pure water, *b*, is proportional to the quantity of dissolved substance, *p*, or $B - b = Kp$, K being a constant characteristic of each substance.

The value of the specific dispersive power B/d varies but little with the concentration, and is practically the same for all the substances examined, the minimum being 0·310 and the maximum 0·396. In the case of salts with a high dispersive power, however, the value is somewhat different.

If M is the molecular weight of the substance, $\frac{B-b}{p}M$ represents the *molecular increase of dispersion*, and is obtained by multiplying M into the coefficient K, which is constant for each substance. The mean value for chlorides of the type MCl is 0·020, the extremes being 0·021 and 0·019; for chlorides of the type $M''Cl_2$, the mean value is 0·044, the extremes being 0·050 and 0·038.

It follows that there is a simple relation between the relative dispersive power of a compound in solution and its chemical type and molecular weight. C. H. B.

Structure of the Line Spectra of the Elements. By J. R. Rydberg (*Zeit. physikal. Chem.*, 5, 227—232).—The author, from a study of the wave-numbers ($n = 10^8\lambda^{-1}$, where λ is expressed in Ångström's units) of the spectra of the elements belonging to the first three groups of the periodic system, arrives at the following generalisations:—

1. The "long" lines in the spectra form pairs and triplets possessing the property that the wave-numbers of the corresponding components differ by a constant quantity, ν, for each element. Groups I and III have only double lines; Group II has triplets in addition.

2. The corresponding components of the pairs form series whose wave-numbers are functions of the successive natural numbers. Each series may be approximately represented by the equation $n = n_0 - \frac{N_0}{(m + \mu)^2}$. N_0 is a general constant for all elements and all series; n_0 and μ are constants for the special series; and m is the number in the series of the member considered. There are three kinds of series—principal, sharp (well-defined), and diffuse (ill-defined). The principal series form the most vivid lines in the spectra, and only occur in the first periodic group; next come the diffuse (really double) lines; and, lastly, the sharp lines. In the several groups the highest members are the weakest, as they are also in each series.

3. Series of the same group (diffuse or sharp) have the same value for μ; and series of the same order (1st, 2nd, and 3rd) have in the various groups the same value of n_0. A notation is given for the whole system of vibrations.

4. The wave-lengths and wave-numbers of the corresponding lines, and also the values of the constants (ν, n_0, μ) of the corresponding series are periodic functions of the atomic weights of the elements.

From the spectra of the neighbouring elements in the periodic system, the author calculates the wave-lengths of the lines of gallium, and finds a satisfactory agreement with the lines actually measured. He finally draws attention to the incompatibility of his results with Lockyer's views as to the dissociation of the elements. J. W.

Absorption Spectra of Oxygen. By G. D. LIVEING and J. DEWAR (*Proc. Roy. Soc.*, **46**, 222—230; compare Abstr., 1889, 1).—This is a continuation of the authors' experiments on the absorption spectra of oxygen and its compounds. The presence of nitrogen seems to reduce the absorption produced by oxygen of given tension. Variations of temperature (−100° to 100°) had very little effect on the absorption. Liquid oxygen was found to be equally constant with change of temperature, the bands above C, D, and F remaining the same for a range of temperature from −181° to above the critical temperature, so that liquid and gaseous oxygen have the same absorption spectra. The persistence of the absorption during condensation is remarkable, since the absorption spectrum is entirely changed when oxygen combines chemically. An examination of ozone gave only a general absorption with four faint bands at wavelengths 1662, 1752, 1880, and 1990. The diffuse bands of oxygen at high pressures may be due to the presence of more complex molecules such as O_4, or to the constraint which the molecules experience during their encounters. With rise of temperature there is a slight weakening of the diffuse bands, a fact which supports the first hypothesis. The authors have re-examined the absorption spectrum of nitric peroxide, and confirm the conclusion of Bell (Abstr., 1885, 949) that this substance in the form of the molecule N_2O_4, whether liquid or gaseous, effects only a general absorption, and that the selective absorptions are due to the presence of the molecular form NO_2. H. K. T.

Maximum Polarisation of Platinum Electrodes in Sulphuric Acid. By C. FROMME (*Ann. Phys. Chem.* [2], **39**, 187—200).—Continuing his researches on the polarisation of platinum electrodes in sulphuric acid (Abstr., 1888, 390; this vol., p. 316), the author has studied the influence of the size of the electrodes on the polarisation. Electrodes of two different sizes were therefore employed, the first being foil of 1 sq. cm. surface and the second wire 0·3 cm. in length and 0·025 cm. in diameter, presenting a surface of 0·015 sq. cm. In order to overcome the difficulty arising from the fact that a small cathode becomes platinised in the course of the experiments, the cathode in every case, whether small or large, was coated with a thick layer of platinum black.

The experiments show that the polarisation alters rapidly with the size of the electrodes, increasing as the size of the cathode or of the anode decreases. Indeed, in very dilute solution, if a small cathode be taken, a polarisation value of 3·72 volts can be reached, using a large anode. Alteration in the concentration of the acid has least effect when large electrodes are taken, the difference between the highest and lowest value being about 0·78 volt, but if one or both of the electrodes are small, the greatest difference in the polarisation reached is very nearly double this number. If the electrodes are both small and the concentration of the acid be varied from 0 to 44 per cent., polarisation will be found at a maximum of 3·87 volts in a 32 per cent. solution, but with a 47 per cent. solution, it reaches its greatest attainable value of 5·5 volts. H. C.

Galvanic Polarisation of Platinum Electrodes in Dilute Sulphuric Acid with High Current Density. By F. RICHARZ (*Ann. Phys. Chem.* [2], 39, 201—235). The author describes a method for measuring the polarisation after the polarising current has been interrupted, making use of the Helmholtz pendulum contact breaker. He finds that, employing platinum electrodes of small surface, the polarisation in dilute sulphuric acid never attains a value of more than 2·5 Daniells. The highest values were obtained for an intensity of about 0·001 ampère, whereas greater intensities gave smaller values for the polarisation, for instance, 2·4 Daniells with 0·4 ampère. This decrease is probably caused by heating of the solution. In the latter case also quantities of ozone, hydrogen peroxide, and persulphuric acid are formed, whereas not in the former, but it is evident that these do not exercise any great influence on the polarisation. H. C.

Electrical Conductivity of Air due to the Formation of Ozone. By J. ELSTER and H. GEITEL (*Ann. Phys. Chem.* [2], 39, 321—331). —From the fact that the air in the vicinity of a bunsen flame is charged with ozone and conducts electricity, the authors were led to examine the electrical properties of the air enveloping a stick of moist phosphorus undergoing slow oxidation with formation of ozone. They found that the process of ozonising here also determined a similar assumption of conductivity by the air, but could not prove an electromotive force to be connected with it. The mere *presence* of ozone is not sufficient to impart conductivity to air, nor does the formation of solid particles of ammonium nitrite in the neighbourhood of the phosphorus exert any appreciable effect. When the formation of ozone is hindered by the presence of the vapour from oil of turpentine, the electric conductivity at once disappears.

Ozone was observed by the authors to be formed when a stream of air was passed over a platinum-wire heated to whiteness by means of an electric current (compare Dewar, Roy. Inst., June 8, 1888).

J. W.

Electrical Conductivity of some Solutions at Temperatures between 18° and 100.° By E. KRANNHALS (*Zeit. physikal. Chem.*, 5, 250—258).—The apparatus used was similar to that described by Ostwald (Abstr., 1889, 4). The solutions examined were those of the chlorides and nitrates of sodium, potassium, and barium; potassium bromide, chlorate, and ferrocyanide; the sulphates of sodium and magnesium, and hydrochloric acid. The concentrations of the solutions varied from 1 gram equivalent per litre to 1 gram equivalent per 1000 litres. The results show that the higher the temperature the greater the increase in the molecular conductivity with rising dilution. The mean temperature coefficients are calculated for various dilutions, as also the values of μ_∞, the conductivity for infinite dilution at the temperatures 18°, 50·3°, 82°, and 99·4°. The quotient μ_v/μ_∞ is found to decrease somewhat with rising temperature, from which the author concludes that the influence of temperature on the degree of dissociation of electrolytes which, at ordinary temperatures and in moderately concentrated solutions, are strongly dissociated, is only slight. The great increase in conductivity with the temperature is to be explained by the decrease in the viscosity of the solution. The author finally calculates the heats of dissociation by the method given by Arrhenius (Abstr., 1889, 1044), but his results are altogether at variance with those of the latter.

H. C.

Electrical Conductivity of Phenols and Hydroxybenzoic Acids. By D. Berthelot (*Compt. rend.*, **110**, 703—705). The solutions contained 0·01 gram-equivalent of the salts, &c., per litre, and the measurements were made with Lippmann's electrometer. The three hydroxybenzoic acids have different conductivities, the resistance increasing in the order ortho-, meta-, para-. The conductivity of the parahydroxybenzoic acid is practically identical with that of benzoic acid. When the acids are treated with 1 equivalent of sodium hydroxide, the numbers obtained are approximately the same in all three cases; the reduction of conductivity is $\frac{3}{4}$ for the ortho-acid. $\frac{7}{10}$ for the meta-acid, and $\frac{2}{3}$ for the para-acid. When a second equivalent of the alkali is added, the conductivities of the meta- and para-derivatives remain practically the same, but differ considerably from that of benzoic acid, since the second equivalent of alkali exerts an appreciable effect. A third equivalent exerts a smaller but still appreciable influence.

In the case of the ortho-acid (salicylic acid) the second and third equivalents of the alkali produce less effect than with the meta- and para-derivatives. The maximum difference in the case of salicylic acid is reached on addition of 1 equivalent of alkali, but in the case of the meta- and para-acids this maximum is given by the second equivalent. It follows that in the ortho-acid the phenolic function is less energetic than in the meta- and para-acids, a result which agrees with the thermochemical measurements of Berthelot and Werner.

C. H. B.

Development of Electricity and Heat in Electrolytes. By M. Planck (*Ann. Phys. Chem.* [2], **39**, 161—186).—Since the ions of an electrolyte are endowed with large electrostatic charges, it follows that before the electromotive forces become active a certain finite determinable amount of free electricity must be formed in the solution. A calculation of the forces necessary to cause a movement of electricity in an electrolyte is made in the present paper, starting with the assumption that in an electrolyte the ions are present in a fully dissociated condition. The passage of electricity from higher to lower potential gives rise to the development of heat, and the movement of the ions is also found to give rise to heating effects, since each ion carries a certain amount of heat with it, and, therefore, the accumulation of a number of ions in any particular portion of the solution will raise the temperature at that spot.

H. C.

Electrolysis of a Mixture of two Salts in Aqueous Solution.

By L. Houllevigne (*Compt. rend.*, **110**, 637—640).—Aqueous solutions of zinc and copper sulphates were electrolysed (1) with varying intensity of current and a constant difference of potential between the two electrodes, and (2) with constant intensity of current and varying difference of potential.

With a solution which contained, per litre, 37·5 grams of zinc and 0·968 gram of copper, the difference of potential being 6·94 volts, a variation from 0·0165 ampère to 0·0506 ampère caused a gradual increase in the ratio Zn/Cu from 1·15 to 5·64. With 48·1 gram of zinc and 2·30 of copper per litre, and a difference of potential of 7 volts, an increase in intensity from 0·0104 ampère to 0·0365 gave an increase in the ratio Zn/Cu from 0 74 to 1·58. It is obvious that the proportion between the deposited ions varies greatly with the intensity of the current, a result different from that obtained by Buff with hydrochloric and sulphuric acids. It is probable, however, that the electrolysis of mixed zinc and copper sulphates is complicated by secondary reactions, and if it is assumed that Buff's law is true, but that secondary action takes place between the deposited zinc and the copper sulphate, and is proportional to the time, it can be shown that the ratio Zn/Cu should increase with the intensity of the current.

With constant intensity of current, but a difference of potential varying from 3·25 to 6·55 volts, and from 2·85 to 5·26 volts, the ratio Zn/Cu remains the same except when the electromotive force approaches the minimum at which brass is deposited. C. H. B.

Electrochemical Effects on Magnetising Iron.

By T. Andrews (*Proc. Roy. Soc.*, **46**, 176—193; compare Abstr., 1889, 92).—This is a continuation of the author's researches on the current produced when the opposite poles of two electrically connected magnets of approximately equal strength are immersed in solutions of various chemical substances. The general results obtained were that the north pole became positive to the south pole. In the present investigation, the solutions were applied to the upper ends of the magnets, as it was thought that the current produced in the previous experiments might have been due to the weakening of the submerged north pole, owing to its relation to the earth. It was found that the north pole was still positive, but that the electromotive force was slightly less than before. In both cases it was frequently observed that the south pole became momentarily positive at the commencement of the experiment.

H. K. T.

Influence of Temperature on the Magnetism of Salts of Metals of the Iron Group.

By P. Plessner (*Ann. Phys. Chem.*, [2], **39**, 336—346).—The variation of the specific magnetic coefficient $K = A/M_2$ (A = magnetic attraction and M = intensity of field) with the temperature was investigated by a method depending on the torsion of a German-silver wire. Solutions of salts of metals of the iron group gave the following values for the constant α in the formula $K = K_0 + \alpha t$, the range of temperature considered being from 10° to 60°.

Ferric chloride .... $\alpha = -0·003542 \pm 0·000043$
Nickel sulphate .... $\alpha = -0·003571 \pm 0·000014$
Cobalt nitrate .... $\alpha_1 = -0·003544 \pm 0·000094$
$\alpha_2 = -0·003567 \pm 0·000087$

These values are practically identical, so that we may take $\alpha = -·0035554 \pm ·0000124$ as the general temperature coefficient for the above solutions.

Solid salts, on the other hand, have different coefficients. Thus, for hydrated manganous sulphate, $\alpha = -0·003114$; for the salt dried at 250°, $\alpha = -0·00269$; for cobalt sulphate dried at 250°, $\alpha = -0·00273$. The variation of the magnetic coefficient of nickel sulphate dried at 250° cannot be expressed by $K = K_0 + \alpha t$, but a sufficient approximation is obtained from the formula $K = K_0(1 + \alpha t + \beta t^2)$, where in one series of experiments $\alpha = -0·001504$ and $\beta = -0·00003324$.

J. W.

Allotropic Forms of Arsenic. By BERTHELOT and ENGEL (*Compt. rend.*, **110**, 498—499).—Crystallised arsenic, and amorphous arsenic obtained by the reduction of arsenious acid by hypophosphorous acid, were dissolved in bromine-water in a calorimeter. The quantities of heat developed at 7° (As = 75 grams) were as follows:—

Crystallised arsenic	+83·0 Cal.
Amorphous arsenic	+84·1 „

These numbers are almost identical with that obtained by Thomsen with crystallised arsenic at 18°, namely 83·7 Cal. Both forms of arsenic develop practically the same quantity of heat when converted into the same compound. The difference is of the same order of magnitude as in the case of graphite and the diamond, or crystallised and amorphous sulphur.

Combination of Sodium and Potassium with Ammonia. By J. MOUTIER (*Compt. rend.*, **110**, 518—520).—A theoretical discussion of the observations of Joannis (this vol. p. 560).

Thermochemistry of Thiosulphates. By J. FOGH (*Compt. rend.*, **110**, 522—523, 524—525, 571—573, 709—711).—See this vol., pp. 694, 790.

Heat of Combustion of Rubidium. By N. BEKETOFF (*Chem. Centr.*, 1890, i, 308; from *Bull. Acad. St. Pétersbourg*, [2], 1, 173—175).—The value for the heat of formation of rubidium hydroxide was determined by introducing the molten metal into a glass tube of known calibre, and when solid, a certain length was cut out, thus enabling the weight to be calculated. The tube, with the metal, was introduced into the calorimeter. By this means the metal was prevented from taking fire, and the reaction proceeded gradually. The author obtained the result, 164800 cal., which is very nearly the same as that for the formation of potassium hydroxide.

The heat of formation of rubidium oxide was determined by deducting the heat of formation of the hydroxide from the oxide, from the heat of formation of the hydroxide from the metal. In order to prepare the oxide free from the peroxide, the mixed oxides obtained by oxidising the metal in absence of water were heated with sufficient metal to reduce all peroxide present to monoxide. The heat of formation of the hydroxide from the oxide was found to be 69900 cal., from which the heat of formation of the oxide is (164800 —69900) = 94900. The heat of oxidation of the metals of the alkalis decreases gradually from lithium to rubidium.

J. W. L.

Heat of Combustion of Organic Isomerides. By I. Ossipoff *J. pr. Chem.* [2], **41**, 424—428).—The author compares the value for the heats of combustion of various organic acids, which he has recently calculated and published (*Compt. rend.*, **108** and **109**), with the values obtained by Stohmann (Abstr., 1889, 1097), and accounts for the differences in some cases.

He also points out that if Q_1 and Q_2 are the heats of combustion of two isomeric organic acids, Q_1 being greater than Q_2, *k* in the formula $[(Q_1 - Q_2)100] \div \frac{Q_1 + Q_2}{2} = k$, will be a constant in some cases, whilst in other cases it will be almost *nil;* thus, for maleïc and fumaric acids, $k = 2{\cdot}5$; for teraconic and terebic acids, $k = 2{\cdot}3$; for α- and β-diphenylsuccinic acids, $k = 2{\cdot}4$; for α-nitrocamphor and phenonitrocamphor, $k = 2{\cdot}6$; and for methylmalonic and succinic acids, $k = 2{\cdot}2$.

A. G. B.

Neutralisation Phenomena of Aluminium and Beryllium Fluorides. By E. Petersen (*Zeit. physikal. Chem.*, **5**, 259—266).—Continuing his work on the heat of neutralisation of fluorides (this vol., p. 1), the author finds the heat of neutralisation of aluminium hydroxide with hydrofluoric acid to be 3 × 23415 cal.; the difference between this and that with hydrochloric acid being 3 × 4773 cal. The avidity of hydrofluoric acid towards aluminium hydroxide is three times as great as that of hydrochloric acid—as in the case of ferric hydroxide. The heat of neutralisation of beryllium hydroxide is given as $Be(OH)_2,2HFAq$ = 19683 cal.

H. C.

Heat of Hydration of Maleïc Anhydride. By I. Ossipoff (*Compt. rend.*, **110**, 586—588).—The dissolution of solid fumaric acid (116 grams) in dilute potash develops + 20·5 Cal.; the dissolution of solid maleïc anhydride in dilute potash develops + 31·6 Cal. Gal and Werner have shown that the heats of neutralisation by soda of fumaric and maleïc acids in solution are practically identical. Assuming that the same equality holds for neutralisation with potash, it follows that the hydration of maleïc anhydride with formation of maleïc acid develops + 9·6 Cal. If, on the other hand, fumaric acid is formed, the heat of hydration would be + 11·1 Cal. The difference 1·5 Cal., identical with the difference between the heats of dissolution, is too small to determine intramolecular changes when once hydration has commenced. It may become operative, however, if hydration is accompanied by exothermic changes, as in the action of a dissolved haloïd acid on maleïc anhydride.

C. H. B.

Berthelot's Law of Maximum Work and Spontaneous Endothermic Reactions. By R. COLLEY (*Zeit. physikal. Chem.*, 5, 242—249).—The author explains the exceptions to Berthelot's law of maximum work which are offered by spontaneous endothermic changes, on the assumption that any system which is not at rest may pass into some other less stable, but still possible, position of equilibrium with the production of negative work which is supplied by the energy originally stored in the system. The stability of a chemical compound depends, therefore, not only on the affinity or chemical attraction of the atoms for one another, but also on the distribution of the atomic energy among the different molecules. H. C.

Trough for Hofmann's Vapour-density Apparatus. By T. H. EASTERFIELD (*Chem. News*, 60, 250—251).—A disc of wood, turned to fit tightly into a retort-stand ring, is hollowed out so as to form an economical mercury trough and to support both the eudiometer and the steam-jacket. It is pierced by two holes, one opening within the steam-jacket, and fitted with a tube for the escape of the steam, the other opening without the steam-jacket and holding a tube to lead away the mercury into a receptacle beneath. D. A. L.

Determination of Vapour-density. By C. SCHALL (*Ber.*, 23, 919—924; compare Abstr., 1889, 331).—In this paper the author describes a simple form of apparatus for determining vapour-densities based on the principles already explained (*loc. cit.*). Instead of passing a measured volume of air into the apparatus, as was previously done, it is more convenient to decompose a weighed quantity of pure sodium carbonate and to compare the pressure of the carbonic anhydride produced with that of the vaporised substance.

If the weight of the substance is s, and that of the carbonic anhydride s', taking the specific gravity of carbonic anhydride compared with air under the same conditions as 1·529, the vapour-density of the substance is—

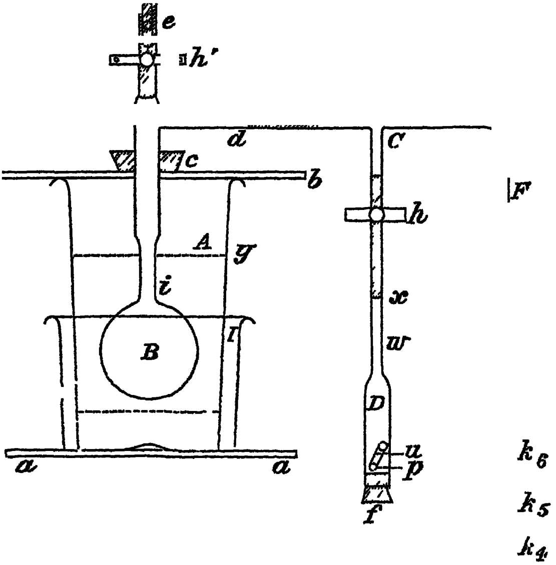
$$D = \frac{s}{s'} \times \frac{53}{22} \times 1{\cdot}529 \times \frac{k_6 - k_5}{k_5 - k_4},$$

$$\text{or } \frac{s}{s'} \times 3{\cdot}682 \times \frac{k_6 - k_5}{k_5 - k_4},$$

where $\frac{k_6 - k_5}{k_5 - k_4}$ is the pressure-proportion of the carbonic anhydride to the vapour. Where $s = s'$, that is to say, when the weight of the substance is equal to that of the sodium carbonate employed, then $D = 3{\cdot}682 \times \frac{k_6 - k_5}{k_5 - k_4}$, so that it is only necessary to determine the pressure-proportion and the vapour-density is obtained by a very simple calculation.

The apparatus employed is shown in the following diagram:—

It consists of the heating space A, enclosed by a beaker, surrounding which, as shown in the figure, is placed the top half of a somewhat wider beaker, in order to prevent the cooling of the heating vapour; with this arrangement, diphenylamine, and substances of even higher boiling point, can be quickly raised to the requisite temperature with a bunsen burner. The heating



substance is placed at the bottom of A, and if it be solid at the ordinary temperature, it should be carefully melted round the sides before placing the beaker on the heating plate *aa*. A flask B, the bulb of which is 150—200 c.c. in capacity, is suspended in the heating space by means of the cork *c*, which rests on the asbestos plate *bb*. The side tube *d*, which should be 100—110 mm. above the bulb, is connected by means of india-rubber tubing with the ⊤-shaped tube C, one limb of which is continued to form the manometer F (internal diameter at the most 4—5 mm.), and dips into a vessel E containing mercury; three freely movable india-rubber rings k_6, k_5, k_4 are placed on the tube F. The other limb of the ⊤-tube C is connected by means of india-rubber tubing to the narrow part *w* of the vessel D into which the small tube *u* containing the weighed quantity of sodium carbonate is pushed with the india-rubber cork *f* before connecting D to C; the cylinder D also contains the dilute sulphuric acid (about 1 c.c.) which is introduced with the aid of a drawn-out glass tube. Above the bulb B the neck of the flask is drawn out, so that its internal diameter is not less than 5 or more than 20 mm.; the tube or sealed bulb containing the weighed quantity of substance is placed at *e* in a piece of closed india-rubber tubing and kept from falling by the pinchcock *h'*.

In carrying out a vapour-density determination, the stopcock *h* is opened, and, D being disconnected, the substance in A is heated in such a way that its vapour rises to about the level of *y*. As soon as the temperature is fairly constant, the mercury in F is raised as high as possible by suction with the mouth at *x*, and *h* is then closed; if the apparatus is air-tight, the mercury soon attains a constant level. The vessel D containing the sulphuric acid and the weighed quantity of sodium carbonate is then attached, *h* is opened, and the level of the mercury in F is marked with the ring k_6. The cylinder D is then inclined in such a way that the acid comes into contact with the carbonate, and by shaking repeatedly any bubbles of gas which remain in the small tube *u* are expelled; the level of the mercury is then marked with the ring k_5. The substance, previously placed at *e*, is now allowed to fall into B and the level of the mercury is marked with the ring k_4. Finally D is disconnected and *h* is opened; the whole operation requiring about 10 minutes after the apparatus has attained a constant temperature.

In a following paper the author will describe the methods to be employed in determining the vapour-density (1) under reduced pressure, (2) in an indifferent gas, and (3) in the case of substances which absorb carbonic anhydride.

Experiments with benzoic acid, naphthalene, phenol, aniline, nitrobenzene, and benzene gave good results, the heating substance employed being diphenylamine, ethyl benzoate, and, in the case of benzene, water. F. S. K.

Molecular Volumes of Aromatic Compounds. By J. SAKURAI (*Chem. Centr.*, 1890, i, 425—426).—The author draws attention to the fact that if the molecular volumes of benzene and its homologues are calculated from the values given by Lothar Meyer and by Löschmidt for the molecular volumes of carbon and hydrogen, they do not agree with the molecular volumes as determined by experiment. He fixes the value of the carbon-atom in the benzene nucleus at 10·5, in the side-chain at 11, but the hydrogen-atom always at 5·5. The table (p. 684) allows of a comparison of the calculated and the determined molecular volumes.

The values calculated by the author for several benzene-derivatives containing oxygen also agree closely with those determined by Kopp, but he considers it somewhat premature to place too much dependence on such theoretical values, since so little is at present known of the influence of combination on the molecular volume.

J. W. L.

Dissociation of Amine Hydrochlorides and Salts of the Fatty Acids in Solution. By J. A. MULLER (*Compt. rend.*, **110**, 588—590).—The dissociation of many salts in solution can be rendered evident by means of phenolphthaleïn. If a concentrated solution of an amine hydrochloride containing a small quantity of phenolphthaleïn is mixed with sufficient free amine to produce a rose colour, the liquid becomes colourless when diluted or when heated. In the latter case the colour reappears on cooling; in the former it reappears on addition of a further quantity of amine. These results show that when an amine hydrochloride dissociates, the action of the hydrochloric acid on the indicator is greater than that of the amine. Many bases, such as pyridine, picoline, lutidine, and hydroxylamine, show no similar phenomena, because their action on phenolphthaleïn is too feeble.

When phenolphthaleïn is added to solutions of the alkaline salts of the fatty acids, the liquids become alkaline when diluted or when heated, the action of the alkali on the indicator being in these cases greater than the action of the acid. In this way it is easy to show that in the case of salts of formic, acetic, propionic, normal butyric, and valeric acids, the amount of dissociation under given conditions increases with the molecular weight of the acid, a result which agrees with Berthelot's observation that the heat of formation in this series of salts decreases with the molecular weight of the acid.

Normal potassium and sodium salts of the strong inorganic acids gave no coloration when diluted or heated, and hence these salts do not dissociate.
C. H. B.

Rise of Solutions in Capillary Tubes and the General Law of this Phenomenon. By M. GOLDSTEIN (*Zeit. physikal. Chem.*, **5**, 233—241; compare Abstr., 1889, 205).—The author finds that the law of vapour tensions and that of the rise of solutions in capillary tubes are similar in nature. If H represents the height of the rise of water and h that of the solution of a substance of molecular weight M, then $H - h/HM = C$, a constant which depends only on the percentage of dissolved substance. If the above expression be multiplied by Van't Hoff's coefficient, i, the law holds also in the case of electrolytes; this is shown by reference to experiments by the author and by Valson. It is pointed out that the above law is in close relation to that enunciated by Traube (Abstr., 1885, 116).

H. C.

Chemical Equilibrium between Hydrogen Chloride and Hydrogen in conjunction with Metals. By M. RIBALKIN (*Chem. Centr.*, 1890, i, 308; from *Bull. Acad. St. Pétersbourg* [2], 1, 279—282).—The chemical equilibrium between copper and hydrogen chloride occurs at temperatures between 230° and 440°, but not at temperatures ranging from 100° to 230°; at 230°, 93 per cent., at 440°, 66 per cent., of the hydrogen chloride is decomposed.

In the case of hydrogen heated with cuprous chloride, no reaction takes place at 200°; at 230°, 5 per cent., and at 440°, 35 per cent. of hydrogen chloride is formed. J. W. L.

Freezing of Colloïdal Solutions. By N. LUBAVIN (*J. Russ. Chem. Soc.*, 21, 397—406).—The investigations of Pfaff, Geiger, and Payen on the freezing of colloïdal solutions have been overlooked by subsequent investigators of colloidal solutions, especially Graham and Van Bemmelen. The author finds that from some of such solutions the substance dissolved is completely or partly separated after freezing, whereas in the case of others the precipitate again passes into solution. A solution of colloidal silicic acid, obtained by mixing soluble glass with hydrochloric acid in aqueous solution, was divided into two parts, one of which was exposed to a temperature of 7—10° for two days, after which it was exposed to the temperature of the laboratory (+15°) for two days. From the frozen solution as much as 96·96 per cent. of the silica was separated by filtration, whereas the original unfrozen solution yielded only 0·72 per cent. of insoluble silicic acid. This is not in contradiction with Graham's statement, that the stability of a colloïdal solution of silicic acid increases with decreasing temperature, for, according to Graham, more concentrated solutions are more easily coagulated. Indeed, on freezing, gradual concentration takes place, owing to the separation of ice, so that the coagulation is accelerated. A colloïdal solution of antimony trisulphide was prepared by Schulze's method, namely, saturating a solution of 1 part of tartar-emetic in 200 parts of water with hydrogen sulphide. Nothing separated from the original solution, even when it was allowed to remain for months at the ordinary temperature; whereas from the same solution, after exposure to a temperature of −6° for 29 hours and subsequent thawing of the ice, complete separation of the antimony sulphide took place. When a very large quantity of the same solution was exposed to a low temperature, the separation was not quite complete. A colloïdal solution of copper sulphide was obtained by the action of hydrogen sulphide on copper glycollate. The separation of the sulphide was incomplete, although the solution was kept one day at −6° and one day at −19°. Nothing separated out at the ordinary temperature. Colloïdal solutions of ferric hydroxide, obtained by the dialysis of different preparations of basic chloride, sometimes remain uncoagulated by freezing, sometimes are partly coagulated. This depends on the purity of such solutions, and partly, perhaps, on the rate of cooling. Solutions of potassium ferric tartrate behaved in a similar manner. One part of starch was dissolved in 100 parts of boiling water, and the solution was kept at a temperature below zero; flocks separated, as shown already by Payen, but the separation was incomplete. It was found that starch solutions which had been subjected to freezing are much more easily and quickly filtered than the same solutions not frozen, so that this process might be used for the better filtration of slimy liquids and precipitates. Neither white of egg nor milk is coagulated, even on freezing at −15° to −20°. The fact that peat falls to pieces after being frozen is explained by the author on assumption that it contains colloïdal substances, which are coagulated by freezing. B. B.

Solubility and Heat of Fusion. By J. Walker (*Zeit. physikal. Chem.*, 5, 193—197).—From the thermodynamical equation, $dp/dt = \rho/Tv$, and the gas-equation, $pv = 2T$, here applied to solutions, the author deduces a relation between the solubility of a substance in any solvent and its heat of fusion. T denotes the absolute temperature, p the osmotic pressure in the saturated solution, v the volume of the solution, and ρ the molecular heat of solution, which is assumed to remain constant within the interval of temperature studied. The determinations of solubility are made above and below the melting point of the substance. Calculating from the solubility of paratoluidine in water, 44·5 cal. was obtained as the heat of fusion of the latter, the value directly determined being 39 cal. For water (dissolved in ether) the heat of fusion, calculated on the assumption that the molecule of the dissolved water is H_2O, amounts to 154 cal., whereas experiment shows it to be 80 cal. If, however, it be assumed that the molecule of water dissolved in ether is H_4O_2, the calculation gives 77 cal., in agreement with the experimental value. This assumption receives support from the observation of Eykman (this vol., p. 324), that the depression of the freezing point produced by water in liquid paratoluidine has only half the normal value. J. W.

Solution-equilibrium of Thorium Sulphate and its Hydrates. By H. W. B. Roozeboom (*Zeit. physikal. Chem.*, 5, 198—216).—Nilson and Krüss (*Ber.*, 15, 2519, and 20, 1665) have shown that when anhydrous thorium sulphate is dissolved in ice-cold water, and the solution warmed to 20°, large quantities of a sparingly soluble hydrate with $9H_2O$ separate. This observation might seem to indicate a stable solution of the anhydrous salt reaching its point of transformation into the above hydrate at 20°, in contradiction to the general rule that on increase of temperature the point of transformation into a lower hydrate, and not into a higher one, is reached. The author has investigated the phenomena in detail, and finds an explanation of the anomaly in the fact that the hydration and dehydration of thorium sulphate proceed at low temperatures with extreme slowness, so that solutions apparently stable with respect to the hydrate $Th(SO_4)_2,9H_2O$ are in reality not so, but undergo steady though slow changes of concentration. The solubilities of the anhydrous salt and of hydrates with 2, 4, 6, 8, and $9H_2O$ respectively are investigated, and the results are given both in tabular and curve form. J. W.

Inorganic Chemistry.

Prolonged Action of the Electric Discharge on Iodine. By C. LUEDEKING (*Chem. News*, **61**, 1—2).—The author has investigated the phenomenon of the disappearance of iodine and the appearance of hydrogen, when the former element is submitted to the spark discharge in hermetically sealed glass tubes. Firstly, he noticed a reduction of the volume of the gas contained in the tube, which he attributes to the disappearance of the oxygen of the air originally contained in the tube. Secondly, analytical results indicate that the iodine is still present, but in the form of iodides and, probably, iodates, these salts being formed at the expense of the bases in the glass; this would account for the etched appearance of the latter after the experiment. The author then shows that the hydrogen is introduced into the tube in the form of hydriodic acid retained by the iodine, and as the iodine ultimately all combines to produce iodides, the hydrogen is left, and "instead of an iodine tube we have a hydrogen tube developed." D. A. L.

Preparation of Hydrobromic Acid. By A. RECOURA (*Compt. rend.*, **110**, 784—785).—The ordinary methods of preparing gaseous hydrogen bromide are inconvenient, and the evolution of the gas cannot be readily regulated. The author proposes a method which is based on the fact that the action of gaseous hydrogen sulphide on liquid bromine with formation of gaseous hydrogen bromide and solid sulphur develops +14·4 Cal., without taking into account the heat developed by the combination of the sulphur with the excess of bromine.

Hydrogen sulphide is bubbled through a layer of bromine contained in a tall, narrow vessel and covered by a layer of water or hydrobromic acid. The gas passes into a second flask which contains a solution of potassium bromide in hydrobromic acid holding a small quantity of red phosphorus in suspension, and the gas which issues from this flask contains neither bromine vapour nor hydrogen sulphide. The current of hydrogen bromide is controlled by regulating the current of hydrogen sulphide. The latter gas should be made in a "continuous" apparatus. C. H. B.

Purification of Hydrofluoric Acid. By R. HAMILTON (*Chem. News*, **60**, 252).—The apparatus employed by the author for distilling commercial hydrofluoric acid consists of a heavy sheet-lead retort, 6 inches high and 4 inches in diameter, with a rim at the top formed by beating the lead over an iron ring 1 inch deep and ⅜ inch thick; the lid is of ½-inch iron plate, covered with lighter sheet lead, and is fixed down by a screw working in a socket in an iron bridge, which is secured to projections on the opposite sides of the iron ring of the rim. A washer of india-rubber is placed between the cover and the rim. The leaden nose of the retort points upwards, and is connected by india-rubber tubing to a Liebig's condenser, the inner tube of which is of thin india-rubber. The retort is charged through a funnel with 25 per cent. hydrofluoric acid, which yields a distillate of convenient strength for analytical work. The first portions of the distillate contain silicate and are discarded, whilst any sulphur is removed by filtration. D. A. L.

Selenic Acid. By C. A. CAMERON and J. MACALLAN (*Proc. Roy. Soc.*, **46**, 13—35).—The authors have prepared anhydrous selenic acid, H_2SeO_4, and compared its properties with those of sulphuric acid. The anhydrous acid was obtained by concentrating the aqueous acid over the water-bath and then heating it with agitation in a vacuum at 180° so long as acid distilled over. The residual acid crystallised on cooling, and contained 99·71 per cent. of anhydrous acid (Se = 78·87). Anhydrous selenic acid has a specific gravity of 2·9508, and melts at 58°, forming a colourless, oily liquid of sp. gr. 2·6083. The presence of a small quantity of water greatly lowers its freezing point, so that it does not solidify until cooled to −51·5°. It crystallises in hexagonal prisms. Tables of the specific gravities of the aqueous acid are given. Anhydrous selenic acid absorbs moisture with avidity, blackens organic matter, and decomposes glycerol, evolving acraldeyde. It reacts violently in the cold with phosphoric chloride, the products of the reaction being now under examination. It dissolves selenious anhydride, but does not in this way form an acid corresponding with the acid $H_2S_2O_8$. Selenic acid forms a monohydrate, H_2SeO_4,H_2O, melting at 25°. It can be obtained by boiling the aqueous acid until its temperature rises to 205°, and then dropping a crystal of the acid into the cooled liquid. Conclusive evidence of the existence of higher hydrates could not be obtained, but there is a considerable evolution of heat on diluting the monohydrate to a strength corresponding with the dihydrate, and a slight development of heat on the addition of more water. Selenic acid, when heated in a vacuum at 200°, decomposes into selenious anhydride, oxygen, and water. At ordinary pressures, the acid distils until a temperature of 260° is reached, when decomposition sets in.

Selenic acid does not dissolve sulphur at ordinary temperatures, but at 63° dissolves it with a deep indigo-blue colour; decomposition sets in at the same temperature with evolution of sulphurous anhydride. It dissolves selenium in the cold, producing a green solution which evolves selenious anhydride at 75°. Tellurium dissolves in selenic acid in the cold with a purple-red colour, but this soon disappears with production of selenious acid. It is probable that the above coloured substances are selenoxides, namely, $SSeO_3$, $SeSeO_3$, and $TeSeO_3$ respectively, analogous to the corresponding sulphoxides produced by dissolving the three elements in sulphuric acid.

Selenic anhydride could not be obtained by passing a mixture of selenious anhydride and oxygen over heated platinum sponge or by the action of ozone on selenious anhydride, but the above selenoxides seem to point to its possible existence. Anhydrous selenic acid, when mixed with phosphoric anhydride and heated at 100°, yields crystals on cooling which on analysis give results agreeing with those of selenic anhydride. The substance is under examination. The selenates of antimony, bismuth, and platinum are described. H. K. T.

Catalytic Formation of Ammonia from Nitrates. By O. Loew (*Ber.*, **23**, 675—680).—The author points out that, as almost all plants can utilise nitrates for building up the albuminoïds, and, as in the latter the nitrogen is partly in amidic, partly in imidic or tertiary union, a preliminary reduction of the nitric acid to ammonia must first take place. The physiological conversion of nitric acid into ammonia may be readily shown by allowing common putrefactive organisms to grow in a 1 per cent. peptone solution containing also 0·2 per cent. of potassium nitrate and a similar amount of potassium phosphate. In presence of air, the formation of nitrite may be observed within two days, and in two months the whole of the nitrogen is converted into ammonia. If air be excluded and 0·2 per cent. of alcohol and of sodium hydrogen carbonate added, the alcohol is oxidised by the oxygen of the nitrate, and gives up its hydrogen to the nitrogen, the products being ammonia and acetic acid. To explain this, it must be assumed that the living protoplasm, which is built up of extremely labile albuminoïds, is in a state of violent molecular agitation, and that the intense atomic motions are communicated both to the alcohol and to the nitric acid, with the result that the above-mentioned exchange takes place.

The author regards the activity of platinum-black charged with oxygen as due, not to the fact that the oxygen is so greatly condensed, but that the oxygen is in a similar state of violent molecular motion. He has, therefore, examined whether the reduction of nitric acid to ammonia may also be accomplished by its means. Pure dextrose and potassium nitrate were dissolved in water and heated for six hours at 60—65° with platinum-black charged with oxygen, and prepared by the method previously described (this vol., p. 453). A quantitative experiment showed that 45 6 per cent. of the nitrogen of the nitric acid had been converted into ammonia. In order to meet the possible objection that the dextrose is first oxidised to aldehydes or similar compounds, which then exert a reducing action on the nitric acid, dextrose solution was warmed alone with the same platinum-black under identical conditions, and the filtrate then digested with a little potassium nitrate. No ammonia could be detected in this case.

In this reduction, two processes take place together, namely, the oxidation of dextrose, in which the oxygen is gradually used up, and the reaction between dextrose and potassium nitrate, in which the oxygen acts merely from its peculiar mode of vibration, and is not absorbed.

If methyl alcohol be substituted for dextrose, it absorbs all the oxygen of the platinum-black so rapidly that only traces of ammonia are formed.

Naegeli, in 1879, in his theory of fermentation, supposes that the latter is due to the transmission of a peculiar kind of molecular motion from the living protoplasm of the yeast to the sugar molecule.

The author points out that Naegeli's ideas may also be applied to many other processes which take place in the cells, and that even the most remarkable of the changes which occur there, namely, the formation of carbohydrates from carbonic anhydride, is very likely to be due to the transmission to the latter of a molecular motion compounded of the vibrations of the living material and of the light absorbed by the chlorophyll. H. G. C.

Oxidation of Hypophosphorous Acid by Spongy Palladium. By R. Engel (*Compt. rend.*, **110**, 786—787).—Contrary to the statements of Wurtz and Graham, palladium precipitated from a solution of the chloride by means of hypophosphorous acid retains a small quantity of hydrogen. The author observed that the quantity of hydrogen evolved was much greater than the quantity which could be liberated from a palladium hydride. Further investigation showed that when spongy palladium is brought in contact with hypophosphorous acid, the latter is rapidly converted into phosphorous acid, and hydrogen is liberated. The palladium seems to retain its activity indefinitely, and 0·5 gram of the metal decomposed the acid obtained from 500 grams of barium hypophosphite. The reaction is not arrested by pressure.

Berthelot has shown that the conversion of hypophosphorous acid into phosphorous acid is exothermic. It is probable that the palladium removes an atom of hydrogen from the hypophosphorous acid, but quickly loses it, whilst the residue of the acid interacts with the water, combining with hydroxyl, and liberating another atom of hydrogen. C. H. B.

Combination of Hydrogen Phosphide and Ammonia with Boron Chloride and Silicon Sesquichloride. By A. Besson (*Compt. rend.*, **110**, 516—518).—Hydrogen phosphide combines with boron chloride with development of heat, and yields the compound BCl_3,PH_3, a white solid which alters rapidly when exposed to air, and is immediately decomposed by water with liberation of hydrogen phosphide. It begins to dissociate at 20° under the ordinary pressure, and if the products of dissociation are slowly cooled, the compound is obtained in bulky, colourless, highly refractive crystals.

Ammonia displaces the hydrogen phosphide from this compound at 8°, and yields the compound $2BCl_3,9NH_3$, which alters but slowly when exposed to air, and does not lose ammonia below 50°, but is immediately decomposed by water with production of a slightly alkaline solution.

Berzelius obtained from ammonia and boron chloride a compound to which he gave the formula $2BCl_3,3NH_3$.

Silicon sesquichloride, Si_2Cl_6, combines directly with ammonia to form a white, solid compound, $Si_2Cl_6,10NH_3$, which does not lose ammonia below 100°, but is decomposed by water with production of a feebly alkaline solution.

Hydrogen phosphide reduces silicon sesquichloride, even at −10°, with production of the solid hydrogen phosphide. C. H. B.

Oxidising and Decolorising Properties of Charcoal. By P. Cazeneuve (*Compt. rend.*, **110**, 788—790).—Animal or vegetable charcoal which has been allowed to cool in contact with air exerts a distinct oxidising influence on such compounds as *α*-naphthylamine, paraphenylenediamine, the colouring matter of wine, &c. Its activity in this respect is comparable with that of hydrogen peroxide. This behaviour explains the well-known fact that certain solutions, such as those of phenolic compounds or of tannin matters, are not decolorised, but acquire a darker colour, when treated with animal charcoal.

It would seem that this oxidising action plays an important part in the decolorisation of liquids, the colouring matter being not only absorbed, but also oxidised. After some time, the colouring matter absorbed by animal charcoal from wine cannot be recovered by treatment with alcohol, because it has been oxidised to colourless compounds. Charcoal which has cooled in contact with carbonic anhydride has, in most cases, a distinctly lower decolorising power than charcoal which has cooled in contact with air. C. H. B.

Condensation of Carbonic Oxide under the Influence of the Silent Discharge. By P. Schutzenberger (*Compt. rend.*, **110**, 560—565).—Brodie and Berthelot observed that when carbonic oxide is subjected to the silent electric discharge, it is converted into carbonic anhydride and a brown substance, to which the former gave the formula C_4O_3, and the latter the formula C_5O_4.

The author finds that the composition of the dark-brown product is variable, and that the condensation of the carbonic oxide ceases as soon as the gas contains 10 per cent. of carbonic anhydride. The experiments were made with a simple discharge tube of the Wilde-Berthelot form, the open end dipping under mercury, whilst the armatures were acidified water. Under these conditions, the rate of condensation varied considerably, but was practically constant for the same tube used in the same way. The solid product had the composition C, 45·6; H, 0·6; O, 53·8 = 100·0. When the armatures of acidified water were replaced by mercury, condensation was much slower, and the black product had the composition C, 46·4; H, 0·9; O, 52·7 = 100·0. If the armatures were surrounded by jackets containing dry air, and every precaution was taken to exclude moisture, very little condensation took place, even when the discharge was continued for 48 hours. It follows that the presence of small quantities of water is essential to the formation of the black product, and the author is of opinion that the electric discharge carries oxygen and water through the glass, and that there is also some evidence of a transport of matter in the opposite direction, since the total quantity of carbon in the condensed product and the carbonic anhydride was less than that in the carbonic oxide which disappeared. C. H. B.

Condensation of Carbonic Oxide and the Penetrability of Glass by Water. By Berthelot (*Compt. rend.*, **110**, 609-612).—Condensation of carbonic oxide under the influence of the silent electric discharge takes place even when the gas is separated from water by the walls of two tubes and by an intervening air space, the gas and the apparatus having been very carefully dried. The condensation and the composition of the residual gas show that the solid matter has the composition C_4O_3, which confirms the author's earlier experiments. The solid product is extremely hygroscopic, and gives off water if it is heated after having been exposed to the air. If, however, it has been kept out of contact with air, no evidence can be obtained of the presence of hydrogen in it. The author concludes that there is no evidence that the discharge causes the passage of water through the glass. C. H. B.

Condensation of Carbonic Oxide. By P. Schutzenberger (*Compt. rend.*, **110**, 681—684).—Carbonic oxide was carefully dried with phosphorus pentoxide, and subjected to the action of the silent discharge in an apparatus surrounded by a jacket of dry air. Condensation took place to the extent of 20 c.c., 5 c.c. of carbonic anhydride being formed, and 15 c.c. of the carbonic oxide condensed to a black substance which contained 0·00012 gram of hydrogen, equivalent to about 0·001 gram of water. No further condensation took place, because, according to the author, the small quantity of moisture present had all been converted into the black product. If, however, the metallic armatures were replaced by armatures of acidified water, condensation recommenced, and went on continuously. The author considers this result as further proof that under the influence of the discharge the elements of water pass through the glass (compare preceding and next abstracts). C. H. B.

Observations on the Preceding Paper and on the Drying of Gases. By Berthelot (*Compt. rend.*, **110**, 684—685).—Glass and mercury can only be perfectly dried when heated to a moderately high temperature. If exposed to moist gases, a film of water condenses on the surface of the glass or metal, and cannot be removed at the ordinary temperature. If the mercury and the india-rubber connections of a mercurial pump are in contact with moist air, traces of water may be introduced into any apparatus which is connected with the pump. The author considers that the traces of moisture which passed into Schutzenberger's apparatus (preceding abstract) were derived from sources of this kind, and did not pass through the glass. C. H. B.

Films of Vaporised Metal. By W. N. Hartley (*Proc. Roy. Soc.*, **46**, 88—90).—Condensed electric sparks from an induction coil are passed between electrodes of the metals to be tested, a perforated plate of mica being interposed in the path. Rings of varying colour and diameter are produced. They are metallic in the case of the noble metals, but consist of oxides when the more oxidisable metals form the electrodes. Gold gives films of extreme tenuity, partly of a deep red or rose tint, but more frequently of a blue colour. The silver films are yellow, with a tinge of rose or violet. Silver containing $\frac{1}{100000}$th of gold gives distinct evidence of gold, and the metal, even when prepared by the processes of Stas, gives a faint indication of gold. H. K. T.

Reduction of Oxides with Magnesium. By C. WINKLER (*Ber.*, 23, 772—792; compare this vol., pp. 331, 451).—This paper deals with the oxides of the third group of the periodic system.

When an intimate mixture of powdered boric anhydride (1 mol.) and metallic magnesium (3 atoms) is ignited, preferably in a current of hydrogen, a dark-brown mass is formed, which is attacked only with difficulty by water or alkalis, but dissolves easily and completely in hydrochloric acid or in solution of ammonium chloride, in the former case with evolution of hydrogen. It appears to be a mixture of magnesium borate (MgB_2O_4) with a boride of magnesium, Mg_9B_2. An attempt to prepare the oxide BO by heating boric anhydride (1 mol.) with magnesium (1 at.) was unsuccessful, the same reaction taking place as when 3 atoms of magnesium were used. Borax (1 mol.) was then heated with magnesium (7 at.), both substances being finely powdered and intimately mixed. The mixture became incandescent, sodium volatilised, and a dark-brown mass was obtained which evolved hydrogen slowly when treated with cold water, rapidly with hot water or hydrochloric acid. By repeatedly boiling it with water, a solution containing sodium metaborate was obtained, together with a residual black powder, probably a magnesium boride, Mg_2B_5, which was oxidisable, and dissolved in hydrochloric acid with evolution of hydrogen; this hydrogen had an unpleasant smell, and not infrequently inflamed spontaneously. The analytical data show that the following reaction, or something very like it, must have taken place:—$3Na_2B_4O_7 + 21Mg = 4Na + 2NaBO_2 + 17MgO + 2Mg_2B_5$. The black powder, when treated with strong hot hydrochloric acid until the evolution of gas has ceased, leaves a residue which resembles amorphous boron in appearance, but has been shown to be a hydride (B_4H) of that element; it is an easily oxidisable substance, and differs markedly from boron in its chemical properties. Evidence was also obtained of the formation of a gaseous boron hydride; indeed the hydrogen evolved in all the cases mentioned above had an unpleasant odour, and was probably mixed with some such gaseous compound. This compound could not be isolated, but it is probably not the normal hydride BH_3.

Aluminium oxide (alumina), 1 mol., when heated with magnesium (3 at.), glows and forms a dark-grey mass which evolves hydrogen and gradually becomes colourless when it is treated with water or hydrochloric acid. This product appears not to be a mixture of metallic aluminium and magnesium oxide, but was found to contain free magnesium and unreduced alumina; probably it contained alumina in the form of a lower oxide, AlO. To see if this was the case, alumina (1 mol.) was heated with magnesium (1 at.) in a current of hydrogen, when a nearly black powder was obtained. This was found to contain more than 40 per cent. of the oxide AlO, together with magnesia and unaltered alumina; these last two substances had combined together to some extent, forming an artificial spinel.

Yttrium oxide is quietly and seemingly completely reduced by ignition with magnesium.

Lanthanum oxide is also completely reduced; a slight incandescence is observable, but the reaction otherwise goes smoothly.

Gallium oxide is reduced by magnesium, the reaction being somewhat violent, not to say explosive, in character.

Indium oxide, when heated with magnesium, becomes incandescent, and gives rise to a violent reaction; the tube was destroyed, and the material scattered. An attempt to prepare a lower oxide, analogous to AlO, was unsuccessful.

Thallic oxide, when heated with magnesium, is decomposed by the first application of heat into oxygen and thallous oxide, and no further reduction takes place. Thallous carbonate, however, is reduced by magnesium with explosive violence, and the glass tube was shattered.

It would thus appear that, in this third group of oxides, the energy with which reduction by magnesium takes place is much greater in the second division of the group than in the first, and in each division increases with the atomic weight of the element concerned.

C. F B.

Potassium Silicofluoride. By K. PREIS (*Listy Chem.*, **13**, 150—151).—Hexagonal crystals of this salt, which was hitherto known only in tesseral crystals, were found, together with calcium sulphate, as a deposit in a large basin containing phosphoric acid of 20° B., prepared from phosphorites in the chemical works of Počky, Bohemia. Small, regular crystals of the same compound were found, together with the hexagonal form. The faces are 0P and 2P, and their inclination = 115° 57′, so that the axial ratio $a : c = 1 : 0·8898$ shows its isomorphism (isodimorphism) with ammonium silicofluoride, the latter being also dimorphous.

B. B.

New Form of Ammonium Chloride. By G. GEISENHEIMER and F. LETEUR (*Compt. rend.*, **110**, 576—577).—A saturated solution of ammonium chloride, which had been used for washing the precipitated double chlorides in the preparation of pure iridium by the method of Deville and Debray, deposited the salt in long, pale-rose or brown-red crystals, which contained 0·71 to 0·93 per cent. of ruthenium in the form of subchloride. On recrystallisation, the crystals became quite white. The crystals were macles; the tangents to the centres of two faces made an angle of 65° 15′, and the tangents to the faces along an edge made an angle of 82° 30′. It is probable that these crystals consist of the modification of ammonium chloride described by Le Bel (this vol., p. 475), made stable by the presence of the small quantity of ruthenium subchloride.

C. H. B.

Action of Sodium Thiosulphate on Silver Salts. By J. FOGH (*Compt. rend.*, **110**, 709—711).—The decomposition of silver nitrate (2 mols.) by sodium thiosulphate (1 mol.) with formation of sodium nitrate, silver sulphide, and dissolved sulphuric acid, is complete in four or five minutes, and develops +46 Cal. at 15°. The calculated result is +45·2, but it is deduced from a large number of different experiments and data, and can only be regarded as approximate. The reaction takes place in two phases, namely, the formation of silver thiosulphate and the decomposition of the latter in presence of water, but the thermochemical disturbances corresponding with each phase could not be determined directly because of the rapidity of decomposition. Calculating from analogy, the heat of formation of silver thiosulphate is +104 Cal., and hence the first phase of the reaction should develop +5·2 Cal., and the second +40 Cal., a result which explains the fact that the decomposition becomes complete without the aid of extraneous energy.

The dissolution of silver thiosulphate in excess of a solution of sodium thiosulphate, develops +34·8 Cal. at 12°. The conversion of silver chloride and bromide into thiosulphate would absorb 13 × 2 Cal., and 17·3 × 2 Cal., and the solution of these compounds in a solution of sodium thiosulphate is determined by the formation of the sodium silver thiosulphate. The conversion of silver iodide into thiosulphate would absorb 48·4 Cal., a quantity greater than that developed by the combination of silver thiosulphate and sodium thiosulphate, and hence a solution of sodium silver thiosulphate yields a precipitate of silver iodide on addition of a soluble iodide, and silver iodide does not dissolve in sodium thiosulphate solution without the aid of extraneous energy. C. H. B.

Monocalcium Phosphate. By I. STOKLASA (*Listy Chem.*, 13, 203—210, 240—243, 273—283).—Monocalcium phosphate, $CaH_4(PO_4)_2 + H_2O$, was prepared by dissolving pure dicalcium phosphate in 31 per cent. phosphoric acid, and recrystallising. It was then washed with absolute alcohol and ether, and dried. Washing with ether only (Erlenmeyer, Birnbaum, Wattenberg) never removes the free phosphoric acid completely, so that if prepared in this way it may contain several per cent. of free phosphoric acid. The presence of the latter may be proved, either by treatment with absolute alcohol, or by dissolving the salt completely in water and estimating volumetrically with decinormal potash in the presence of methyl-orange. Alcohol containing only small quantities of water decomposes monocalcium phosphate. The author finds that even the purest preparations decompose in closed vessels spontaneously, so that about 0·05 of free acid is formed in a month.

Monocalcium phosphate is not hygroscopic, as usually stated, especially by Birnbaum and Packard. It attracts some moisture in an atmosphere saturated with aqueous vapour, but loses it again in dry air. The hygroscopic nature of the preparation observed by the authors quoted above is, as the author shows, due to the presence of free phosphoric acid, of which at least 0·2 per cent. must have been present in Birnbaum's specimen. Steam at 80° decomposes monocalcium phosphate. With regard to the very discrepant statements as to the decomposition of monocalcium phosphate by cold water, the author has treated pure preparations with varying quantities of water, and gives his results in a tabular form; the decomposition being represented by the general formula $aCaH_4(PO_4)_2,H_2O + H_2O = (a - 1)CaH_4(PO_4)_2,H_2O + CaHPO_4 + 2H_2O + H_3PO_4$. For example, for 1 part of salt and 1 part of water $a = 4$, and, therefore, the quantity of undecomposed salt going into the aqueous solution $(a - 1) = 3$, 26 per cent. of the salt being decomposed in the above manner. With increase in the quantity of water, more salt goes into solution, and when 1 part of salt is treated with 200 parts of water, the decomposition is very small, whereas the solution is complete; here

$a = 1024$, and from this only 1 part is decomposed = 0·1 per cent. The decomposition is regular, for, whereas, for the proportion of 1 salt : 1 water, the quantity of free phosphoric acid formed = 7·51, for 1 salt : 25 water, that quantity becomes one-half this = 3·75, and for every increase of 25 parts of water again one-half of the previous amount. The salt dissolves in 200 parts of water to a clear solution, and at this point it becomes impossible to prove the existence of the free acid, which would indicate decomposition. Above this limit the monocalcium phosphate is re-formed from its products of decomposition—dicalcium phosphate and phosphoric acid.*

Free phosphoric acid, added to monocalcium phosphate solutions, prevents their decomposition. If we add to monocalcium phosphate such a quantity of free phosphoric acid as would be formed by the decomposition of the salt, no decomposition takes place; for example, for 1 salt : 1 water, this quantity will be 7·5 per cent., as seen from the result stated above. If Erlenmeyer finds the solubility of the salt 1 : 100, it follows that the presence of 0·4 per cent. of free phosphoric acid in his salt had prevented the decomposition and increased the solubility.

The author's conclusions as regards the solubility of superphosphates and disuperphosphates in water, are of technical interest.

Strontium Chlorate and the Velocity of its Decomposition by Heat. By A. POTILITZIN (*J. Russ. Chem. Soc.*, **21**, 451—466; compare Abstr., 1888, 219; 1889, 338; this vol., p. 333).—Strontium chlorate, according to Wächter (*J. pr. Chem.*, 1843, **30**, 231) and Topsöe, is anhydrous; according to Louchay, it crystallises with 5 mols. H_2O. It is always described as very deliquescent. The author prepared the salt by repeated recrystallisation of the commercial preparation, until its solution gave no precipitate with silver nitrate. At the ordinary temperature, the salt crystallises in transparent, rhombic octahedra, which are almost insoluble in absolute alcohol, and not deliquescent. It attracts some moisture in wet weather, and loses it again in dry weather; if, however, the salt contains strontium chloride, it is deliquescent. It forms supersaturated solutions, and, according to the author's theory, it ought to exist in allotropic modifications (this vol., p. 333); this was found to be the case. On gradually cooling its hot saturated solution to 10°, small, monoclinic scales are obtained, but after a time the ordinary octahedral crystals are deposited from the same solution. A third form of this salt is obtained at the ordinary temperature from a very strong supersaturated solution, but only when the liquid has a certain concentration; it forms long prisms or scales, but if these are left in the mother liquor, from which they have separated, they soon dissolve again. A fourth form of the salt separates from a solution of the salt at 70—90°; these crystals are long, rhombic prisms, but only a small quantity was obtained. The hydrated salt, $Sr(ClO_3)_2 + 3H_2O$, was prepared by taking a 59 per cent. solution of the salt, and cooling it to −40°; fine, needle-shaped crystals then separated, together with some ice, and on placing these in another solution containing 64 per cent. of the salt, cooled to −20° or −25°, they continued to grow, and then formed four-sided prisms with a pyramidal end, belonging to the rhombic system; these lose their water completely, when exposed to the air at the ordinary temperature. A solution of the salt containing 64 per cent., when cooled in a closed vessel, to −95°, is gradually converted into a gelatinous mass, and no change is brought about by the introduction of a crystal of the anhydrous or of the hydrated salt, but when the solution becomes mobile at −70° to −60°, a crystal of the hydrated salt grows slowly, and crystals of the trihydrated salt are formed in the liquid. The composition of the above gelatinous mass, formed at −95°, corresponds with the formula $Sr(ClO_3)_2 + 8H_2O$.

---

* Probably a state of unstable equilibrium sets in between these three substances, if Mendeléeff's theory of solution is correct.—B. B.

On heating the anhydrous salt, a very slow decomposition ensues at 290°. When, at a higher temperature, 10 per cent. of oxygen has been given off, the salt fuses, and then consists of a mixture of $Sr(ClO_3)_2 + Sr(ClO_4)_2 + SrCl_2$. The rate of decomposition of the chlorate is somewhat rapid at first, up to the point when the salt begins to fuse; then the decomposition becomes slower. When the loss amounts to 10 per cent., it fuses completely, and the rate of decomposition again increases up to a loss of 16 to 20 per cent. at 368°, after which the rate of decomposition is found to diminish; the loss amounting to 28—29 per cent. after heating for 30 minutes at 395°. The total decomposition (a loss of 37·7 per cent.) is reached only after 19 hours 35 minutes. The decomposition of strontium chlorate, in its different phases, is represented by the general formula $ASr(ClO_3)_2 = mSrCl_2 + nSr(ClO_4)_2 + pO$. Different samples of the chlorate were heated for different intervals of time up to a temperature of 368°, and the products of reaction were again weighed and analysed in the same manner as in the case of lithium chlorate. A small quantity of strontium oxide was formed at the same time. As long as any excess of chlorate is present, the reaction tends to produce a maximum of perchlorate, and this maximum is reached when about three-fourths of the chlorate is decomposed. In this phase the decomposition is represented by the following reaction:—

$$11Sr(ClO_3)_2 = 9SrCl_2 + 2Sr(ClO_4)_2 + 25O_2.$$

Later on the quantity of perchlorate diminishes, and when 25 per cent. of oxygen has been evolved, the relation becomes $7Sr(ClO_3)_2 = 6SrCl_2 + Sr(ClO_4)_2 + 17O_2$. That strontium perchlorate is decomposed according to the equation $ASr(ClO_4)_2 = nSrCl_2 + mSr(ClO_3)_2 + pO_2$, has been shown by direct experiments, which will form the object of a future communication. B. B.

Beryllium. By G. Krüss and H. Moraht (*Ber.*, 23, 727—737).— The material employed in this investigation was a light-green leucophane from Arendal, in Norway. In order to isolate the beryllium oxide, the mineral, separated as far as possible from the tourmaline contained in it, was finely powdered, mixed with water to form a paste, and an excess of concentrated sulphuric acid added. After evaporating off most of the acid, the above treatment was repeated, and the residue extracted with water, the extract poured into an excess of ammonium carbonate solution, and an excess of ammonia added. After remaining for 10 days, the precipitate was filtered off, the filtrate boiled, and the precipitate then formed was collected, washed, and ignited. The residue consists chiefly of beryllium oxide, mixed with ferric oxide and alumina. The last two compounds are, as A. Zimmerman has pointed out (*J. pr. Chem.*, 76, 1), extremely difficult to remove, and in the further purification his method was adopted. The mixture of oxides was dissolved in hydrochloric acid, precipitated with ammonia, and a quantity of ammonium carbonate solution added, which was insufficient to dissolve the whole of the precipitate. After 10 days the solution was filtered, and, as suggested by Humpidge (*Proc. Roy. Soc.*, 39, 1), a strong current of steam passed through the solution, and the first portion of the precipitate taken, and subjected to the same treatment four times. The precipitate of beryllium oxide finally obtained was free from iron and snow-white.

The reduction of the oxide by means of magnesium powder (this vol., p. 451) gave a metal contaminated with silica. To obtain a purer beryllium, the oxide was converted into potassium beryllium fluoride, H_2BeF_4, by dissolving the oxide in hydrofluoric acid, adding potassium fluoride to the concentrated solution, and recrystallising the salt repeatedly from water. This was heated to bright redness for 31 minutes with the calculated quantity of sodium in a steel crucible. In the residue, hexagonal crystals of beryllium could be seen, as well as beryllium powder, slightly contaminated with iron and beryllium oxide. In a second experiment, the mixture was heated at a lower red heat for 26 minutes; the beryllium thus obtained was free from iron, but contained a considerable quantity of beryllium oxide.

Beryllium oxide behaves as a feeble acid towards strong bases. *Potassium beryllate*, $Be(OK)_2$, obtained by dissolving beryllium oxide in aqueous or alcoholic potash, forms a snow-white mass with a silky lustre, but cannot be obtained free from potassium carbonate.

Towards feeble acids beryllium oxide behaves as a base. Aqueous sulphurous acid dissolves freshly precipitated beryllium hydroxide, and the solution, on evaporation, leaves a gummy mass, of the composition $BeSO_3,BeO$. If this be treated with alcohol and a little sulphurous acid, and the solution again allowed to evaporate, a second amorphous basic sulphite, $3BeSO_3,BeO$, is obtained. If, however, the freshly precipitated hydroxide be added to a saturated alcoholic solution of sulphurous anhydride, the solution gives a white, crystalline residue on evaporation in a vacuum over sulphuric acid and alkali. Its analysis shows it to be the normal sulphite $BeSO_3$, but it is decomposed by both alcohol and water.

Freshly precipitated beryllium hydroxide does not act on boric acid, and barium borate gives no beryllium borate on treatment with beryllium sulphate, but simply the hydroxide. The borate may, however, be obtained by precipitating beryllium chloride solution with borax solution, or by neutralising the same with sodium carbonate in presence of a large excess of boric acid. It is a white precipitate, resembling beryllium hydroxide, and has the composition $5BeO,B_2O_3$.

The beryllium oxide obtained by the method above described dissolves in concentrated hydrochloric acid with a greenish-yellow colour. This fact, although not previously published, has, according to private communications to the authors, also been observed by Joy, Nilson, and Petterson, and is due to the presence of some impurity, which may be removed as follows:—The colourless solution obtained after the purification with ammonium carbonate is treated with ammonium sulphide, thoroughly shaken, allowed to remain for two days in a well-closed bottle, and filtered from a small quantity of black precipitate formed. The beryllium carbonate obtained on boiling the filtrate and the beryllium oxide formed from the latter by ignition, then dissolve in concentrated hydrochloric acid with formation of a perfectly colourless solution.

The beryllium oxide thus purified was utilised for a redetermination of the atomic weight of beryllium. The numbers obtained varied from 9·08 to 9·25, the lower number being that previously obtained by Nilson and Petterson. H. G. C.

Lead Tetrachloride. By I. FRIEDRICH (*Listy Chem.*, **17**, 67—68). —In this preliminary notice the author refers to the work of Nikoljukin (*J. Russ. Chem Soc.*, 1885, 207—210), who prepared the double salts of ammonium chloride and of potassium chloride with lead tetrachloride without entering more fully into the subject. The very stable ammonium double salt yielded, by a method which the author proposes to describe more fully, a liquid of 3·2 sp. gr., which above 0° is decomposed into lead dichloride and free chlorine; the analysis of this compound shows that it is lead tetrachloride, $PbCl_4$.

B. B.

Lead Oxides. By G. KASSNER (*Arch. Pharm.* [3], **28**, 171—178). —The author briefly discusses views which have been published on the composition of the various oxides of lead. In a previous paper (this vol., p. 561) he has described the production of plumbates corresponding with the ortho-acid H_4PbO_4, which has not yet been isolated. The already known hydrate PbO_2,H_2O, obtained as a bluish-black deposit at the positive pole when lead solutions are decomposed by the electric current, may be represented by $PbO(OH)_2$, and as it contains a molecule less water than the ortho-acid, may be called metaplumbic acid; lead sesquioxide may be expressed as a salt of this acid, $PbO\colon O_2\colon Pb$. The oxide Pb_3O_4 follows as an orthoplumbate, $Pb(O_2Pb)_2$. The peroxide, PbO_2, is to be considered as the anhydride both of orthoplumbic and metaplumbic acid. Other compounds of lead and oxygen are known besides the ortho- and meta-plumbates, such compounds as Pb_4O_5, Pb_5O_7, &c. These compounds cannot be considered as simple molecular aggregates of PbO and Pb_3O_4, but must be chemical compounds, seeing that they resist the action of weak solvents which would otherwise take up PbO. Structural formulæ which may represent Pb_2O_3 are given. The composition of the earthy plumbates indicates that only tetratomic lead is present.

Genther has shown that lead oxide does not contain PbO, but a polymeride of this, either Pb_3O_3 or Pb_6O_6; consequently in the formation of the plumbates this polymeric molecule must undergo decomposition; it is, therefore, probable that the polymeric molecule only exists as such in the cold, whilst molten lead oxide consists of the simple molecule PbO. J. T.

Lead Thiosulphate. By J. Fogh (*Compt. rend.*, **110**, 522—523).—When dilute solutions of lead acetate and sodium thiosulphate are mixed, the lead is completely precipitated in the form of anhydrous thiosulphate, PbS_2O_3, with development of +5·8 Cal. at 10°. This corresponds with +8·6 Cal. for the solid acetate and thiosulphate. The lead thiosulphate immediately after precipitation dissolves completely in a solution of sodium thiosulphate with absorption of −0·392 Cal. at 11°. The dried precipitate requires a stronger solution of the sodium salt for rapid solution, but the absorption of heat (−0·418 Cal.) is practically the same, and hence the physical condition of the thiosulphate is not changed during the process of washing and drying. It follows that as the heats of formation of lead acetate and sodium acetate and thiosulphate from their elements are known, the heat of formation of the lead thiosulphate from its elements can be calculated from the result of the first experiment. Taking the heat of formation of dissolved thiosulphuric acid as +79·4 Cal.,

$$Pb + S_2 + O_3 = Pb_2S_2O_3, \text{ develops } +152 \text{ Cal.}$$

C. H. B.

Decomposition of Lead Thiosulphate by Heat: Lead Trithionate. By J. Fogh (*Compt. rend.*, **110**, 524—525).—When dry lead thiosulphate is heated, it yields lead sulphide, lead sulphite, lead sulphate, and sulphurous anhydride; but if the thiosulphate is boiled with water for a long time, the sole products are lead sulphide and lead trithionate in equal molecular proportions.

Lead trithionate also separates very slowly in small, slender needles from a mixture of saturated solutions of lead acetate and potassium trithionate. When dried in a vacuum, it is anhydrous. If heated gently, sulphur is given off; and if heated more strongly, sulphur vapour and sulphurous anhydride are evolved, and a black residue is left. It is only slightly soluble in water, and the solution may be boiled for some time without alteration, but if evaporated on a water-bath, partial decomposition into sulphide and sulphate takes place.

Lead trithionate dissolves completely in a solution of sodium thiosulphate; heat of dissolution = − 5·0 Cal. at 10°—

$$Pb + S_3 + O_6 + Aq = PbS_3O_6 \text{ diss. .. develops } +280·2 \text{ Cal.}$$
$$Pb + S_3 + O_6 = PbS_3O_6 \text{ solid .... ,, } +285·2 \text{ ,,}$$

The conversion of lead thiosulphate into the sulphide and the trithionate is endothermic and, if the trithionate is all dissolved, is accompanied by an absorption of about −6·0 Cal. C. H. B.

Lead Sodium Thiosulphates. By J. Fogh (*Compt. rend.*, **110**, 571—573).—Lead sodium thiosulphate is obtained by mixing solutions of sodium thiosulphate and lead acetate, and adding alcohol to the mixture. If the solutions are concentrated, the liquid separates into two layers, and when the lower layer is treated with more alcohol, it solidifies to a white, amorphous mass of variable composition. The heat of solution of this product indicates that it is a mixture of lead sodium thiosulphate and hydrated sodium thiosulphate, and it is probable that the complex lead sodium thiosulphates described by previous investigators were really mixtures of the same kind.

If the solutions are dilute, a white, gelatinous precipitate forms and gradually changes to crystalline plates. When dried in a vacuum, the crystals have the composition $PbS_2O_3,2Na_2S_2O_3$, and are identical with the double salt described by A. Lenz. The heat of solution of this compound in a dilute solution of sodium thiosulphate is −4·1 Cal. at 10°, and hence its heat of formation from its constituent salts is +5·3 Cal. C. H. B.

Conditions of the Reaction between Copper and Nitric Acid. By V. H. Veley (*Proc. Roy. Soc.*, **46**, 216—222).—Spheres of copper, introduced into dilute nitric acid and kept in violent agitation (compare Trans., 1889, 361), were found to be more rapidly attacked by acid which had been previously used in similar experiments than by fresh acid. The increased rate of solution was found to be due to the nitrous acid generated. Nitric acid of sp. gr. 1·41 was freed from nitrous acid by passing a current of air through it at at a temperature not exceeding 30°. When the copper spheres were introduced into this acid, no evolution of gas occurred for three minutes, but the acid contained a considerable quantity of nitrous acid after five minutes. If carbamide be added to the acid, the action is considerably retarded, but proceeds rapidly when once commenced. In one experiment in which 1 gram of carbamide was added to a litre of the acid, the copper sphere remained unattacked during a period of an hour. A current of air driven through the acid has the same effect as carbamide in removing nitrous acid and preventing the solution of the copper. H. K. T.

Action of Sulphuric Acid on Aluminium. By A. Ditte (*Compt. rend.*, **110**, 573—576).—When aluminium foil is placed in sulphuric acid of 2·5 per cent., it at first seems to undergo no change, but after a time the surface loses its polish and becomes matt, and bubbles of gas appear and increase in quantity as the surface becomes rougher. Eventually the aluminium dissolves completely. In a vacuum, the phenomena are similar, but follow one another more rapidly, the air condensed on the surface being given off first, followed as soon as the pressure is low by the hydrogen liberated by the action of the acid. Like amalgamated zinc, the aluminium is attacked immediately on its immersion in the acid, but the surface becomes covered with a film of hydrogen, which prevents further action.

If the sulphuric acid is mixed with a small quantity of any chloride with a heat of formation greater than that of aluminium chloride (platinum, gold, copper, mercury), the evolution of hydrogen is much more rapid. The chlorides of iron, zinc, &c., have no such effect.

In presence of traces of the active chlorides, the evolution of hydrogen is at first rapid, but after a time it slackens, and a white deposit of basic aluminium sulphate, $2Al_2O_3,SO_3$, is formed, and increases in quantity until the whole of the aluminium has been dissolved.

Aluminium, under atmospheric pressure, is not attacked by a solution of aluminium sulphate, but in a vacuum, air is first disengaged from the surface of the metal, and the latter is then converted into the basic sulphate with evolution of hydrogen. The same change takes place readily even under atmospheric pressure if a trace of one of the active chlorides is added.

The displacement of copper from copper sulphate by aluminium is an exothermic change, but does not take place under ordinary conditions even in presence of free acid. After prolonged contact, the aluminium is slowly attacked, the rapidity of the reaction increasing as the surface of the metal becomes roughened. In presence of a trace of one of the active chlorides, the deposition of copper is much more rapid, even in absence of free sulphuric acid.

The same explanation holds in all cases where the aluminium does not readily enter into a reaction which would be exothermic. The surface of the metal becomes covered with a thin layer of gas, which prevents further change, but which can be removed by reduction of pressure or by the roughening of the surface of the aluminium in consequence of the deposition of another metal upon it. C. H. B.

Action of Nitric Acid on Aluminium. By A. DITTE (*Compt. rend.*, **110**, 782—784).—The action of nitric acid and nitrates on aluminium, like the action of sulphuric acid and sulphates (preceding abstract), is impeded by the formation of a film of gas on the surface of the metal. If the action takes place in a vacuum, or if the liquids are heated, dissolution of the metal takes place much more rapidly. Very dilute nitric acid yields nitrogen, nitric oxide, and ammonia. Nitric acid of 3 per cent., mixed with a small quantity of platinum chloride, dissolves aluminium with very slight evolution of gas and formation of considerable quantities of ammonium nitrate. Aluminium dissolves in a solution of the normal nitrate, especially on heating, with evolution of hydrogen and formation of the basic nitrate $2Al_2O_3,N_2O_5,10H_2O$. At the ordinary temperature, dissolution takes place very slowly, but the action is somewhat more rapid in a vacuum. The decomposition of water by aluminium would result in the formation of the hydroxide and hydrogen, either of which can form a protecting film on the surface of the metal. In presence of any salt which will dissolve the aluminium hydroxide, the metal is gradually attacked. Salts which do not dissolve alumina have no influence on the change. C. H. B.

Fluoroxy-salts of Molybdenum. By F. MAURO (*Gazzetta*, **19**, 179—195).—After an historical account of the molybdenum compounds of the type MoX_5, the author calls attention to the fact that the pentachloride and the compound $MoCl_5,POCl_3$ are the only compounds of that class the composition of which is firmly established, inasmuch as Blomstrand's analyses of his violet and brown oxychlorides

(*J. pr. Chem.*, **71**, 459) do not agree sufficiently well with the formulæ calculated, whilst the generally received formula for the blue oxide, Mo_2O_5, depends on the analyses of Wohler and Buff (*Annalen*, **110**, 275), and of Rammelsberg (*Ann. Phys. Chem.*, **127**, 290), all of which agree better with the formula Mo_3O_8. Rammelsberg's analyses of the hydrated oxide $Mo_2O_5,3H_2O$ likewise agree better with the formula $Mo_3O_8,5H_2O$.

Normal potassium fluoroxyhypomolybdate, $MoOF_3,2KF,H_2O$, is best obtained by adding potassium hydrogen fluoride to a solution of hydrated molybdenum dioxide in hot hydrofluoric acid; on cooling, the hypomolybdate separates in very thin, blue plates. It may also be prepared by the electrolysis of a solution of potassium fluoroxymolybdate, $MoO_2F_2,2KF,H_2O$, in dilute hydrofluoric acid. It crystallises from a solution containing excess of hydrofluoric acid in large, transparent, monoclinic laminæ, having a vitreous lustre—

$$a : b : c = 0{\cdot}99975 : 1 : 1{\cdot}03200;\ \beta = 80^\circ\ 56'\ 27''.$$

Forms observed—(100), (010), (001), $(10\bar{1})$, (021), (111), (110), $(11\bar{1})$, $(11\bar{2})$.

Principal angles $001 : 100 = 80^\circ\ 56'$; $001 : 10\bar{1} = 129^\circ\ 24'$; $001 : 021 = 63^\circ\ 52'$; $001 : 111 = 51^\circ\ 7'$; $001 : 110 = 83^\circ\ 34'$; $001 : 11\bar{1} = 120^\circ\ 9'$; $110 : 1\bar{1}0 = 89^\circ\ 16'$.

From these figures it appears that potassium fluoroxyhypomolybdate may be regarded as geometrically isomorphous with the salts $MoO_2F_2,2KF,H_2O$; $WO_2F_2,2KF,H_2O$; $NbOF_3,2KF,H_2O$; and $TiF_4,2KF,H_2O$.

It acquires a more intense blue colour after prolonged exposure to the air, but it undergoes no further change. It loses the greater part of its water of crystallisation when placed in dry air over calcium chloride, and it turns green and becomes anhydrous on heating at 100°. When ignited for several hours in the air, it loses hydrofluoric acid, and is converted into normal potassium molybdate. It is soluble in water and in hydrochloric acid with decomposition, and like other substances of this class it is a powerful reducing agent, precipitating salts of silver, copper, gold, &c.

Hexagonal potassium fluoroxyhypomolybdate, $3MoOF_3,5KF,H_2O$, is obtained by dissolving the preceding salt in hydrofluoric acid and concentrating the solution; on cooling, the hypomolybdate separates out in very slender blue, vitreous, acicular crystals, which appear under the microscope as prisms with a hexagonal section. It is soluble in water with decomposition, and has considerable reducing power; it gives off hydrofluoric acid on heating to 230°.

Normal ammonium fluoroxyhypomolybdate, $MoOF_3,2NH_4F$, is obtained by gradually adding ammonia to a solution of the hydrated molybdenum dioxide in hydrofluoric acid until the dark-green colour changes to brownish-red; more hydrofluoric acid is then added, until the original colour is just restored. On concentrating the solution at a moderate temperature, the ammonium salt separates out in large blue or green, vitreous, transparent, rhombic prisms or tables, which become deep blue on exposure to the air—

$$a : b : c = 0{\cdot}84289 : 1 : 1{\cdot}01998.$$

Forms observed :—(010), (001). (011), (034), (012), (201), (605), (101), (221).

Principal angles :—001 : 011 = 45° 34′; 001 : 034 = 37° 25′; 001 : 012 = 27° 01′; 001 : 201 = 67° 33′; 001 : 605 = 55° 27′; 001 : 101 = 50° 26′; 001 : 221 = 72° 28′; 221 : 22$\bar{1}$ = 35° 04′; 201 : 20$\bar{1}$ = 41° 54′; 201 : 011 = 74° 30′; 011 : 221 = 49° 29′.

This salt is, therefore, isomorphous with the compounds—

$$MoO_2F_2,2NH_4F, \quad NbOF_3,2NH_4F, \quad \text{and} \quad WO_2F_2,2NH_4F.$$

From the isomorphism of the compounds $MoOF_3,2KF,H_2O$ with $MoO_2F_2,2KF,H_2O$, and of $MoOF_3,2NH_4F$ with $MoO_2F_2,2NH_4F$, it would appear that the substitution of an atom of fluorine for an atom of oxygen does not affect the crystalline form of the compound.

Hexagonal ammonium fluoroxyhypomolybdate, $3MoOF_3,5NH_4F,H_2O$, is obtained by concentrating a solution of the normal salt in hot hydrofluoric acid. On cooling, it separates out in very small, sky-blue, vitreous, acicular crystals, which appear under the microscope as hexagonal prisms with their principal axis coincident with the direction of optic extinction; in this respect it resembles the compounds $3MoOF_3,5KF,H_2O$, $3NbOF_3,5KF,H_2O$, and $3NbOF_3,5NH_4F,H_2O$. It has some reducing power and is decomposed by water; on exposure to the air, its colour changes to a deep blue.

Other ammonium fluormolybdates prepared by the author have been already described (see Abstr., 1889, 106). S. B. A. A.

Phosphotrimetatungstic Acid and its Salts. By E. PÉCHARD (*Compt. rend.*, **110**, 754—757).—*Phosphotrimetatungstic acid*,

$$P_2O_5,12WO_3 + 42H_2O,$$

is obtained by evaporating below 100° a mixture of phosphoric and metatungstic acids in any proportions whatever. If the metatungstic acid is in excess, the final crystals consist of phosphopentametatungstic acid. Phosphotrimetatungstic acid forms brilliant crystals, seemingly triclinic, which do not effloresce and are soluble in water or alcohol. They are not decomposed by acids in the cold, but tungstic acid separates on heating. With bases, the acid yields salts of the general type $M'_2O,P_2O_5,12WO_3$, which can also be obtained by the direct combination of metatungstic acid and phosphates. Excess of an alkali yields a mixture of a normal tungstate and normal phosphate. The sodium salt crystallises with 18 mols. H_2O in fine crystals, isomorphous with the acid; it is insoluble in alcohol. The potassium salt,

$$K_2O,P_2O_5,12WO_3 + 9H_2O,$$

is amorphous, insoluble in cold water, and only slightly soluble in hot water; the ammonium, cæsium, and rubidium salts have similar properties. The thallium salt, $Tl_2O,P_2O_5,12WO_3 + 4H_2O$, is a very finely divided, amorphous substance. The lithium salt, which conforms to the general type, and crystallises with 21 mols. H_2O, forms brilliant crystals, apparently rhombohedric. The barium, strontium, and calcium salts crystallise in rhombohedral crystals with 15, 17, and 19 mols. H_2O respectively, dissolve in water, but are insoluble in alcohol. The magnesium, cadmium, and zinc salts form rhombohedral crystals with 10, 13, and 7 mols. H_2O respectively. The copper salt (11 mols. H_2O) is also rhombohedral, but effloresces very rapidly; the lead salt (6 mols. H_2O) is white, and insoluble in cold water, but crystallises from boiling water in slender needles. The silver salt, $Ag_2O,P_2O_5,12WO_3 + 8H_2O$, is insoluble, and is not affected by light. The mercurous salt is yellowish, and is insoluble in water and dilute nitric acid. C. H. B.

Atomic Weight of Zirconium. By G. H. Bailey (*Proc. Roy. Soc.*, **46**, 74—87).—In this paper, experiments with a view to the preparation of pure zirconia, prior to the determination of the atomic weight of zirconium, are described. Crude zirconia was dissolved in hydrochloric acid, and crystallised out as oxychloride. A solution of the latter was treated with hydrogen sulphide, filtered, the filtrate rendered alkaline with ammonia, and any further precipitate of sulphides removed. The filtrate was then acidified, and oxalic acid added to throw down gadolinium earths. The oxychloride still contained iron, which was removed by repeated crystallisations from concentrated hydrochloric acid, the crystals being finally washed with a mixture of the acid with 1 part of alcohol and 10 parts of ether. The zirconia now contained only soda, which was removed by repeated precipitation with ammonia and re-solution with hydrochloric acid.

The following forms of zirconium were examined—the metal, the chloride, oxychloride, bromide, and sulphate. The only method which gives the metal free from foreign impurity is Phipson's, in which zirconia is heated with magnesium powder. The black powder so obtained consists mainly of zirconia, and contains only a small amount of metallic zirconium. Nearly pure metal can be obtained by using magnesium foil, the foil being afterwards treated with hydrochloric acid. The author finds that concentrated sulphuric acid acts rapidly on zirconium in the cold.

The peroxide can be precipitated in acid or ammoniacal solution, preferably the former, by means of hydrogen peroxide. It has the composition $ZrO_3,3H_2O$ when dried over phosphoric anhydride. At 100° its composition becomes Zr_2O_5.

Zirconium tetrachloride was prepared in the usual way, and was sublimed in a current of chlorine through a tube drawn out into bulbs, a lower temperature being used for each bulb. The bulbs were then sealed and their contents analysed. The results were not concordant.

Zirconium oxychloride is apt to retain hydrochloric acid, and if heated it passes into basic salts. Samples were purified (1) by washing with alcohol and ether, (2) by placing in a vacuum over solid potash. The ratio of chlorine to zirconium oxide was determined, and the results compared with one another and with those of Berzelius. They were not concordant.

The sulphate was prepared by heating the powdered zirconia with sulphuric acid, the excess of acid being driven off at a temperature of 350—400°, it being found that the excess of acid was completely expelled at 350°, whilst the salt was decomposed only at temperatures above 400°.

Atomic weight of zirconium.—The decomposition of zirconium sulphate was considered to be the most accurate method for the determination of this value. Owing to the rapidity of the decomposition loss is apt to occur. The crucible in which the decomposition was effected was therefore enclosed in a second one, and heated very slowly. The mean of eight determinations gives 90·401 as the atomic weight of zirconium ($H = 1$). H. K. T.

Vanadium in Potassium Hydroxide. By E. F. Smith (*Chem. News*, **61**, 20—21).—By treating ordinary stick potash with hydrogen sulphide, acidifying with hydrochloric acid, &c., as much as 0·5 gram of impure vanadium sulphide was obtained from 3 lbs. of potash. D. A. L.

Atomic Weight of Bismuth. By A. Classen (*Ber.*, **23**, 938—953). —The purest commercial bismuth contains various impurities, such as copper and iron, but the principal one is lead; the author's first attempts to prepare the metal in a chemically pure condition were carried out as follows:—(1) The purest commercial metal (250 grams) was dissolved in nitric acid, the solution repeatedly evaporated with concentrated hydrochloric acid until free from nitric acid, the chloride dissolved in concentrated hydrochloric acid, and the solution mixed with alcohol, whereon the lead was partially precipitated as chloride. The filtered solution was then placed in 10 beakers (each of 4 litres capacity), the bismuth precipitated as oxychloride by adding water, the precipitate washed by decantation until free from hydrochloric acid, redissolved in hydrochloric acid, and reprecipitated with water; this process was repeated 12 times. The oxychloride obtained in this way was dissolved in hydrochloric acid, the diluted solution treated with ammonia and ammonium carbonate, the precipitate washed by decantation until free from ammonia, dissolved in hydrochloric acid and reprecipitated with ammonia and ammonium carbonate; this process was twice repeated. The precipitate was then dissolved in hydrochloric acid, reprecipitated with water, washed, dried, and fused with 98 per cent. potassium cyanide; the resulting metal was then repeatedly melted with potassium cyanide, the whole melt finally cast into a mould, and when cold, the metal separated, washed well with water, and polished.

(2.) The purest commercial bismuth nitate was treated as described in the first process.

The metal purified by either of these methods was found, on spectroscopic examination, to contain lead, so that bismuth cannot be freed from this metal by fractional precipitation.

Chemically pure bismuth can, however, be obtained by electrolysis. When a nitric acid solution of the metal, purified as described above, is electrolysed under suitable conditions, chemically pure bismuth is deposited on the negative electrode, and the whole of the lead is deposited as peroxide, together with bismuth peroxide, on the positive electrode. The electrolysis is carried out in the following manner:—About 200 grams of the purified metal is dissolved in pure nitric acid, and the cold solution placed in a beaker; a platinum basin, resting on the bottom of the beaker and connected with a positive electrode of the usual form, serves as the positive, and a platinum cone as the negative, electrode. The current can be obtained either from galvanic batteries or from a dynamo, and is so regulated by means of resistance coils, that the bismuth separates in a crystalline condition. The bismuth and lead peroxides are deposited together on the platinum basin, and the negative electrode together with the adherent bismuth can be easily removed without agitating the liquid. The bismuth is separated from the electrode, washed with alcohol, melted with potassium cyanide as described under (1), and polished.

In this way it is obtained in a perfectly pure condition, as is shown not only by spectroscopic examination, but also by measurements of its electrical resistance (compare v. Aubel, Abstr., 1889, 807), which is the best test of absolute purity.

The specific heat of the pure metal was found by v. Aubel to be 0·0318 between 61·6° and 21·7°, as the average of 10 determinations by Kopp's method.

The specific gravity of the pure metal was determined by the author and found to be 9·7474, as the average of four experiments, and the specific gravity of pure melted bismuth oxide 9·0444.

Pure bismuth that has cooled slowly melts at 264°, but traces of impurities raise its melting point considerably.

After discussing the methods employed by previous investigators (Lagerhjelm, Schneider, Dumas, Marignac, Bailey, and Löwe), the author gives a brief account of his own preliminary attempts to determine the atomic weight of bismuth (1) by converting the metal into oxide, (2) by converting the metal or oxide into sulphide, (3) by converting bismuth triphenyl into oxide, and (4) by converting bismuth triphenyldibromide into oxide, but none of these methods gave satisfactory results.

The following method was finally adopted, and found to be both simple and accurate:—The pure metal is placed in a platinum basin (90 mm. in diameter), standing in a larger platinum basin (120 mm. in diameter), and covered with a third platinum basin (92 mm. in diameter), over which is inverted a fourth platinum basin (105 mm. in diameter), in such a way that it rests on the bottom of the largest basin; dilute nitric acid, most carefully purified, is then added, and the whole apparatus heated in the water-bath until solution is complete. The platinum basins which serve as covers are washed with dilute nitric acid, the washings added to the bismuth solution, the whole evaporated to dryness, and the residue heated first to 90—100° in an air-bath, and then, after keeping 24 to 48 hours, gradually to 250°, at which temperature the nitrate is gradually decomposed; the residual oxide is then heated to its fusing point until its weight becomes constant.

The average of nine determinations gave 208·923 (O = 16) or 208·401 (O = 15·96) as the atomic weight of bismuth, or when reduced to a vacuum 208·90235 and 208·38009 respectively, the values given above for the sp. gr. of the metal and its oxide being taken.

F. S. K.

New Bismuth Potassium Iodide. By L. Astre (*Compt. rend.*, **110**, 525—527).—With a view to prepare Nicklès's salt, $BI_3,KI + 2H_2O$, 38·1 grams of iodine, 14·82 grams of potassium chloride, and 100 grams of water were allowed to remain in contact with 40 grams of powdered bismuth for about two months. At the end of this time, the product consisted of slender, brown needles mixed with potassium chloride and the excess of bismuth, with a small quantity of bismuth potassium chloride. The only solvent which will dissolve the double iodide without decomposition is ethyl acetate. By spontaneous evaporation of this solvent, crystals are obtained which always have the same composition and are similar in appearance to the crystals in the crude product. The percentage composition of the crystals is as follows:—

	I.	Bi.	K.	H_2O.
Found (mean of three preparations)............	64·8	32·6	2·5	—
Calc. for $KI,2BiI_3$	65·4	32·5	2·1	—
Calc. for $KI,BiI_3 + 2H_2O$	65·4	27·08	5·03	2·40

The product is therefore a double iodide, different from Nicklès's salt. It is obtained more rapidly by heating the preceding mixture at 100° in a well-closed flask for 24 hours, cooling and extracting with ethyl acetate.

C. H. B.

Atomic Weight of Gold. By J. W. Mallet (*Proc. Roy. Soc.*, **46**, 71—73).—Five methods were used in this determination:—(1.) A neutral solution of auric chloride was divided into two accurately weighed portions. In one the gold was precipitated with sulphurous anhydride and weighed. With the other, the amount of metallic silver, in the form of nitrate, required to precipitate its chlorine was determined (five experiments). (2.) A similar method was applied to a solution of auric bromide (six experiments). (3.) A similar treatment was applied to a solution of potassic aurobromide (four experiments). (4.) A determination was made of the loss by ignition of a weighed quantity of trimethylammonium aurochloride (five experiments). (5.) A comparison was made of the weights of gold and silver simultaneously deposited by the same current from solutions of aurocyanide and argentocyanide of potassium respectively (five experiments). (6.) A comparison was made of the weight of gold deposited from potassium aurocyanide with the volume of hydrogen liberated from dilute sulphuric acid by the same current (three experiments). (7.) A determination was made of the quantity of hydrogen obtainable by the dissolution of zinc in dilute sulphuric acid. A definite quantity of this zinc, taken in excess, was used to precipitate gold from a neutral solution of auric chloride and the gold thrown down was determined. The excess of zinc was dissolved in sulphuric acid and the volume of the evolved hydrogen was noted. From these data the hydrogen equivalent to the precipitated gold was calculated (six experiments).

The general mean of the results is 196·910. If methods 5 and 6, which are the least satisfactory, are excluded, the value 196·882 is obtained. Finally, if the mean of the first three methods is taken, the value 196·762 is obtained, a result higher than that of Krüss, but lower than that of Thorpe and Laurie. H. K. T.

Potassium Nitrosoplatinochloride. By M. Vèzes (*Compt. rend.*, **110**, 757—758).—When a concentrated solution of potassium platinonitrite is mixed with excess of hydrochloric acid and gently heated, nitrogen oxides are evolved and a yellow, crystalline powder separates, which is a mixture of potassium platinochloride and another salt of very similar appearance. The latter, however, crystallises in a different form, and the crystals act on polarised light; when heated alone, it evolves nitrogen oxides, and when heated in hydrogen, it yields an appreciable quantity of water and ammonium chloride. It is potassium nitrosoplatinochloride, K_2PtCl_5NO, and is analogous to the potassium nitrosorutheniochloride, K_2RuCl_5NO, described by Joly (Abstr., 1889, 352 and 678).

It is noteworthy that the percentage of potassium and platinum is practically the same in the platinochloride and the nitrosoplatinochloride. C. H. B.

Mineralogical Chemistry.

Mineral Synthesis. By E. Weinschenk (*Zeit. Kryst. Min.*, **17**, 486—504).—1. The author has prepared artificially a number of sulphides by the distillation of oxides with ammonium chloride and sulphur; a method first employed by Wöhler in 1836. The synthesis of a mineral, the author notes, can only be regarded as successful, not only when the chemical composition is copied, but also when the product has all the physical properties of the mineral. The sulphides prepared in sufficient quantity to enable the physical properties to be determined were iron pyrites, magnetite, cobalt sulphide, cupric sulphide, and galena. Nickel, manganese, and zinc gave unsatisfactory results, and silver sulphide could not be obtained in crystals by this method.

2. The minerals of the apatite group were prepared by the wet method. Apatite was obtained in well-developed crystals by heating a mixture of calcium chloride, ammonium phosphate, and excess of ammonium chloride in a closed glass tube at 150° to 180°. Other phosphates were obtained in a similar manner, as were also chlorarsenates and vanadates.

3. Oxides of metals that are more electropositive than copper were obtained in a crystallised condition by the action of metals on ammoniacal copper solutions. Magnetite, cuprite, and arnimite were obtained in this way. The last mineral was discovered by Weisbach (Abstr., 1888, 1259).

4. Sulphides were obtained by the decomposition of thiocyanates in acid solution. By the employment of ammonium thiocyanate, it is

possible to obtain an atmosphere of hydrogen sulphide at a high pressure. This method was employed for the preparation of a large number of sulphides and yielded a series of good results. The mixture in each case was heated at a temperature of 230° to 250° for four to six hours in a closed tube. In this way the author obtained galena from lead acetate, silver glance from silver acetate, covelline from copper sulphate, cinnabar from mercury chloride, orpiment from arsenious acid, troilite from iron ammonium sulphide, cuprous sulphide from cuprous chloride, mercurous sulphide from mercurous chloride, millerite from nickel sulphate solution, cobalt monosulphide from cobaltous chloride, and alabandine from manganese sulphate.

Mercury Sulphates from a Furnace at Idria. By G. SEYFRIEDSBERGER (*Zeit. Kryst. Min.*, **17**, 433—444).—The mercury sulphates found in 1887 in pulling down a mercury furnace at Idria appear in two forms, a crust filled with geodes of small, pellucid crystals, and a white, crystalline, amorphous mass of globular structure. Both varieties are planted on yellow brick or mortar. The crystallised substance, which appears to be genetically the older of the two, gave on analysis 81·95 per cent. of Hg_2O and 16·72 per cent. of SO_3, and undoubtedly has the formula Hg_2SO_4. Its sp. gr. is 8·353. The crystalline substance on analysis yielded 27·02 per cent. of SO_3, and has consequently the formula $HgSO_4$. Its sp. gr. is 5·995. The crystallised sulphate is believed by the author to be trimetric, the observed forms being $\infty\bar{P}\infty$, $\infty\breve{P}\infty$, $0P$, ∞P, $\infty P\frac{2}{3}$, $\breve{P}\infty$, $\frac{1}{2}\bar{P}\infty$, $\bar{P}\infty$, $\frac{2}{3}\bar{P}\infty$, P.

B. H. B.

Supposed New Mineral from Montana. By R. PEARCE (*Zeit Kryst. Min.*, **17**, 402—403; from *Proc. Colorado Scient. Soc.*, **2**, 70).—A massive mineral found in the Gagnon mine, Butte, Montana, resembles bornite. Its hardness is 3·5 to 4, and its sp. gr. 4·95. Analysis gave the following results:—

S.	Cu.	Ag.	Zn.	Fe.	Insol.	Total.
20·51	41·10	24·66	9·80	2·09	1·02	99·18

The author is inclined to regard the mineral as a bornite in which copper is partly replaced by silver, and iron by zinc. B. H. B.

Artificial Silver-bismuth-glance. By R. SCHNEIDER (*J. pr. Chem.* [2], **41**, 414—424; compare this vol., p. 337).—When finely powdered bismuth sulphide is shaken with a feebly ammoniacal 1 per cent. solution of silver nitrate, practically no change occurs, a mere trace only of silver being thrown down as sulphide; but if the silver nitrate solution be neutral, the silver will be precipitated as sulphide and the bismuth converted into basic nitrate.

One gram of finely powdered potassium bismuth sulphide is put into a flask (60 c.c.) together with 25—30 c.c. of air-free water and a solution of 0·550 gram of silver nitrate to which ammonia has been added until the brown precipitate just redissolves; the flask is then filled up with air-free water and continually shaken. After 12—24 hours, the supernatant liquid is found to be free from silver; it is then decanted, and the residue shaken with air-free water for two days, then filtered, washed with water and absolute alcohol, pressed between filter-paper, and dried at 100°.

Thus prepared, silver-bismuth-glance has the composition Ag_3S,Bi_2S_3, and is a dark-grey powder; if crystals of bismuth sulphide are employed instead of powder in the above prescription, the resulting glance is crystalline and of the same form as the bismuth sulphide. It fuses without decomposition; the fused mass is light-grey and of metallic lustre; its fracture shows a homogeneous, leafy, crystalline structure; it is brittle, but not easily powdered. The powder is grey; its hardness is about 3·5; its sp. gr. at 15° is 6·96, that of the mineral being 6·92 (Rammelsberg). Cold nitric acid and hydrochloric acid do not attack it, but both acids decompose it when hot.

Artificial silver-bismuth-glance was also prepared by fusing silver sulphide and bismuth sulphide together in molecular proportion; the fused mass had all the above properties. A. G. B.

Sylvanite and Nagyágite from Nagyág. By W. Hankó (*Zeit. Kryst. Min.*, 17, 514; from *Math. és term. tud. Értesitö*, 6, 340—349). —Analyses of sylvanite (I) and nagyágite (II) from Nagyág gave the following results:—

	Au.	Ag.	Te.	Fe.	Cu.	Pb.	Sb.	S.	SiO_2.	Total.
I.	26·08	11·57	61·98	0·30	0·09	trace	—	—	0·32	100·34
II.	7·61	—	17·85	0·34	—	57·20	6·95	9·95	0·31	100·21

The sp. gr. of the sylvanite is 8·036, and that of the nagyágite 7·347. B. H. B.

Arsenical Pyrites from Wunsiedel. By K. Oebbeke (*Zeit. Kryst. Min.*, 17, 384—385).—In the marble quarry to the east of Wunsiedel, a fragment of a tin-white, hard, striated mineral has been found in a state of intimate association with the granular limestone. The mineral has a hardness of 6, and blowpipe tests indicated that it was arsenical pyrites. Analysis yielded—

As.	S.	Fe.	Total.	Sp. gr.
46·91	18·64	34·31	99·86	6·123

No notice has hitherto appeared of the occurrence of arsenical pyrites in the granular limestone of Wunsiedel. This mineral has, however, been found in the same rock at Auerbach. B. H. B.

Nickel Ore from Gosenbach. By Heusler (*Jahrb. f. Min.*, 1890, i, Ref. 206; from *Niederrhein. Ges. Bonn Sitzungsber.*, 1887, 67).—In the "Storch und Schöneberg" mine at Gosenbach, in the Siegen district, a nickel ore that occurs in small quantities gave on analysis the following results:—

Sb.	As.	Ni.	S.	Pb, Zn.
32·9	5·27	27·43	34·40	traces

The formula deduced from these results is $3NiS,(\frac{1}{5}As,\frac{4}{5}Sb)_2S_3$. Further investigation is necessary to determine whether the ore is a simple mineral.
B. H. B.

New Forms of Crystallised Silica. By MICHEL-LÉVY and MUNIER-CHALMAS (*Compt. rend.*, **110**, 649—652).—The authors describe the appearance and optical properties of certain forms of silica from the cretaceous rocks of the Paris basin. Two, to which they give the names *quartzine* and *lutecite*, are varieties respectively of chalcedony and quartz, from which they differ in the mode of development of the fibres and crystals, and in their optical properties.
C. H. B.

Pseudobrookite from Vesuvius. By J. A. KRENNER (*Jahrh. f. Min*, 1890, i, Ref. 218—219; from *Foldtani Közlöny*, **18**, 153—157).—On a piece of lava from the eruption of 1872, the author discovered small crystals of pseudobrookite, exhibiting the forms $\infty\bar{P}\infty$, $\infty\bar{P}2$, $\frac{1}{3}\bar{P}\infty$. The axial ratio is $a : b : c = 0·9683 : 1 : 1·0957$. The author notes the geometrical similarity with Guiscardi's guarinite, a mineral found in the sanidine bombs of Vesuvius. The analyses of the two minerals present no analogies, the formula of guarinite being CaO,SiO_2,TiO_2.
B. H. B.

Composition of Limestones from the "Montagnola Senese." By A. FUNARO (*Gazzetta*, **19**, 34—38).—A deep grey talcose argillaceous and calcareous schist of the triassic period, from Pietra Lata, near Ripostena, and an adjoining friable pulverulent rock, probably a product of the decomposition of the schist were first examined. They are both soluble with effervescence in dilute acids, leaving an abundant siliceous residue, and have the following composition:—

	$CaCO_3$.	$MgCO_3$.	Fe_2O_3.	P_2O_5.	Insoluble residue.
Schist	75·20	1·20	0·60	—	21·75
Do. decomposed	82·00	0·74	0·60	traces	15·00

The fact of the altered rock containing more lime and less silica than the original is an indication that the former contains detritus of neighbouring calcareous formations; this is confirmed by the presence of traces of phosphates in the decomposed rock.

Some limestones occurring near Montagnola, and a white earth lying between these rocks and the schists, gave the following results:—

	Rock.	Locality.	$CaCO_3$.	$MgCO_3$.	SiO_2 and silicates.	Oxide of Fe.
1.	Limestone	Fungaja..	98·10	0·68	1·05	traces
2.	„	„ ..	91·75	0·83	0·75	„
3.	„	S. Colomba	93·25	0·75	5·00	„
4.	White earth	Campo alla Pania ..	81·25	0·37	17·50	„
5.	White earth	Fungaja..	38·80	0·57	56·25	1·00
6.	„	Campo alla Pania ..	4·60	0·76	86·70	6·75
7.	White earth	Campo alla Pania ..	0·50	0·57	95·20	0·75

(1) is a crystalline, (2) a friable, and (3) a spongy limestone; they are all adjacent rocks; the last two are probably derived from the decomposition of the first. (4) occurs between Campo alla Pania and Personata; it lies adjacent to the limestones, and is derived from their decomposition; it is a very fine, white earth, well adapted for the manufacture of porcelain, and has hitherto escaped notice. (6) and (7) are siliceous earths derived from the decomposition of the argillaceous schists.

A spongy, dolomitic limestone and a grey powder which occupied the interstices in the rock were next examined. The rock is grey, banded with white; when struck with the hammer, it emits a sulphureous and bituminous odour; the powder is ashy, non-adherent, and very finely grained. (1) is the solid rock from Val Maggiore, (2) is an altered rock from the same locality, (3) is a dolomitic powder from Cetunala, and (4) is the powder from the interstices of (2).

	$CaCO_3$.	$MgCO_3$.	Water.	Insoluble matter.
1	69·0	27·69	—	0·77
2	73·0	21·94	4·00	1·00
3	75·5	42·37	—	1·00
4	54·0	42·82	—	0·75

Analyses (3) and (4) exhibit the ordinary mode of decomposition of dolomitic rocks by loss of calcium carbonate; as this is, however, only the case at high temperatures (the reverse taking place at low temperatures), it would appear that the rock had been decomposed in deep strata, where the temperature is sufficiently elevated.

S. B. A. A.

Occurrence of Celestine and Barytes near Torda. By A. KOCH (*Zeit. Kryst. Min.*, 17, 510—511; from *Math. es term. tud. Ertesitö*, 6, 78—83).—Celestine and barytes occur in large quantities near Torda, in Torda-Aranyos Co., Hungary, in a bituminous limestone. The celestine is mined on an industrial scale. Three varieties occur with different specific gravities. The white, columnar variety has a sp. gr. of 3·89, whilst the bluish-white and the pellucid crystals have specific gravities of 3·93 and 3·94 respectively. The mineral is very pure, the mean of analyses of the different varieties giving the following results:—

SrO.	SO_3.	Total.
56·37	43·63	100·00

The barytes occurs in massive, white beds and veins, or in greyish-white, semi-transparent crystals. It is very pure, as is shown by the following analytical results:—

BaO.	SO_3.	Total.
65·47	34·40	99·87

B. H. B.

Mean Composition of the Celestine Bed of Koppánd. By E. NYIREDI (*Zeit. Kryst. Min.*, 17, 515; from *Vegytani Lapok*, 6, 56—58).—The author examined samples of about 9 lbs. in weight, taken from different portions of the bed. The mean composition was found to be as follows:—

$SrSO_4$.	$CaSO_4$.	$CaCO_3$.	SiO_2.	Fe.	Total.
87·42	7·34	4·46	0·50	trace	99·72

B. H. B.

Crystallised Basic Copper Nitrate identical with Gerhardtite. By L. BOURGEOIS (*Compt. rend.*, **110**, 541—543).—If an aqueous solution of cupric nitrate and urea in equivalent proportions is heated in sealed tubes at 130°, it yields very thin, brilliant, pale, bluish-green leaflets of the basic nitrate, $Cu(NO_3)_2,3Cu(OH)_2$. It is insoluble in water, but easily soluble in dilute acids; sp. gr. 3·41. Its crystals are rectangular lamellæ derived from a rhombic prism of 94° 30′, and it is identical in composition and properties with the native basic cupric nitrate, *gerhardtite*, described by Brush and by Wells and Penfield.

Wells and Penfield, by heating copper nitrate solution with metallic copper at 150° in sealed tubes, obtained a basic nitrate of the same composition, but crystallising in forms derived from a monoclinic prism. The author was unable to obtain these crystals; under the conditions described, the product was identical with that obtained in presence of urea. The same product is formed when a solution of cupric nitrate is slowly concentrated. C. H. B.

Dahllite, a New Norwegian Mineral. By W. C. BRÖGGER and H. BÄCKSTRÖM (*Zeit. Kryst. Min.*, **17**, 426; from *Öfv. vet. akad. förh.*, 1888, 493).—The new mineral was found at Ödegården, Bamle, Norway, as a fibrous crust on apatite. It is of a pale-yellow colour, but colourless in thin sections. Its sp. gr. is 3·053, and its hardness almost equal to that of apatite. Analysis yielded:—

CaO.	FeO.	Na_2O.	K_2O.	P_2O_5.	CO_2.	H_2O.	Total.
53·00	0·79	0·89	0·11	38·44	6·29	1·37	100·89

These results are in accord with the formula,

$$4(Ca,Fe,Na_2,K_2)_3P_2O_8,2CaCO_3 + H_2O.$$

The microscopic examination indicated that the mineral was quite unaltered, and homogeneous. This new mineral, the only combination of a phosphate and a carbonate yet known, has been named dahllite, in honour of the well known mineralogists Tellef and Johann Dahll. B. H. B.

Vivianite from the Szentes Artesian Well. By K. v. MURAKÖZY (*Zeit. Kryst. Min.*, **17**, 521; from *Foldtani Kozlöny*, **18**, 465—466).—The mineral, which was obtained from the artesian well of the town of Szentes, Csongrád Co., Hungary, at a depth of 160 metres, was found in the form of grains in the clay. On analysis it gave the following results:—

FeO.	Fe_2O_3.	P_2O_5.	H_2O.	SiO_2.	Total.
40·00	0·83	26·86	24·37	7·94	100·00

B. H. B.

Delvauxite and Diadochite from Vysočany, Bohemia. By F. KOVÁŘ* (*Listy Chem.*, **14**, 1—6, 36—42).—The author has analysed six samples of delvauxite from diluvial clays, and confirms the formula $2(Fe_2P_2O_8),Ca_3P_2O_8,4Fe_2(OH)_6 + 9H_2O$. Diadochite from the same locality was found to correspond with the formula $3Fe_2P_2O_8,2Fe_2(SO_4)_3,Fe_2(OH)_6 + 36H_2O$. Plattner finds the same formula with $45H_2O$, Cèsar $33H_2O$. Diadochite has evidently been formed from delvauxite, and often an intimate mixture of both kinds of minerals is found. B. B.

Crystals of Sarkinite. By G. FLINK and A. HAMBERG (*Zeit. Kryst. Min.*, **17**, 431—432; from *Geol. fören forh.*, **10**, 380).—In the Harstig mine, at Pajsberg, in Sweden, the authors found a crystallised mineral, which on analysis presented great similarity to two minerals already known, sarkinite and polyarsenite. Indeed, it is probable that these three minerals are identical, as their hardness, colour, lustre, and composition are the same. Igelström's name of polyarsenite has the priority, but it is unsuitable in that the mineral is an arsenate and not an arsenite. The author's therefore prefer Sjogren's name of sarkinite. The analytical results were as follows:—

MnO.	CaO.	MgO.	H_2O.	As_2O_5.	P_2O_5.	Total.
51·92	1·22	0·38	3·48	41·50	trace	98·42

Formula, $(MnO)_4As_2O_5 + H_2O$. The mineral crystallises in the monosymmetrical system, the axial ratio being $a : b : c = 2·0013 : 1 : 1·5880$; $\beta = 62° 14'$. The forms observed were ∞Ꝑ∞, 0P, ∞P, 2Ꝑ∞, P. The colour is pink, the hardness 4 to 5, and the sp. gr. 4·22. B. H. B.

Serpentine from Finland. By Miss M. TUHAJTCHINSKY (*Zeit. Kryst. Min.*, **17**, 526; from the *Proc. Soc. Naturalists, St. Petersburg*, **19**, 3).—A series of light (I to III) and dark (IV to VI) varieties of serpentine from Ilopunwara, near Pitkäranta, in Finland, were analysed with the following results:—

	I.	II.	III.	IV.	V.	VI.
SiO_2....	38·07	39·66	39·12	41·02	35·90	39·51

Serpentine from Montville, New Jersey. By G. P. MERRIL (*Zeit. Kryst. Min.*, 17, 418—419; from *Proc. U.S. Nat. Museum*, 1888, 105—111).—The author has investigated the origin of the well-known Montville serpentine. It occurs in association with crystalline dolomite. The centre of the masses usually consists of a white or grey mineral, often erroneously believed to be dolomite, which, as a matter of fact, consists of diopside, as is shown by the following analyses:—

	SiO_2.	MgO.	CaO.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	H_2O.	Total.
I.	51·45	18·43	24·02	2·94	1·06	0·96	trace	1·08	99·94
II.	40·23	39·46	—	2·18	4·02	trace	—	14·24	100·13
III.	54·21	19·82	24·71	0·59	0·20	0·27	—	0·14	99·94
IV.	42·38	42·14	—	0·07	0·97	0·17	—	14·12	99·85

I, Grey pyroxene; II, green serpentine, the product of its decomposition; III, white pyroxene; and IV, yellow serpentine, the product of its decomposition.

The serpentine contains a fairly high proportion of water. The lime set free by the alteration of the diopside is recrystallised as granular calcite of a bluish tint or in fibres. Free silica was not observed, and it may therefore be concluded that sufficient magnesia was present to combine with the excess, and to form serpentine. The author is of opinion that further investigations of small distinct masses of serpentine, enclosed in calcareous or slaty rocks, will indicate a similar mode of origin. B. H. B.

Nephrite and Jadeite. By F. W. CLARKE and G. P. MERRIL (*Zeit. Kryst Min.*, 17, 413; from *Proc. U.S. Nat. Museum*, 1888, 115—130). The authors have submitted the ethnological specimens of jade, nephrite, &c., in the U.S. National Museum, to careful examination. The following are selected from the numerous analyses given:—

	1.	2.	3.	4.	5.
SiO_2	56·01	58·11	58·18	59·18	58·33
Al_2O_3	1·98	0·24	23·53	22·96	21·63
Fe_3O_3	—	5·44	—	1·87	1·71
FeO	6·34	0·38	1·67		0·73
MnO	—	trace	—	—	—
CaO	12·54	12·01	2·35	1·52	4·92
MgO	21·54	21·97	1·72	0·67	3·09
Na_2O	—	—	11·81	12·71	8·13
K_2O	—	—	0·77	trace	0·22
Ignition	1·91	1·78	0 53	0·90	0·93
Total	100·32	99·93	100·56	99·81	99·69
Sp. gr.	2·989	—	3·190	3·32	3·27

Nos. 1 and 2 are analyses of jade from Alaska, found *in situ* in the Jade Mountains, about 150 miles from the Kowak river. Numerous varieties are found at this locality, but microscopic examination proves that they are all nephrites. The authors therefore conclude that the jade tools found in Alaska have not been derived from Siberia, as has hitherto been supposed. Jade tools from the State of Oaxaca, in Mexico (Analysis 3), are similar in composition to Damour's jadeite. The series of jade tools from Central America are shown to belong to three groups. The first is jadeite, more or less impure; the second has the sp. gr. of quartz, and also belongs partly to this species; whilst the third includes those of low specific gravity, and is characterised by softness. Jadeite from Sardinal (Analysis 4) was found under the microscope to be a finely granular aggregate of colourless crystals of pyroxene, and a specimen of this mineral from Culebra (Analysis 5) consisted of a fibrous aggregate of colourless elongated fibres and scales. Nephrite and jadeite may be distinguished by the fact that the former is fibrous and massive, whilst the latter is distinctly granular. The authors deny that nephrites from different localities may be distinguished under the microscope.

B. H. B.

Constitution of certain Zeolites. By C. Doelter (*Jahrb. f. Min.*, 1890, i, Mem. 118—139).—The author has prepared artificially a number of zeolites, with a view to obtain information as to their constitution and mode of formation. The zeolites he has prepared synthetically are apophyllite, okenite, chabasite, heulandite, desmine, laumontite, thomsonite, analcime, natrolite, scolezite, and prehnite. All these zeolites are soluble in water, especially when containing carbonic acid, at an elevated pressure, and can thus be recrystallised. The temperatures employed amounted to 120° to 160°. Several of the zeolites are soluble in liquid carbonic anhydride at a much lower temperature (25°). Analcime, heulandite, and more rarely chabasite, may be obtained from solutions of salts containing silica, alumina, calcium carbonate, or sodium carbonate, in closed tubes at a temperature of 130° to 190°. All zeolites consist of a silicate resembling nepheline, pyroxene, or felspar, to which meta- or orthosilicic acid is added. In most cases, the zeolites also contain varying quantities of water of crystallisation, the number of molecules of water being dependent on the temperature. The water of crystallisation may be driven off by increasing the temperature, but in most cases it may be taken up again. The hydrates varying with the temperature may possess different crystalline forms. A given number of molecules of water cannot be driven off without effecting the decomposition of the compound. This water is present as silicic acid. By melting and recrystallising, the silicate that forms the basis of the zeolites may in several cases be obtained. This silicate is an ortho- or metasilicate. The formulæ of the zeolites may be tabulated thus—

Apophyllite ..	$Ca(K_2)SiO_3 + H_2SiO_3 + H_2O$.
Okenite	$CaSiO_3 + H_2SiO_3 + H_2O$.
Pectolite	$CaNa_2Si_2O_6 + H_2SiO_3$.
Chabasite	$CaAl_2Si_2O_8 + 2SiO(OH)_2 + 6H_2O$.
Heulandite...	$CaAl_2Si_4O_{12} + 2SiO(OH)_2 + 3H_2O$.
Desmine.....	$CaAl_2Si_4O_{12} + 2SiO(OH)_2 + 4H_2O$.
Laumontite ..	$CaAl_2Si_2O_8 + 2SiO(OH)_2 + 2H_2O$.
Thomsonite ..	$2\{(CaAl_2Si_2O_8)(Na_2Al_2Si_2O_8)\} + 5H_2O$.

Analcime	$Na_2Al_2Si_2O_8 + 2SiO(OH)_2$.
Natrolite	$Na_2Al_2Si_2O_8 + Si(OH)_4$.
Scolezite	$CaAl_2Si_2O_8 + Si(OH)_4 + 2H_2O$.

B. H. B.

Analyses of Idocrase. By G. LINDSTRÖM (*Zeit. Kryst. Min.*, **17**, 430—431; from *Geol. fören. forh.*, **10**, 287).—The varieties of idocrase analysed by the author were (1) jewreinowite, from Frugard, and (2) cyprine, from Telemarken.

The results were as follow:—

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CuO.	CaO.	MgO.
I.	39·15	0·19	18·27	1·14	1·57	0·10	0·18	34·98	2·39
II.	37·90	0·26	19·47	0·40	0·21	0·91	0·73	36·06	2·17

	K_2O.	Na_2O.	F.	H_2O.	Total.
I.	0·07	0·06	1·73	0·55	100·38
II.	0·11	0·14	1·72	0·67	100·75

The idocrase from Ala contains no fluorine, whilst that from Monzoni contains 0·31 per cent., as well as traces of boric acid.

B. H. B.

Anorthite from Miyakejima, Japan. By Y. KIKUCHI (*Zeit. Kryst. Min.*, **17**, 421; from *J. Imp. Coll. of Sci.*, *Tokyo*, **2**, 31).—The volcano of the island of Miyake consists of anorthite-basalt, rendered porphyritic by crystals of anorthite, which also occur in considerable quantities loose. The angles made by the direction of extinction with the edge formed by the faces 0P and $\infty\breve{P}\infty$ is —38° to —40° on cleavage plates taken parallel to 0P, and —40° to —41° on plates parallel to $\infty\breve{P}\infty$. The mineral has a sp. gr. of 2·761, and yielded on analysis the following results:—

SiO_2.	Al_2O_3.	CaO.	MgO.	Na_2O.	H_2O.	Total.
44·03	36·80	19·29	0·20	0·23	0·12	100·67

B. H. B.

Phillipsite from Somoskö. By A. KALECSINSZKY (*Zeit. Kryst. Min.*, **17**, 521—522; from *Jahrb. kongl. ung. geol. Anstalt*, 1888, 128—131).—Well-developed, white crystals of phillipsite from cavities in the basalt of Somoskö, Nógrád Co., Hungary, gave on analysis the following results:—

SiO_2.	Al_2O_3.	CaO.	K_2O.	H_2O.	Total.	Sp. gr.
49·65	21·88	6·99	5·28	16·16	99·96	2·201

B. H. B.

Artificial Production of Rock-forming Minerals. By K. KOZIOROFFSKI (*Zeit. Kryst. Min.*, **17**, 527—528; from *Com. Univ. Warsaw*, **1**, 1—9).—The author has melted together SiO_2, Al_2O_3, $CaCO_3$, $MgCO_3$, Na_2CO_3, $FeCO_3$, Fe_2O_3, and Fe_3O_4 in various proportions at a white heat in a Siemens crucible furnace for 30 to 48 hours. A mixture, having the composition of a basalt (3 olivine, 1 augite, 3 labradorite, 0·5 Fe_3O_4), was only partially melted. The melted portion was crystalline, and consisted chiefly of polysynthetic twin-crystals of a plagioclase, probably oligoclase. Another mixture having the composition of ophite (1 anorthite and 2 augite) yielded crystals of plagioclase, spinel, and magnetite, in an amorphous glass. A mixture having the composition of a trachyte (1 andesine, 10 orthoclase, and 2 augite) yielded an amorphous-green glass. On heating this glass for 10 days, sphærolites were formed. These consisted partly of long, radiating needles of an acid felspar, and partly of minute crystals of augite. Leucite was also formed.

Fayalite crystals from a mill-cinder from an ironworks near Moscow were found to have the following composition:—

SiO_2.	FeO.	Total.
31·69	67·78	99·47

Under the microscope a number of magnetite inclusions were observed. B. H. B.

Solubility of some Substances in Sea-water. By J. THOULET (*Compt. rend.*, **110**, 652—654).—Pumice, shells, coral, and globigerinæ, in somewhat small grains, were left in contact with sea-water and distilled water for several months, the water being renewed every week. The solids were then washed with equal volumes of distilled water, dried, and weighed. The loss of weight gave the quantity which had been dissolved. The experiments were made in the dark in order to avoid the development of algæ. The solubility of the four substances in distilled water is very small, but is considerably greater than their solubility in sea-water. This difference is probably due in part to the fact that distilled water always contains carbonic acid, whereas sea-water is alkaline. C. H. B.

Organic Chemistry.

Results and Aims of Stereochemical Research. By V. MEYER (*Ber.*, **23**, 567—619).—The author first gives an historical review of the development of stereochemical or space formulæ. Although it was long tacitly understood that the four hydrogen-atoms in methane must be arranged symmetrically in space around the carbon-atom, Van't Hoff and Le Bel were the first to point out the important advantages that are derived by the adoption of the tetrahedral symbol for the carbon-atom to which the above view naturally leads. By this method they were able to explain the isomerism of a number of compounds, such as the lactic acids, the formulæ of which contain asymmetrical carbon-atoms, and therefore in space are capable of two enantiomorphic methods of representation. Geometrical isomerism is then possible amongst substances containing an asymmetrical carbon-atom, and it was likewise shown that such geometrical isomerides frequently show optical activity. A distinct connection was traced between the presence of an asymmetrical carbon-atom and the optical activity of the substance in which it occurs; so that we are now able to say that, although a substance containing an asymmetrical carbon-atom may not be optically active, the reverse is never true; and if a substance has optical properties, it will be certain to contain an asymmetrical carbon-atom. Not only so, but in the case of a number of substances containing asymmetrical carbon-atoms, and yet optically inactive, the inactivity has proved to be only apparent and due to the fact that in each case the substance in question was really a mixture of two isomerides of equal but opposite rotatory power; for instance, the propylene glycols investigated by Le Bel, mandelic acid by Lewkowitsch, and Ladenburg's inactive conine. Some facts, however, as for instance the occurrence of the two inactive hydrobenzoïns, still remain to be explained.

An explanation of the occurrence and stability of ring compounds has also been made possible by the adoption of the tetrahedral carbon-atom. As Baeyer has pointed out, the angles of a regular pentagon are very nearly equal to those which the lines representing the directions of the valencies in the tetrahedral carbon-atom make with one another; hence by joining the valencies of five such carbon-atoms, one with another, a closed ring would practically be obtained. It will be seen that the carbon-atoms in this case are assumed to lie in a plane. That in benzene (the most stable and readily formed of the ring compounds) six and not five carbon-atoms are present, is explained by the author as due to the fact that only a very slight tension would be necessary in the introduction of this additional carbon-atom, whereas the stability of the compound would be enormously increased by the symmetry thus given to the molecule. In support of this, it is pointed out that it is impossible to arrange the valencies symmetrically in a ring of only five carbon-atoms. Baeyer's assumption that in the case of the formation of double and treble linking the valencies are subject to tension, and the compounds formed in consequence unstable, is one with which the author does not agree. He points to the formation of acetylene directly from carbon and hydrogen at white heat. The instability of such compounds as the polyacetylenecarboxylic acids and diacetylene is not surprising when one remembers the remarkable constitution of these substances, and may not be due to the treble linking which they contain. It may rather be caused by a tendency for the atoms to rearrange themselves into more stable configurations, just as the unstable silver oxalate passes on explosion into silver and carbonic anhydride.

Passing on to the work of Wislicenus, the author points to the development of the view that carbon-atoms, united by a single bond, are free to rotate, and, therefore, only take up the most stable position; whereas in the case of a double bond this rotation is prevented, and the atoms compelled, in some cases, to take up positions of unstable equilibrium. On the assumption that the specific affinities of the groups united with the carbon-atoms determine the stability or instability of alternative arrangements in the latter case, the actual positions in space occupied by the above groups with relation to one another may, in some cases, be predicted. The well-known instance of fumaric and maleïc acids is here alluded to. The conversion of maleic into fumaric acid by the action of hydrobromic acid cannot, however, be explained on Wislicenus' assumption of the intermediate formation of a monobromosuccinic acid, because, as Anschütz has shown, such an acid would be a very stable compound, and would not undergo change into fumaric acid under the conditions of the above transformation. The formula given by Anschütz (Abstr., 1887, 916) for maleïc acid is, however, untenable, as it would lead to the assumption of the existence of two isomeric succinic acids, for which there is no experimental evidence, and, as far as the structure of the fumaric and maleïc acids is concerned, the views of Wislicenus must be considered correct.

Grave objections have, however, been raised to the view that carbon-atoms united by a single affinity are free to rotate, and will, therefore, only take up the most favourable position, by the work of the author and Auwers on the benzildioximes (Abstr., 1888, 597; 1889, 403, 713). Only one such compound should be known, since a benzildioxime contains no asymmetrical carbon-atom, and the carbon-atoms are only united by a single bond, and therefore should be free to rotate and to take up the one most favourable position. In spite of these facts, three isomeric benzildioximes have up to the present been discovered, and the existence of these isomerides can only be explained by assuming that in this case free rotation of the carbon-atoms about the bond of union does not take place, and that in consequence three different stable arrangements are possible corresponding with the three isomerides. The discovery of the isobenzaldoxime by Beckmann, containing the group —NH·O—, at first appeared to open out the possibility of this group being also present in the benzildioximes, and the isomerism being therefore due to differences in structure; but this has since been disproved by Auwers and Dittrich (Abstr., 1889, 1192). There is now no doubt as to the structural identity of the benzildioximes, whatever be the explanatien of their isomerism.

Goldschmidt (this vol., p. 253) considers Beckmann's benzaldoximes as identical in structure, since both combine with phenylcarbimide to form isomeric additive products. There is, however, no *a priori* reason why a substance containing the group —NH·O— should not combine with phenylcarbimide as readily as one containing the NOH-group, and therefore the above cannot be held to prove anything. The author has further evidence that Beckmann's isobenzaldoxime contains the imido-group, since the methyl salt of this compound, on treatment with hydrochloric acid, yields β-methylhydroxylamine NHMe·OH, melting at 85—90°, whereas the α-benzaldoxime yields α-methylhydroxylamine NH_2·NMe, melting at 148°.

Hantzsch and Werner (this vol., p. 348) have put forward an explanation of the occurrence of isomeric benzil mono- and dioximes which is based on the assumption that the nitrogen-atom may be represented as a tetrahedron, and that when a nitrogen-atom is united by two of its valencies to a carbon- or second nitrogen-atom, we may have cases of isomerism similar to that of fumaric and maleïc acids. The isomerism of the benzaldoximes is explained in accordance with this view, but, as above shown, the structure of these two compounds is in all probability not identical, and therefore the explanation and support it offers to the hypothesis fall to the ground. Again, all unsymmetrical oximes of the formula OH—N:CXY should exist in two isomeric forms; but this is altogether contradicted by experience. Auwers has undertaken a special investigation of the oxime $\mathrm{OH{\cdot}N{:}CPh{\cdot}C_6H_4Me}$, but without being able to detect signs of the formation of an isomeride. Whilst the oximes of benzil occur in isomeric forms, those of phenanthraquinone exhibit no isomerism, according to the author's view limited rotation being possible in the first case but not in the second, as will be seen by a comparison of the two formulæ  $\begin{matrix}\mathrm{Ph{\cdot}C{:}O}\\ |\\ \mathrm{Ph{\cdot}C{:}O}\end{matrix}$ and  $\begin{matrix}\mathrm{C_6H_4{\cdot}C{:}O}\\ |\quad\;\; |\\ \mathrm{C_6H_4{\cdot}C{:}O}\end{matrix}$. According to the views of Hantzsch and Werner, however, a corresponding number of isomerides should be obtained from each, which is not the case. Hantzsch and Werner also offer no explanation of the non-occurrence of isomerism in the dioxime derived from diacetyl, which has been explained by the author as due to the fact that whereas the C_6H_5- and NOH-group are in an equal degree negative in character, this is not the case with Me and NOH.

If the tetrahedral representation were tenable for the nitrogen-atom, we should have to assume that substituted ammonias can exist in the isomeric forms  $\mathrm{N}\begin{matrix}\diagup\mathrm{H}\\ -x\\ \diagdown b\end{matrix}$ and  $\mathrm{N}\begin{matrix}\diagup\mathrm{H}\\ -b\\ \diagdown a\end{matrix}$, but this is not so. We must therefore assume that in ammonia the hydrogen-atoms are placed symmetrically with regard to the nitrogen-atom, and this can only find expression in a plane formula. In ring compounds, such as pyridine, the valencies probably no longer lie in a plane, since they replace those of a carbon-atom; but of this little can as yet be ascertained.

In conclusion, the author touches on one or two questions connected with the possible space representation of the oxygen- and sulphur-atoms, and he urges the necessity of the employment of space formulæ and of no longer regarding the atoms as mere points without shape or dimensions. H. C.

Chemical Constitution of Carbon Compounds and the sign and variations of their Rotatory Power. By P. A. GUYE (*Compt. rend.*, 110, 714—716).

—Admitting that the valencies of carbon are directed towards the solid angles of a regular tetrahedron, and calling the six planes of symmetry which characterise the compound CR_4 the *planes of carbon symmetry*, it is evident that so long as the carbon remains symmetrical the centre of gravity of the molecule will be found in one, at least, of these planes. On the other hand, if the carbon becomes asymmetrical, the centre of gravity will be outside these planes. In the first case, the *product of asymmetry*, that is, the product of the distances of the centre of gravity of the molecule from each of the planes of symmetry, will be zero; in the second case, it will have a definite value. If the signs + and — are given to these distances, measured from one side or the other of each plane of symmetry, the *product of asymmetry* will be positive or negative, according to circumstances.

It follows that whenever the displacement of one radicle by another leaves the centre of gravity on the same side of the planes of symmetry, the rotatory power of the compound will retain the same sign; if, as a result of substitution, the centre of gravity is removed further away from the planes of symmetry, the rotatory power will be increased; if it is brought nearer to the planes, the rotatory power will be reduced; if, as a result of substitution, the centre of gravity is displaced from one side of one of the planes of symmetry to the other side, the sign of the optical rotation will be changed.

These deductions are experimentally verified in the case of amyl alcohol and amyl chloride, bromide, iodide, cyanide, and acetate; mono-, di-, and tri-amylamines and their hydrochlorides; asparagin and aspartic acid and their salts and compounds with acids; dextrotartaric acid and its derivatives, malic acid and its derivatives, and many other compounds.

The increase in rotatory power consequent on a removal of the centre of gravity further away from the planes of symmetry is well shown in the case of the ethereal salts of tartaric acid.

	Methyl.	Ethyl.	Propyl.	Isobutyl.
$[\alpha]_D =$	+2·14°	+7·66°	+12·44°	+19·87°

In dibenzoyltartaric acid the centre of gravity passes to the opposite side of the plane, cutting the edge COOH—OBz, and consequently dibenzoyltartaric acid is lævogyrate, $[\alpha] = -117\ 68°$.

The substitution of alkyl radicles for the basic hydrogen leaves the centre of gravity on the same side of that particular plane, but reduces its distance, and consequently the rotatory power of the ethereal salts diminishes as the molecular weight of the alkyl radicle increases.

	Methyl.	Ethyl.	Isobutyl.
$[\alpha]_D =$	−88·78°	−60·02°	−41·92°

Diacetyltartaric acid is lævogyrate ($[\alpha]_D = -23·14°$) for a similar reason, but in this case the introduction of a sufficiently heavy alkyl radicle carries the centre of gravity to its original side of the plane of symmetry, and the sign of rotation changes.

	Methyl.	Ethyl.	Propyl.	Isobutyl.
$[\alpha]_D =$	−14·29°	+1·02°	+6·52°	+10·29°

C. H. B.

Limitation of the free Rotation of singly bound Carbon-atoms. By C. A. Bischoff (*Ber.*, **23**, 623—630).—Assuming that by the accumulation of alkyl groups in a molecule, such as that of succinic acid, the carbon-atoms are caused to approach one another (compare this vol., p. 741), it is possible that the vibrations of some of the atomic complexes of which the molecule is composed may become limited, owing to interference with one another, and two systems which have hitherto been regarded as capable of free rotation round a common axis might, under certain conditions, have their power of rotation limited; in other words, configurations which are at present looked on as identical, because the one can be converted into the other by simple rotation, would become dissimilar, and compounds possessing these two configurations would differ from one another in properties in a manner somewhat analogous to, but probably to a smaller extent than that in which geometrically isomeric substances differ from one another.

This hypothesis is similar to that put forth by Riecke and V. Meyer, but it differs from the latter in assuming that the limitation of free rotation is brought about in the manner described above, and not by the purely chemical nature of the substituting radicles.

If energy is supplied to a system the rotation of which is supposed to be limited in this way, it may be conceived that the impact of any two groups which interfere with one another may become powerful enough to force asunder again those carbon-atoms, the mutual approach of which has led to interference; in this way the one configuration would be converted into the other.

The author names isomerism of this nature "dynamical isomerism," and explains his hypothesis with the aid of diagrams. The fact which led to the origination of this hypothesis is the formation of two ethyldimethylsuccinic acids by the hydrolysis of ethyl ethylisobutenyltricarboxylate (this vol., p. 743).

In accordance with the above theory, propyldimethyl-, isopropyldimethyl-, and benzyldimethylsuccinic acid can also exist in two dynamically isomeric forms; the results of experiments on benzyldimethylsuccinic acid are described in another paper (this vol., p. 774).

F. S. K.

Fluoroform. By MESLANS (*Compt. rend.*, **110**, 717—719).—Two parts of iodoform, two parts of silver fluoride, and one part of chloroform are mixed in a flask, which is cooled to 0° and is connected with a lead worm, kept at −23°, followed by a U-tube containing silver fluoride heated at 100°. The temperature of the flask is allowed to rise gradually, and the gas which is evolved is collected over mercury. It is purified from chloroform vapour by prolonged contact with fragments of dry caoutchouc, and from carbonic oxide by means of a solution of cuprous chloride in hydrochloric acid. The product is a colourless gas, with a pleasant odour resembling that of chloroform; it burns with difficulty with a blue flame and abundant evolution of hydrogen fluoride; it is only slightly soluble in water, chloroform, or benzene, but alcohol dissolves about five times its own volume. Its sp. gr. is 2·445, and it liquefies under a pressure of 40 atmos. at 20°; if the pressure is suddenly released, it solidifies.

This gas is *fluoroform*, CHF_3; when heated with alcoholic potash at 160°, it yields potassium formate and fluoride. Sodium heated in the gas burns brilliantly, with deposition of carbon and sodium fluoride and formation of methane.

When silver fluoride and iodoform react in absence of chloroform, much heat is developed, iodine is liberated, and a fluoriodoform is produced.

C. H. B.

Determinations of Molecular Weights of Organic Compounds by Raoult's Method. By E. PATERNO and R. NASINI (*Gazzetta*, 19, 195—209).—*Polymeric Compounds.*—Ethyl cyanate and cyanurate in a benzene solution gave results agreeing with the molecular formulæ EtCNO and $Et_3(CNO)_3$. Metacinnamene, obtained by the spontaneous polymerisation of pure cinnamene, gave in a benzene solution a result corresponding with $(C_8H_8)_3$; more concentrated solutions (3—9 per cent.) gave a value intermediate between $(C_8H_8)_4$ and $(C_8H_8)_5$.

Isomerides, &c.—Apiole and isoapiole in benzene solution both gave results agreeing with the formula $C_{12}H_{14}O_4$. Ciamician and Silber's view that these compounds are not polymerides is thus confirmed.

Urimidosuccinic Acids.—Both the lævogyrate and the inactive varieties gave in dilute aqueous solution a result corresponding with the molecular formula $C_5H_6N_2O_4$.

Benzene Hexachlorides.—The α-compound gave a normal result in acetic acid and concentrated benzene solutions; the β-compound is isomeric with it.

Diphenic Anhydride.—The numbers obtained from the acetic solution point to the formula $(C_6H_4{\cdot}CO)_2O$ as molecular, but it would appear that the anhydride is dissociated by solution in acetic acid.

Naphthalene Picrate.—Concentrated acetic solutions give approximately normal figures; dilute solutions indicate that complete dissociation into naphthalene and picric acid has taken place. Normal results were obtained from benzile, carvacrol, carvacrol hydrosulphide, and from amarine in benzene solutions, and from dimethylquinol, benzoïn, dehydracetic acid and amide, and benzimidobenzoate in acetic acid solutions. Thymoquinone and camphoric chloride gave normal results, but in the case of camphoric chloride it was apparent that some dissociation had taken place. Usnic acid, both in acid and in benzene, and anilide in a dilute benzene solution gave abnormal results, probably due to some decomposition.

Colloïdal Substances.—2 per cent. solutions of albumin and gelatin barely reduced the freezing point by 0·01°; it would therefore appear that these colloïds have an extremely complicated molecular structure. The calculations from the observed data were all made by Raoult's method.

The behaviour of paraldehyde, anethoïl, phenol, and bromoform as solvents was examined; the results obtained with paraldehyde were irregular on account of the readiness with which it undergoes partial dissociation into aldehyde; anethoïl gave more uniform results, but the experiments were discontinued on account of its peculiar behaviour; the addition of a crystal to the mass when cooled a few tenths of a degree below the freezing point induces congelation, as with other solvents, but instead of the temperature rising at once to the freezing point, it continues to descend with extreme slowness, and then returns. Bromoform could not be obtained sufficiently pure; experiments with phenol-derivatives are still in progress. The author concludes that paraldehyde and, to a lesser extent, anethoïl may be useful in special circumstances. S. B. A. A.

Products of the action of Propionitrile on Chlorides of the Fatty Acids in presence of Aluminium Chloride.—Triethyl Tricyanide. By R. OTTO and J. TRÖGER (*Ber.*, **23**, 759—768).—In a preliminary notice (Abstr., 1889, 957) the authors stated that by the action of aluminium chloride on a mixture of propionitrile and propionic chloride, propionylpropionitrile appeared to be formed, which at once took up the elements of water, forming propionylpropionamide. In the further course of the investigations, acetic chloride was substituted for propionic chloride, and the same compound obtained as before. This formation shows that the constitution previously assigned to the substance is incorrect and further investigation has shown that it is *dipropionamide*, $NH(CO{\cdot}CH_2{\cdot}CH_3)_2$. This has been confirmed by a direct comparison of the compound in question with the dipropionamide obtained by the usual reactions.

Dipropionamide crystallises in rectangular tablets or long needles which melt at 153—154°, sublime readily, and distil without decomposition at 210—220°. It is sparingly soluble in cold, readily in hot, water, and still more readily in alcohol. It is quickly converted into propionic acid and ammonia by both potassium hydroxide and dilute sulphuric acid. Its formation in the above reaction is probably due to the fact that a portion of the propionitrile is reduced to propionamide, which, by the action of the hydrochloric acid formed from the aluminium chloride, passes into dipropionamide.

Triethyl tricyanide, like the tricyanides obtained by Krafft and Hansen (Abstr., 1889, 696), has basic properties, and may be converted into a hydrochloride by passing hydrogen chloride over the fused compound. By the action of water this readily passes into ammonium chloride and propionic acid, on which account no platinochloride could be prepared. According to T. Weyl, triethyl tricyanide has a poisonous action on dogs and guinea-pigs, resembling that of certain ptomaines. H. G. C.

Molecular Weight of the solid α-Dichloropropionitrile. By R. OTTO (*Ber.*, **23**, 836—837).—The solid compound (m. p. 73—74°) obtained by the action of dry chlorine on propionitrile (*Annalen*, **116**, 195; **132**, 181) has the molecular formula $(C_3H_3Cl_2N)_3$, as is proved by molecular weight determinations by Raoult's method in glacial acetic acid solution. F. S. K.

Coloration of Organic Substances by Thiocyanic Acid. By C. PARENTI (*Gazzetta*, **19**, 175—179).—The reddish coloration which thiocyanic acid imparts to animal and vegetable tissues is generally held to be due to the presence of minute traces of iron; this is denied by Miguel (Abstr., 1877, 457), who found that paper presumably free from iron acquired a red coloration on exposure to the vapour of thiocyanic acid, although it was not coloured by the aqueous acid. The author has repeated this experiment, and finds that paper in which no iron can be detected by analysis exhibits the phenomena described by Miguel, but if it is previously digested for several days in pure dilute hydrochloric acid, then thoroughly washed and dried, it is no longer affected by the acid. On the other hand, if the purified paper or cotton cloth is wetted with water to which one drop of an extremely dilute solution of ferric chloride has been added, and dried, it regains its original character. It follows that the coloration is due to the presence of traces of iron, which are so small that they are only detected by the extremely delicate action of the fumes of thiocyanic acid. The coloration is not affected by anhydrous ether, absolute alcohol, benzene, carbon bisulphide, or chloroform, but it is destroyed by excess of water; a drop of a mixture of ether or alcohol and water leaves a stain, which, on drying, becomes first green and then white. This reaction is so delicate that it may be used as a test for the presence of water in ether or absolute alcohol; in the last case the test must be made in a closed vessel, as absolute alcohol abstracts sufficient moisture from the air to give the green stain.

Miguel's distinction between the red coloration given to paper imbued with ferric chloride by fumes of thiocyanic acid and the yellowish-red coloration given by the aqueous acid is due to the action of the liberated hydrochloric acid, which, in presence of water, facilitates the decomposition of thiocyanic acid into perthiodicyanic acid.

S. B. A. A.

Purification of Alcohol. By E. WALLER (*Chem. News*, **61**, 53—54).—The alcohol is agitated with powdered potassium permanganate until distinctly coloured, and after some hours treated with a pinch of pulverised calcium carbonate. It is then carefully distilled, but not to dryness, and is collected for use when the distillate ceases to give a yellow coloration with strong potash or soda within 20 or 30 minutes.

D. A. L.

Etherification by Uranium Salts. By O. POHL (*Listy Chem.*, **14**, 104—105).—On pouring amyl alcohol over uranium nitrate, the latter is decomposed by the action of light, and, at the ordinary temperature, valeraldehyde, free valeric acid, amyl valerate, and amyl nitrate, together with some reduction products containing oxides of uranium, are formed. The same kind of reaction takes place with methyl and ethyl alcohols. Amyl nitrate, after exposure to light, yields after some time ethereal salts of valeric acid, having a very agreeable odour. On pouring ethyl alcohol over uranium acetate, acetaldehyde, acetic acid, and ethyl acetate are formed. Uranium acetate, treated in the same manner with amyl alcohol, yields amyl acetate and ethyl valerate.

B. B.

Action of Chlorine on Tetramethylethylene. By A. CHOUPOTSKY and N. MARIUTZA (*J. Russ. Chem. Soc.*, **21**, 431—434).—Tetramethylethylene was obtained by synthesis from isobutyric chloride and zinc methyl. This hydrocarbon, when subjected to the action of chlorine at the ordinary temperature, yielded the monochlorotetramethylethylene, $C_6H_{11}Cl$, which was purified by fractional distillation. On heating it with water in sealed tubes, it was found that it gradually disappeared, and at last *dimethyl isopropenyl carbinol*, $C_6H_{12}O$, was obtained as an aromatic liquid of sp. gr. 0·8560 (at 0°), and 0·8416 (at 19·5°). It boils at 117·5—118°, and yields an acetate and a dibromide. Etherification with acetic acid (Menshutkin's method) confirms the view that it is a tertiary alcohol, $CMe_2(OH)\cdot CMe{:}CH_2$.

B. B.

Action of Acids on Dimethyl Isopropenyl Carbinol. By N. Mariutza (*J. Russ. Chem. Soc.*, 21, 434—436).—Dimethyl isopropenyl carbinol (see foregoing abstract) was subjected to the action of sulphuric and hydrochloric acids. When it was heated at 100° with dilute sulphuric acid (containing 1 per cent. or more), the product was a viscid oil, boiling above 100°, seemingly the product of condensation of a hydrocarbon formed by the action of very dilute acids.

After heating for 20 to 30 minutes in a water-bath with hydrochloric acid of 0·1 per cent., a very mobile liquid hydrocarbon, boiling at 68—69°, was obtained. It yields two additive products with bromine, the lower one containing less bromine being formed at a low temperature, the higher one after a longer time, or on gently warming; the latter has the formula $C_6H_{10}Br_4$. The hydrocarbon is C_6H_{10}, and as it is produced by the removal of one molecule of water from an alcohol of the above constitution, its formula can be only $CH_2{:}CMe\cdot CMe{:}CH_2$, *diisopropenyl*. B. B.

Derivatives of Heptamethylene. By Markownikoff (*Compt. rend.*, 110, 466—468).—Suberone, contrary to the statement of Spiegel, is easily reduced to the corresponding alcohol, $C_7H_{13}\cdot OH$, by the action of sodium in presence of alcohol. This *suberonyl alcohol* is a colourless, somewhat viscid liquid, with a mouldy odour different from that of suberone. It is insoluble in water, and boils at 184—185° under a pressure of 741 mm.; sp. gr. at 15° compared with water at the same temperature = 0·9595. It combines easily with phenylcarbimide to form *suberonyl phenylcarbamate*, $NHPh\cdot CO\cdot OC_7H_{13}$, which crystallises in long, colourless, quadrangular prisms melting at 85°.

Concentrated hydrochloric and hydriodic acids dissolve suberonyl alcohol, and if the solution is heated for some time and then diluted with water, suberonyl chloride or suberonyl iodide is precipitated. The former is lighter than water, and distils without decomposition; the latter is heavier than water, and decomposes when distilled.

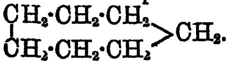
Suberonyl iodide, when treated with alcoholic potash, yields *suberonylene*, C_7H_{12}, which has a strong odour, boils at 114·5°, and combines energetically with bromine to form a heavy liquid with an odour of terebenthene. A small quantity of suberonyl ethyl ether, $C_7H_{13}\cdot OEt$, is formed in the same reaction.

When suberonyl alcohol is heated at 230—250° with 7 vols. of hydriodic acid of sp. gr. 1·96, it yields *heptamethylene*, C_7H_{14}, which boils at 98—101°; sp. gr. at 0° = 0 7791. It is a colourless liquid with a feeble odour similar to that of pure benzene. It is not attacked by bromine in the cold, and is only slowly dissolved by sulphuric or nitric acid, or a mixture of the two. The hydrocarbons C_8H_{16} and C_9H_{18}, with the nucleus C_6H_{12}, readily combine with bromine in presence of traces of aluminium bromide. The boiling point and specific gravity of heptamethylene are almost identical with those of heptanaphthene (100—101° and 0·7788).

Suberoxime dissolves in hydrochloric acid, and is reprecipitated by an alkali, but redissolves in excess. It is easily reduced by sodium in alcoholic solution, and yields *amidoheptamethylene*, a viscid liquid with a strong odour resembling that of the volatile alkaloids.

Suberone when reduced yields, in addition to the alcohol, a liquid of high boiling point. which is probably the corresponding pinacone.

These compounds are all regarded as derivatives of heptamethylene,



$$\begin{matrix} CH_2{\cdot}CH_2{\cdot}CH_2 \\ | \\ CH_2{\cdot}CH_2{\cdot}CH_2 \end{matrix}\!\!>CH_2.$$

C. H. B.

Pentatomic Alcohol and an Unsaturated Glycerol from Diallyl Carbinol. By W. DOUBINEVITCH (*J. Russ. Chem. Soc.*, 21, 467—474).—The preparation of a pentatomic alcohol was attempted in vain by Saytzeff, by Dieff, and lastly by Reformatsky (see this vol., p. 353). Diallyl carbinol was suspended in water in a flask, and treated, with constant agitation, with a 1 per cent. solution of potassium permanganate. In order to prevent the decomposition of the products of reaction which takes place when the solution is heated, magnesium sulphate was added, and the neutral volatile products, consisting chiefly of unchanged diallyl carbinol, were distilled off. From the residue, manganese dioxide was separated by filtration, and the filtrate evaporated to dryness at 40—50°. The residue was then treated with alcohol of 96 per cent., and after the alcohol had been distilled off, the residue was extracted with ether containing 5 per cent. of alcohol, and the solution filtered. At last, after extracting the residue with pure ether forty times, and evaporating the ethereal solution, a thick, nearly colourless, extremely bitter liquid was obtained, soluble in water and alcohol, but only sparingly in ether. It boils at 203—204° under a pressure of 37 mm., and has a sp. gr. of 1·0923 at 17·5°. Its composition corresponds with the formula $C_7H_{11}(OH)_3$. With bromine, it yields a very unstable additive product, $C_7H_{14}O_3Br_2$, and the glycerol, on being treated with acetic anhydride at 165°, yields an acetate, $C_7H_{11}O_3Ac_3$, of sp. gr. 1·0862 at 0°. The above residue, after extraction of this trihydric glycerol with ether, was dissolved in water, acidified with 10 per cent. sulphuric acid, and repeatedly shaken with ether in order to remove organic acids; these were found to consist chiefly of formic acid; no other organic acids were isolated. After this, the sulphuric acid solution was neutralised with potash, and treated with a large amount of alcohol, in order to precipitate potassium and magnesium sulphates, and the filtrate after evaporation was again treated in the same way. From this solution, a thick, oily liquid was precipitated on adding ether; this was dissolved in alcohol, neutralised with alcoholic potash, the potassium salts removed by filtration, and finally the alcoholic solution was fractionally precipitated by ether. All the fractions were found to be homogeneous, and only the first contained a trace of mineral salts. After drying, the *pentatomic alcohol*, $C_7H_{11}(OH)_5$, was obtained as a viscous mass of an agreeably sweet taste, closely resembling that of glucose. It could not be obtained in the crystalline state. It is soluble in water and alcohol, but quite insoluble in ether, differing in this respect from its first anhydride obtained by Dieff (*loc. cit.*). On heating it at 170°

with acetic anhydride and some acetic acid, used as a solvent, the *pentacetate*, $C_7H_{11}O_5Ac_5$, was obtained as a thick liquid, almost insoluble in water. The pentabenzoate could not be obtained in the pure state. The oxidation of diallyl carbinol takes place in two phases: at first only one double link of the carbinol is attacked, and the triatomic alcohol, $OH\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot CH{:}CH_2$, is formed; then the elements of hydrogen dioxide are again taken up with the production of the pentatomic alcohol,

$$OH\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot CH(OH)\cdot CH_2\cdot OH.$$

The author proposes to investigate the process of dehydration of the pentatomic alcohol in order to ascertain why in Reformatsky's and Saytzeff's experiments its first anhydride was obtained instead of it.

B. B.

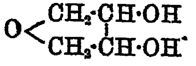
Derivatives of Erythrol. By E. GRIMAUX and C. CLOEZ (*Compt. rend.*, **110**, 462—465).—Hydrofurfurane bromide, obtained by Henninger's method, was heated in sealed tubes with fuming hydrobromic acid at 110° for six hours. The solid product is erythrene tetrabromide, and may be recrystallised from alcohol.

Erythrane, prepared by Henninger's method, yields hydrofurfurane when heated with 2·5 parts of glacial formic acid. This result shows that hydrofurfurane is not derived from erythrene, but from its anhydride erythrane, which behaves as a dihydric alcohol.

If bromine dissolved in chloroform is added to a chloroform solution of erythrol, and the mixture is allowed to evaporate spontaneously, erythrol bromide, $CH_2Br\cdot CHBr\cdot CH(OH)\cdot CH_2\cdot OH$, is obtained in hard, bulky, hexagonal tables which melt at 81—82° and are very soluble in alcohol, ether, and chloroform.

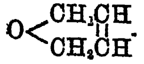
Another bromhydrin was obtained by Champion, by the action of hydrobromic acid on erythrol. The authors obtained the same compound, $CH_2Br\cdot CH(OH)\cdot CH(OH)\cdot CH_2Br$, by heating erythrol with ten times its weight of fuming hydrobromic acid at 100° for 120 hours, or at 120° for 18 hours. It crystallises from chloroform in small, nacreous tables which melt at 135°. Erythrene tetrabromide melting at 114° is also formed at the same time.

From these results the authors conclude that the compounds obtained by the reduction of erythrol have the following constitutions:—



$$O<\begin{array}{l}CH_2\cdot CH\cdot OH\\ \phantom{CH_2\cdot{}}|\\ CH_2\cdot CH\cdot OH\end{array}.$$

Erythrane.



$$O<\begin{array}{l}CH_2\cdot CH\\ \phantom{CH_2\cdot{}}\|\\ CH_2\cdot CH\end{array}.$$

Hydrofurfurane.

$CH_2{:}CH\cdot CH(OH)\cdot CH_2\cdot OH.$

Dehydr-erythrol.

$CH_2{:}CH\cdot CH{:}CH_2.$

Erythrene.

C. H. B.

Benzoic Acetals of Sorbite. By J. MEUNIER (*Compt. rend.*, **110**, 577—580).—The monobenzoic acetal, or *monobenzylal sorbite*, $C_6H_{12}O_6Bz$, is obtained by mixing a solution of sorbite in its own weight of water with the requisite volume of benzaldehyde, and one-tenth its volume of hydrochloric acid of 22° B. A large proportion crystallises from the liquid and a further quantity is obtained by neutralising the mother-liquor with sodium carbonate. It is purified by recrystallisation from warm alcohol or warm water. It crystallises from water in transparent, highly refractive, rectangular prisms, which melt without decomposition at 163—164° if heated slowly, or at 172—175° if heated rapidly. From alcohol, in which it is less soluble than in water, it separates in smaller crystals. When boiled with very dilute acids, the acetal is decomposed with liberation of benzaldehyde.

Dibenzylal sorbite, $C_6H_{12}O_6Bz_2$, is obtained by mixing a concentrated solution of sorbite with its own volume of hydrochloric or sulphuric acid, and adding benzaldehyde. A white, amorphous solid, insoluble in water, is obtained and was previously described as the dibenzoic acetal (Abstr., 1889, 479). It is, however, a mixture of two substances, one of which dissolves in 1000 parts of boiling water and gelatinises on cooling, whilst the other is quite insoluble in hot water and has exactly the composition of dibenzylal sorbite.

The dibenzoic derivative melts at 162°, is insoluble in water containing sulphuric acid, and is not decomposed when boiled with it.

The product which dissolves in hot water, on the other hand, is completely decomposed in presence of minute quantities of hydrochloric and sulphuric acids. The gelatinised mass can be freed from water by filtration and pressure. The product melts at about 200°, but has no definite melting point; dissolves in acetic acid, benzene, chloroform, and especially ether, from which it gelatinises; and contains about 2 per cent. less carbon than dibenzylal sorbite.

C. H. B.

Formation of Volatile Fatty Acids from Dextrose. By O. Loew (*Ber.*, **23**, 865—866).—When air-dried platinum-black, prepared by the method lately described (this vol., p. 453), is placed in dilute solutions of dextrose, a rancid odour soon becomes noticeable and increases in intensity for two days; on warming the fresh mixture at 60—70°, the smell is stronger and becomes noticeable even more quickly. This action takes place even in presence of an antiseptic such as benzoic acid, so that it cannot be due to a ferment.

Levulose and lactic acid do not behave like dextrose in this respect; the slight odour observed resembles rather that of formic acid.

No odour is observed when freshly prepared platinum-black which has not been exposed to the air, or when platinum-black which has been used before is employed; the smell is observed, however, when this inactive black is treated with hydrogen peroxide, or dried in the air and then placed in the solution of dextrose. If the dextrose solution is boiled with the active black and a little calcium carbonate, the concentrated, filtered solution gives off no rancid odour on treatment with sulphuric acid, probably because the occluded oxygen is so quickly used up in converting the dextrose into gluconic acid, or some similar compound, that the other reaction cannot take place.

When cane-sugar is treated with active platinum-black, the rancid odour is not observed, but inverted sugar yields traces of formic acid, and a disagreeably smelling acid which, from an analysis of its silver salt. is probably valeric acid, although it may be a mixture of several acids. F. S. K.

Action of Ethyl Acetoacetate on Dextrose in presence of Alcoholic Ammonia. By P. BIGINELLI (*Gazzetta*, 19, 215—217). —When a solution of dextrose (10 grams) in 75 per cent. alcohol (35 grams), ethyl acetoacetate (15 grams), and a solution of ammonia (1 gram) in 94 per cent. alcohol are mixed and left for one or two days, a granular deposit is formed consisting of a mixture of dextrose and a compound of dextrose and ammonia; later on, another substance separates, which after repeated crystallisation may be obtained in silky, white needles; these melt at 189—190°, and have the composition, $C_{16}H_{20}O_8N$. This substance dissolves sparingly in cold water and in alcohol, and is almost insoluble in ether and chloroform; it has a feeble reducing action on Fehling's solution. Both the aqueous and alcoholic solutions have a neutral reaction; the former is coloured red by a solution of ferric chloride. It dissolves in acids, and in both aqueous and alcoholic potash. When suspended in alcohol, it is not affected by a current of nitrous acid.

If the mixture of dextrose, &c., mentioned above is heated in closed tubes at 100—110°, groups of acicular crystal, are formed which melt at 130—131°, and have the composition $C_{10}H_{16}NO_5$.

This preliminary note is published by the author in order to reserve the right of further investigation in this field. S. B. A. A.

Pentacetyllevulose. By E. ERWIG and W. KOENIGS (*Ber.*, 23, 672—675; compare Abstr., 1889, 952, 1431).—*Pentacetyllevulose*, $C_6H_7O(OAc)_5$, can be prepared by dissolving levulose (3 grams) in warm glacial acetic acid (3 c.c.), gradually adding the solution to almost boiling acetic anhydride (9 c.c.) containing 0·1 to 0·2 gram of zinc chloride, and then boiling for five minutes to complete the reaction. The yield is about 66 per cent. of the levulose employed. It is a soft, colourless, hygroscopic resin, readily soluble in alcohol, ether, chloroform, benzene, and glacial acetic acid, but only sparingly in light petroleum and carbon bisulphide; it is soluble in, and partially decomposed by boiling water, and its solution in chloroform is feebly dextro-rotatory. When boiled for two hours with decinormal sulphuric acid diluted with an equal volume of water, it is completely decomposed, levulose being regenerated. It reduces Fehling's solution on boiling, and is completely decomposed when boiled with potassium dichromate and glacial acetic acid. It does not combine with phenylhydrazine. F. S. K.

Extraction of Raffinose from Molasses: Separation of Raffinose from Saccharose. By L. LINDET (*Compt. rend.*, 110, 795—798).—The molasses is diluted with five or six times its weight of cold water and agitated with mercuric sulphate, which precipitates the impurities The liquid is filtered, treated with bartyta to neutralise the sulphuric acid resulting from the decomposition of the mercuric sulphate, boiled, and concentrated in a vacuum. The syrup is dissolved in methyl alcohol, which precipitates a further quantity of impurities.

One hundred parts of methyl alcohol dissolve 9·5 parts of raffinose and 0·4 part of saccharose. The solubility of saccharose increases as the alcohol is more and more hydrated. One hundred parts of ethyl alcohol of 95° dissolve only six parts of raffinose. The solubility of saccharose in ethyl alcohol increases with the degree of hydration, but that of raffinose remains almost constant. The following table gives the quantities of raffinose and saccharose dissolved by 100 parts of alcohol of different strengths:—

	95°.	90°.	83°.	80°.
Saccharose	0·30	1·00	2·23	6·20
Raffinose	0·06	0·08	0·10	0·21

The methyl alcohol solution of the syrup is dehydrated at its boiling point by means of lime, the raffinose is precipitated by the addition of ordinary alcohol, and the product is recrystallised from ethyl alcohol of 80—85°. C. H. B.

Melezitose. By A. ALECHIN (*J. Russ. Chem. Soc.*, 21, 407—421).—Berthelot and Villiers have studied this carbohydrate and attributed to it the formula $C_{12}H_{22}O_{11} + H_2O$. The author has prepared melezitose from Persian manna, called terenjabin, a product of *Alhagi Maurorum* (D.C.) Terenjabin containing about 38 per cent. of melezitose was dissolved in 4 parts of warm water and the impurities removed by decantation. The clear solution was then evaporated to half its bulk on a water-bath and allowed to remain for 3 to 4 days, when the melezitose separates out completely in the crystalline state. It was purified by dissolving it in hot water, adding an equal volume of strong alcohol, and filtering the boiling solution; on cooling, the melezitose separates and is again recrystallised. The formula of the crystals, which are rhombic prisms, is $C_{18}H_{32}O_{16} + 2H_2O$; they become opaque on exposure to the air and lose their water at 110°; when anhydrous, they melt at 147—148°. Anhydrous melezitose is also obtained by precipitating the hot aqueous solution with strong alcohol. Its sp. gr. at 17°/4° is 1·540. It is less soluble in water than saccharose, 100 parts at 17° containing 26·8 parts of anhydrous melezitose, and 75 6 parts at 100°. The spec. rotatory power of the anhydrous melezitose $[\alpha]_D = + 87·72° + 0 074p$, that of the hydrated compound $[\alpha]_D = +83° + 0·07014p$ (p = percentage in 100 parts of the solution). For an imaginary 100 per cent. solution $[\alpha]_D = + 95° 12'$. Melezitose, on inversion with dilute mineral acids, yields at first *turanose* and dextrose; the former is a new saccharose of the formula $C_{12}H_{22}O_{11}$ with $[\alpha]_D = + 65°$ to 68°; it is insoluble in alcohol, by which it is separated from its solution, and melts at 65—70°. On long continued action of the acid, dextrose alone is obtained. Pure melezitose does not itself ferment when submitted to the action of ferments or diastase, but only the products of its inversion. The phenylhydrazine-derivative of melezitose is an unstable compound melting at 172°. The acetyl-derivative, $C_{18}H_{21}O_{16}Ac_{11}$, forms rhombic prisms of sp. gr. =

1·32 at 0°/4°, melting at 117° with $\alpha[\text{D}] = +110·44°$. Several determinations of the molecular weight of melezitose by Raoult's method confirm the formula $C_{18}H_{32}O_{16} + 2H_2O$; by the same method the molecular formula of the undecacetyl-derivative is confirmed, but for the new "turanose" results were obtained corresponding with the formula $C_6H_{12}O_6$, although its sodium-derivative is $C_{12}H_{21}O_{11}Na$.

B. B.

Callose, a new Fundamental Substance in Vegetable Membrane. By L. Mangin (*Compt. rend.*, 110, 644—647).—Callose occurs in various organs of a very large number of plants and is especially important in the thallophytes, but was not found in certain Uredineæ. Its existence is often difficult to prove owing to its admixture with other substances and its resistance to the action of solvents.

The callose was not isolated sufficiently pure for analysis. It is distinguished from cellulose by its insolubility in Schweizer's reagent even after the action of acids, and by the yellow coloration which it gives with iodophosphoric acid. From pectic compounds, it is distinguished by its insolubility in ammonia, and alkaline carbonates in the cold, and its different behaviour with colouring matters. It is colourless, amorphous, insoluble in water and alcohol, but dissolves readily in sodium or potassium hydroxide of 1 per cent., and is also soluble in concentrated sulphuric acid and concentrated solutions of calcium chloride and stannous chloride. It does not dissolve in cold solutions of alkaline carbonates or ammonia, but swells up and gelatinises. With various staining fluids, callose gives reactions which serve to distinguish it from other substances in the vegetable membrane. With iodine it acquires a yellow coloration. C. H. B.

Preparation of Hydrazine from Aldehyde-ammonia. By T. Curtius and R. Jay (*Ber.*, 23, 740—752).—It has previously been observed by Curtius (*Diazoverb. der Fettreihe*, Munich, 1886) that aldehyde-ammonia, when treated with nitrous acid in acid solution, yields an oily nitrosamine, which is volatile in a current of steam and may be distilled in a vacuum without decomposition. From the analysis and vapour-density of the substance, the conclusion was drawn that it contained 3 mols. of aldehyde and 2 atoms of nitrogen. The condensation of 3 mols. of ethyl diazoacetate to form triazoacetic acid, investigated by the authors (Abstr., 1889, 393), has led them to examine this nitrosamine further, in the hope of obtaining hydrazine from it more readily than by the previous methods. They find that hydrazine can be formed in the manner shown below, but the yield is so small that this reaction cannot be employed as a method for its preparation.

When a solution of sodium nitrite is added to a well-cooled solution of aldehyde-ammonia in dilute sulphuric acid, the nitrosamine separates and may be extracted with ether, the aqueous solution being then several times treated with small quantities of sodium nitrite and sulphuric acid, and extracted after each treatment with ether. The combined extracts are shaken with a solution of sodium carbonate and with water, and finally with solid potassium carbonate, the ether evaporated, and the residual oil distilled in a current of steam. The oil thus obtained, on analysis, gave numbers agreeing with the formula $C_7H_{12}N_2O_3$, which was confirmed by a determination of its vapour-density. It is a lemon-yellow liquid, which has a camphor-like odour, and boils at 95° under 35 mm. pressure without decomposition. It is insoluble in water, but miscible with alcohol, ether, chloroform, and benzene. It gives Liebermann's reaction for nitroso-compounds, and is converted by hot dilute sulphuric acid into paraldehyde, and must therefore be a nitroso-derivative of an imido-paraldehyde or *paraldimine*, its constitution being represented by the formula

$$C_5H_{11}O_2\cdot CH\colon N\cdot NO.$$

When hydrogen chloride is passed into a moist ethereal solution of nitrosoparaldimine, a white, crystalline precipitate of *paraldimine hydrochloride*, $C_5H_{11}O_2\cdot CH\colon NH,HCl$, separates; this crystallises in small, anisotropic, colourless needles, which are unaltered in dry air, and blacken on heating. On remaining in moist air, they pass without change of form into ammonium chloride. They are insoluble in ether, chloroform, and benzene, but are readily taken up by water and absolute alcohol, which at once convert them into paraldehyde and ammonium chloride; this decomposition is brought about still more readily by the action of acids. Nitrous acid converts it into a nitrosamine identical with the compound obtained from aldehyde-ammonia.

By the action of silver oxide on paraldimine hydrochloride suspended in dry ether, free *paraldimine*, $C_5H_{11}O_2\cdot CH\colon NH$, is obtained as a mobile, colourless liquid boiling at 140° almost without decomposition, and solidifying in a freezing mixture. Its vapour-density was found to be 4·451, corresponding with a molecular weight of 128·5. On remaining in a sealed tube for a few weeks, it passes into a solid, glassy mass, which has the same percentage composition. The liquid readily loses ammonia in presence of water or alcohol, forming paraldehyde.

Amidoparaldimine or *paraldylhydrazine*, $C_5H_{11}O_2\cdot CH\colon N\cdot NH_2$, is prepared by treating an ethereal solution of nitrosoparaldimine with zinc-dust and acetic acid. After the addition of alkali, the solution is extracted with ether, the ethereal extract dried over barium oxide, and evaporated in a vacuum. The free base is not volatile without decomposition, and could not be obtained pure. When hydrogen chloride is passed through the dry ethereal solution, the *hydrochloride* separates in needles, which are exceptionally hygroscopic. Both of these compounds are decomposed by boiling dilute sulphuric acid, with formation of hydrazine sulphate, but, as already mentioned, the yield is very small. It may also be obtained directly from nitrosoparaldimine by treating the latter with dilute sulphuric acid and zinc-dust until the oil has disappeared, quickly filtering, and boiling vigorously for a few minutes.

The small yield of hydrazine obtained is probably due to the fact that in the reduction of the nitroso-compound the reaction does not stop with the formation of paraldimine, but goes further with formation of the compound $C_5H_{11}O_2\cdot CH_2\cdot NH\cdot NH_2$, and that this compound, like diethylhydrazine, does not lose the hydrazine-group by the action of acids. H. G. C.

Constitution of Citrazinamide. By S. Ruhemann (*Ber.*, **23**, 831—832).—A reply to Lovén (*Ber.*, **22**, 3053), defending the formula proposed by the author for citrazinamide.

Chlor- and Hydroxy-acids of the Fatty Series. By P. Melikoff and Petrenko-Krittchenko (*J. Russ. Chem. Soc.*, **21**, 393—397).—The authors have studied the behaviour of α-hydroxy-β-halogen-lactic acids and the corresponding butyric acids on distillation with water, and show that carbonic anhydride, hydrogen chloride, and an aldehyde or ketone containing one atom of carbon less than the original acid are obtained. The sodium salt of the first acid yields acetaldehyde, that of the second, propaldehyde. Chlorhydroxyisobutyric acid, under the same conditions, yields dimethyl ketone, and it is therefore a β-halogen-α-hydroxy-acid. The same is the case as regards the chlorhydroxyvaleric acid, melting at 75°, obtained from tiglic and hydrochloric acids, as it yields ethyl methyl ketone. The formation of ethyl methyl ketone confirms the generally adopted formula of tiglic acid, $CHMe{:}CMe{\cdot}COOH$. B. B.

Action of Methyl Diazoacetate on the Ethereal Salts of Unsaturated Acids. By E. Buchner (*Ber.*, **23**, 701—707).—Methyl diazoacetate combines with methyl acrylate in the same manner as with methyl fumarate and cinnamate (Abstr., 1888, 1274), forming a well-crystallised additive compound, $C_3H_4N_2(COOMe)_2$, which, on heating for 40 minutes at 160—185°, loses all its nitrogen and yields an oil boiling between 205° and 215° (718 mm.) and having the composition $C_7H_{10}O_4$. The vapour-density of 155 agrees with this formula, but the further examination showed that the oil is a mixture of the methyl salts of two isomeric acids which may be separated by their different solubilities in water or ether. The acid which is less soluble in water crystallises from that liquid in compact forms, probably belonging to the rhombic system, melts at 175°, and distils without decomposition. It has the composition $C_5H_6O_4$, and is not acted on by alkaline potassium permanganate and sodium amalgam, and appears, therefore, to be a *trimethylenedicarboxylic acid*, in which, from its mode of formation, the carboxyl-groups must be attached to different carbon-atoms. A trimethylenedicarboxylic acid (1·2) has been previously prepared by Conrad and Guthzeit (Abstr., 1884, 992), but as this melts at 139°, and readily passes into the anhydride on distillation, it cannot be identical with the acid above described. This has also been confirmed by a direct comparison of the two acids. The author has also shown that Conrad and Guthzeit's acid is unacted on by alkaline potassium permanganate or sodium amalgam, and has confirmed the similar results obtained by Fittig and Roeder (*Annalen*, **227**, 18) and by W. H. Perkin, jun. (Trans., 1885, 812) for trimethylenedicarboxylic acid (1·1).

The existence of two trimethylenedicarboxylic acids (1·2) can readily be explained by Baeyer's extension of Van't Hoff's hypothesis to compounds having a closed chain of atoms (Abstr., 1888, 1071). Two forms should theoretically exist, in one of which (the Γ-*cis* or maleïnoid form) the carboxyl-groups lie on the same side of the ring, whilst in the other (the Γ-*cistrans* or fumaroid form) they lie on opposite sides. As Conrad and Guthzeit's acid readily yields an anhydride, it probably represents the Γ-*cis* modification, whilst the acid described in this paper, which at most forms an anhydride only with difficulty, must be the Γ-*cistrans* acid.

The latter may also be crystallised from ether, from which it separates in white aggregates of needles, the aqueous solution of which gives a slight brown coloration with ferric chloride. The *zinc* salt is much more readily soluble in cold than in hot water, and on heating the solution separates in nodular aggregates of microscopic crystals. The *silver* salt is sparingly soluble even in boiling water; on heating, it yields a colourless, crystalline sublimate, possibly consisting of the anhydride.

The second acid, which is more soluble in water than the foregoing, but less soluble in ether, forms fascicular groups of seemingly monoclinic needles, and melts at 138°. On boiling it with acetic chloride, it yields an anhydride which melts at 86—87°, and decomposes completely at 130°. The *zinc* salt, like that of the foregoing acid, is less soluble in hot than in cold water, whilst the *lead* and *silver* salts form crystalline precipitates. The acid reduces alkaline potassium permanganate immediately, and on reduction with sodium amalgam yields glutaric acid, which was identified by its analysis, melting point, and characteristic zinc salt. The acid under discussion must therefore be a *glutaconic acid*, and is probably identical with the one described by Conrad and Guthzeit as melting at 132—133°. H. G. C.

Molecular Weights of some Acids of the Oleïc Series. By O. Šůlc (*Listy Chem.*, **13**, 201—203).—The author finds that the lowering of the freezing point, as obtained by Raoult's method, for crotonic, chlorocrotonic, and chlorisocrotonic acids, in acetic acid solution, corresponds with a simple molecule. An aqueous solution of crotonic acid indicates again a simple molecule, whereas a solution of the same acid in benzene points to a double molecular weight, $(C_4H_6O_2)_2$. B. B.

Acids Poor in Carbon obtained from Baku Petroleum. By O. Aschan (*Ber.*, **23**, 867—875).—The alkaline solution obtained as a bye-product in the purification of Baku petroleum contains water, hydrocarbons, and a mixture of various acids; when the crude acid mixture (100 kilos.) obtained therefrom is distilled, a small portion passes over between 220° and 270°. This fraction can be freed from hydrocarbons by dissolving it in 5 per cent. soda, acidifying the clear solution with dilute sulphuric acid, and extracting the precipitated oils with ether; the yield of this product is about 6 kilos.

Methyl hexamethylenecarboxylate, $C_6H_{11}\cdot COOMe$, can be prepared from this mixture of acids by treating it with methyl alcohol and concentrated sulphuric acid, and repeatedly fractionating the methyl salts thus produced; in this way 105 grams of the pure methyl salt was obtained. It is a colourless oil of sp. gr. 0·90547 at 18·4°, boils at 165·5—167·5° corr. (thermometer entirely in the vapour), and has an agreeable, fruity odour, which is, however, at the same time, somewhat nauseous. The free *acid*, $C_6H_{11}\cdot COOH$, obtained by hydrolysing the methyl salt with alcoholic potash, is a thick, colourless, disagreeably smelling oil of sp. gr. 0·95025 at 18·4°. It is not acted on by bromine at the ordinary temperature, but, on heating, evolution of hydrogen bromide commences; it is only slowly oxidised by nitric acid of sp. gr. 1·3, and very slowly by potassium permanganate in cold sodium carbonate solution. It decomposes calcium chloride with evolution of hydrochloric acid, and its barium and calcium salts are not decomposed by carbonic anhydride. It dissolves freely in concentrated sulphuric acid, but, on warming, decomposition sets in: it is gradually decomposed by phosphoric anhydride at the ordinary temperature. The *potassium* salt, $C_6H_{11}\cdot COOK$, is very readily soluble in water and alcohol, and is very hygroscopic. The *sodium* salt, $C_6H_{11}\cdot COONa$, separates from alcohol in ill-defined, hygroscopic prisms. The *calcium* salt, $(C_6H_{11}\cdot COO)_2Ca + 4H_2O$, separates in needles when its aqueous solution is evaporated over sulphuric acid; it loses its water completely on exposure to the air and is readily soluble in water and alcohol. When a concentrated aqueous solution is heated, the salt separates as a semi-solid, amorphous mass which becomes hard and granular when dried. The *barium* salt, $(C_6H_{11}\cdot COO)_2Ba$, is very readily soluble in alcohol, but more sparingly in water. When the acid is dissolved in baryta-water, the excess of barium hydrate precipitated with carbonic anhydride, and the filtered solution concentrated on the water-bath, it solidifies to a mass of anhydrous plates, which retain their crystalline form if they are quickly separated from the mother liquors; if, however, the crystals are allowed to remain in the solution, they deliquesce to a syrup on cooling, and on drying there remains a vitreous, amorphous mass which becomes crystalline when heated on the water-bath; the amorphous salt is also formed when aqueous solutions are evaporated at the ordinary temperature. The *silver* salt, $C_6H_{11}\cdot COOAg$, is moderately easily soluble in hot water. The *cadmium* salt, $(C_6H_{11}\cdot COO)_2Cd$, crystallises in anhydrous, nacreous plates, and is only sparingly soluble in cold water. The *chloride*, $C_6H_{11}\cdot COCl$, prepared by treating the acid with phosphoric chloride, boils at 167—169°, and is only very slowly decomposed by water. The *amide*, $C_6H_{11}\cdot CONH_2$, obtained by treating the chloride with dry ammonium carbonate, crystallises from water in nacreous plates, melts at 123·5°, and is moderately easily soluble in water and very readily in the other ordinary solvents; it dissolves freely in concentrated sulphuric acid, but is reprecipitated in crystals on the addition of water. The *anilide*, prepared from the chloride, separates from alcohol and from a mixture of benzene and light petroleum in slender needles melting at 93—94°.

The acid $C_8H_{14}O_2$ (b. p. 237—239°) and the acid $C_9H_{16}O_2$ (b. p. 251—253°), described by Markownikoff, have also been obtained in a pure condition from the mixture of acids referred to above.

F. S. K.

Glycollic Nitrile: Direct Synthesis of Glycollic Acid. By L. HENRY (*Compt. rend.*, **110**, 759—760).—Formaldehyde and hydrocyanic acid in aqueous solution combine completely with development of heat and formation of glycollic nitrile, $CN{\cdot}CH_2{\cdot}OH$. The liquid is evaporated at a gentle heat and extracted with ether. Glycollic nitrile is a colourless, limpid, odourless liquid, with a peculiar, sweetish taste; it is very soluble in water, alcohol, and ether, but is insoluble in carbon bisulphide, chloroform, and benzene. At −72° it solidifies to a crystalline mass, and the temperature rises to −67°; it boils with partial decomposition at 183° under a pressure of 759 mm., but if completely dried, it boils without change at 119° under a pressure of 24 mm.; sp. gr. at 12° = 1·100.

A minute quantity of potassium carbonate converts the nitrile into a brownish, crystalline mass which has not yet been examined; acetic chloride acts energetically and destructively; acetic anhydride acts energetically with great development of heat, and yields the acetate, $CN{\cdot}CH_2{\cdot}OAc$, which boils at 177°. Dilute acids rapidly convert the nitrile into glycollic acid with great development of heat.

C. H. B.

Hydroxytetric Acid. By C. CLOEZ (*Compt. rend.*, **110**, 583—586).—Demarçay obtained tetric and hydroxy-tetric acids by the action of alcoholic potash on the product of the action of bromine on ethyl methylacetoacetate. The author adopted Demarçay's method, except that, since no carbonic anhydride was evolved and the formation of dibromacetone was improbable, the product of the action of bromine on the ethyl methylacetoacetate was washed with water as soon as the colour of the bromine had disappeared. The ethyl dibromomethylacetoacetate was added gradually to alcoholic potash cooled by means of water, and the liquid, after dilution with water, was concentrated until all alcohol was expelled, strongly acidified with sulphuric acid, and exhausted with ether. When the ether is distilled off, hydroxytetric acid is obtained. Potassium hydroxide in methyl alcohol, aqueous potash, or even baryta-water, can be substituted for alcoholic potash. If ethyl dibromomethylacetoacetate is boiled with water, it readily saponifies, but the products contain a large proportion of black, insoluble substances. The same result is obtained even in presence of barium carbonate.

Hydroxytetric acid has the composition $C_5H_6O_4$, and after treatment with animal charcoal, crystallises from hot water in colourless crystals melting at 201—202°.

Ethyl hydroxytetrate, $C_5H_5O_4Et$, is obtained by the action of water on ethyl dibromomethylacetoacetate in presence of barium chloride, and is extracted by treatment with chloroform, from which it separates in colourless prisms which melt at 67—68°, and have a distinctly acid reaction. The silver ethyl salt crystallises in slender, colourless needles somewhat soluble in cold water, and but slightly altered when exposed to light. When treated with potassium hydroxide, the ethereal salt is decomposed, and on acidification with sulphuric acid, hydroxytetric acid is obtained.

If a solution of hydroxytetric acid in dilute alcohol is treated with gaseous hydrogen chloride, a colourless, neutral liquid is obtained which boils at 224—226°, and has the composition of a diethyl-derivative of hydroxytetric acid. C. H. B.

Potassium Hydrogen Malonate, Quadromalonate, and Quadroxalate. By G. Massol (*Compt. rend.*, **110**, 793—795).—*Potassium hydrogen malonate*, $C_3H_3KO_4 + \frac{1}{2}H_2O$, crystallises in large, non-deliquescent, monoclinic prisms which lose their water of crystallisation at 120—130°, and decompose at a higher temperature with evolution of acetic acid; heat of dissolution of the anhydrous salt = − 5·11 Cal.; heat of dissolution of the hydrated salt = − 9·58 Cal.; heat of hydration ($\frac{1}{2}H_2O$) + 3·755 Cal. in the solid condition; heat of neutralisation of solid malonic acid by one equivalent of solid potassium hydroxide + 27·87 Cal.

Potassium quadromalonate, formed by the direct combination of the acid with the preceding salt, crystallises in large, brilliant, anhydrous prisms; heat of dissolution −13·52 Cal. The combination of the dissolved acid with the dissolved hydrogen-salt to form the dissolved quadromalonate develops +0·10 Cal.

Potassium quadroxalate crystallises with 4 mols. H_2O, which are expelled at 110°; heat of dissolution of the hydrated salt −17·94 Cal.; of the anhydrous salt −12·79 Cal. The combination in solution of the hydrogen salt with the free acid to form the quadroxalate develops +0·05 Cal.; the combination of the solid salt and acid to form the solid quadroxalate would develop +0·95 Cal.; heat of hydration of the solid quadroxalate +2·29 Cal.

The heats of formation of all the potassium malonates are distinctly lower than those of the corresponding oxalates. C. H. B.

Symmetrical Diethylsuccinic and Methylethylsuccinic Acids. By Buitchichin and Zelinsky (*J. Russ. Chem. Soc.*, **21**, 376—389).—In a former paper (Abstr., 1889, 377), the authors have shown that two diethylsuccinic acids may be obtained from the product of the action of potassium cyanide on ethyl α-bromobutyrate. The symmetrical ethyl cyanodiethylsuccinate is not so easily acted on by hydrochloric acid as the corresponding dimethyl-compound, and the hydrolysis therefore was effected by means of alcoholic potash. The potassium diethylethenyltricarboxylate thus formed was decomposed with weak hydrochloric acid, and the liberated acids extracted with ether. In this way, a mixture of the two isomeric diethylsuccinic acids was obtained, and the acids separated by recrystallisation, taking advantage of the difference in their solubility. The sparingly soluble acid melts at 190—191°, and is the "fumaroïd" form, whereas the easily soluble "maleïnoïd" acid melts at 127—128°. These two acids are identical with those obtained by Bischoff and Hjelt (Abstr., 1888, 1057) from ethyl malonate by synthesis. On heating, both acids behave in a manner analogous to the dimethylsuccinic acids (compare Abstr., 1889, 692). They both yield the same anhydride, an oily liquid boiling between 244° and 246°. On adding water, the anhydride obtained from either of the two acids gives a mixture of much "maleïnoïd" acid (m. p. 127—128°) with a very small quantity of the "fumaroïd" acid (m. p. 190—191°). It is impossible to convert one acid into the other by boiling with water or weak hydrochloric acid, except under pressure, as found by Bischoff and Hjelt. The *ethyl salts*, prepared from ethyl iodide, and the corresponding silver salts are not identical, for although the "fumaroid" compound boils at 235—239°, and the "maleïnoid" at 237—239°, the sp. gr. of the first at 18° F. is 0·9736 and that of the second 0·9904, referred to water at 0°.

In a similar way, the ethylmethylsuccinic acids were prepared (*a*) by the action of ethyl sodiocyanopropionate on ethyl bromobutyrate, and (*b*) of ethyl sodiocyanobutyrate on ethyl bromopropionate. The ethyl α-cyanomethyl-β-ethylsuccinate obtained in (*a*) boils at 275—278°, its sp. gr. is 1·0542; the ethyl α-cyanethyl-β-methylsuccinate obtained in (*b*) boils at 283—285°, and its sp. gr. is 1·0172. Both ethyl salts were hydrolysed by hydrochloric acid, and in each case a mixture of two acids melting at 169—170° and at 84—85° was obtained. The ethereal salt boiling at 283—285° yields a larger proportion of the acid melting at 84—85°, that boiling at 275—278° yields a larger proportion of the acid melting at 169—170°. The "fumaroïd" acid is more sparingly soluble in water than the "maleïnoïd" acid. The calcium salt of the "fumaroïd" acid contains $5H_2O$, that of the "maleïnoid" acid $1H_2O$, and the corresponding barium salts contain $2H_2O$ ("fumaroid") and $5H_2O$ ("maleïnoïd"). At a higher temperature, both acids yield one and the same anhydride, boiling at 244—245°, which, on addition of water, yields chiefly the "maleïnoid" acid (m. p. 84—85°) with only a small admixture of the "fumaroïd" acid (m. p. 169—170°). Here again, as in the case of diethylsuccinic and dimethylsuccinic acids, there is a possibility of passing over from the acid with a higher melting point—"fumaroïd"—into the "maleïnoïd" acid of lower melting point, so that the anhydrides exist only for the "maleïnoïd" form. All "maleïnoïd" forms of the disubstituted succinic acids give off the elements of water at a lower temperature than the corresponding "fumaroïd" isomerides.

B. B.

Theory of Anhydride Formation in the case of Acids of the Succinic Series. By C. A. Bischoff (*Ber.*, **23**, 620—623).—The author has studied the behaviour of a large number of acids of the succinic series with the view of ascertaining what conditions determine the formation of an anhydride, more especially with regard to the influence of alkyl-groups (compare Auwers and Meyer, this vol., p. 479).

The fact that pyrocinchonic acid and xeronic acid cannot be obtained, whilst maleïc acid and fumaric acid are capable of existence, is best explained by assuming that, in the substitution of hydrogen by methyl- or ethyl-groups the carboxyl-groups are brought nearer together, probably because the doubly-bound carbon-atoms approach one another; the result of this may be that the space which would be occupied by the hydroxy-groups of the acid molecule, if the latter could exist, is no longer available, and anhydride formation results.

That the formation of an inner anhydride is also facilitated when an ethyl-group is substituted for a methyl-group is exemplified by the behaviour of levulinic acid and its homologues. Levulinic acid and both α- and β-ethyllevulinic acid distil unchanged; α-ethyllevulinic acid, on the other hand, as has been shown by Thorne (Trans., 1887, 336) is slowly converted into a lactone on distillation. By assigning to these levulinic acids the constitution of γ-hydroxy-acids, it is seen that this difference in behaviour is analogous to that exhibited in the case of maleïc acid and its homologues.

The conclusion to be drawn from these considerations, is that anhydride formation takes place the more readily the larger the atomic complex which replaces the hydrogen; how far this conclusion is in accordance with experiment is shown in the paper on anhydride formation (this vol., p. 744).

The formation of imides and anil-derivatives, which has been especially studied in the case of the two symmetrical dimethylsuccinic acids, has been found to be influenced in an analogous manner.

F. S. K.

Preparation of Mono-, Di-, and Tri-substituted Succinic Acids from Ethyl Malonate. By C. A. Bischoff (*Ber.*, 23, 631—633).—The method previously described for the preparation of succinic acid from ethyl malonate can be employed for the preparation of mono-, di-, and tri-substituted succinic acids. For this purpose, ethyl sodiomalonate is treated with the ethyl salt of a chloro- or bromo- mono- or di-substituted acetic acid, and the sodium-derivative of the product is treated with the iodide or chloride of an alcohol radicle, or the sodium-derivative of the ethyl salt of a substituted malonic acid is treated with the ethereal salt of a chloro- or bromo- mono- or di-substituted acetic acid. The identity of the ethereal salts obtained by these two methods was proved by measurements of their physical constants (compare this vol., p. 745).

The crude substituted ethyl ethenyltricarboxylate obtained by either of these two methods is fractionated, and each fraction heated with sulphuric acid (1 : 1) at 150—170° until the whole is soluble in alkali; the reaction which takes place consists essentially in the elimination of carbonic anhydride (1 mol.) and ethylene (3 mols.). The product is then freed from sulphuric acid, and the various acids obtained separated by fractional crystallisation. In the case of the benzyl-derivatives of ethyl ethenyltricarboxylate, alcoholic potash is employed instead of sulphuric acid, as they are only slowly hydrolysed when heated with sulphuric acid.

F. S. K.

Methylsuccinic, Ethylsuccinic, and Asymmetrical Dimethylsuccinic Acid. By C. A. Bischoff and A. v. Kuhlberg (*Ber.*, 23, 634—638).—Ethyl ethenyltricarboxylate, $COOEt\cdot CH_2\cdot CH(COOEt)_2$, prepared from ethyl sodiomalonate and ethyl chloracetate, boils at 278·3° (corr.) and yields succinic acid on hydrolysis.

Ethyl propenyltricarboxylate, $COOEt\cdot CHMe\cdot CH(COOEt)_2$, prepared from ethyl sodiomalonate and ethyl α-bromopropionate, boils at 270·3° (corr.), and yields pyrotartaric acid on hydrolysis.

Ethyl methylethenyltricarboxylate, $COOEt\cdot CH_2\cdot CMe(COOEt)_2$, can be obtained from ethyl sodiomethylmalonate and ethyl chloracetate, or from ethyl sodioethenyltricarboxylate and methyl iodide; it boils at 273·5° (corr.), and on analysis yields methylsuccinic acid (m. p. 112°).

Ethyl butenyltricarboxylate, COOEt·CHEt·CH(COOEt)$_2$, obtained from ethyl sodiomalonate and ethyl α-bromobutyrate, boils at 278° (corr.), and gives ethylsuccinic acid (m. p. 98°) on hydrolysis.

Ethyl isobutenyltricarboxylate, COOEt·CMe$_2$·CH(COOEt)$_2$, prepared from ethyl sodiomalonate and ethyl α-bromisobutyrate, boils at 277·3° (corr.); on hydrolysis, it yields asymmetrical dimethylsuccinic acid (m. p. 140°) and small quantities of an acid of lower melting point, but no methylglutaric acid.

Ethyl ethylethenyltricarboxylate, COOEt·CH$_2$·CEt(COOEt)$_2$, obtained from ethyl sodioethylmalonate and ethyl chloracetate, or from ethyl sodioethenyltricarboxylate and ethyl iodide, boils at 281·5° (corr.), and gives ethylsuccinic acid (m. p. 98°) on hydrolysis. F. S. K.

The Two Symmetrical Dimethylsuccinic Acids. By C. A. BISCHOFF and E. VOIT (*Ber.*, **23**, 639—644; compare Abstr., 1889, 490).—Ethyl methylpropenyltricarboxylate, COOEt·CHMe·CMe(COOEt)$_2$, prepared from ethyl sodiomethylmalonate and ethyl α-bromopropionate, or from methyl iodide and ethyl sodiopropenyltricarboxylate, boils at 279° (corr.), and on hydrolysis gives symmetrical para- and anti-dimethylsuccinic acids melting at 194° and 120° respectively (*loc. cit.*). Anti-dimethylsuccinimide, $C_6H_9O_2N$, crystallises in concentrically grouped needles or hexagonal plates, and is readily soluble in water, alcohol, benzene, chloroform, and acetone, but only sparingly in ether, and very sparingly in light petroleum.

F. S. K.

Relation of the Two Symmetrical Dimethylsuccinic Acids to Pyrocinchonic Acid. By C. A. BISCHOFF and E. VOIT (*Ber.*, **23**, 644—646).—The fact that pyrocinchonic acid on reduction yields the two symmetrical dimethylsuccinic acids is in accordance with Wislicenus' hypothesis.

When para- or anti-dimethylsuccinic acid is treated with bromine, it is converted into pyrocinchonic acid; the anhydrides of both para- and anti-dimethylsuccinic acid yield pyrocinchonic acid on heating at 90—100° with bromine in chloroform solution. F. S. K.

Symmetrical Ethylmethylsuccinic, Trimethylsuccinic, Symmetrical and Asymmetrical Diethylsuccinic, and Ethyldimethylsuccinic Acids. By C. A. BISCHOFF and N. MINTZ (*Ber.*, **23**, 647—652).—Ethyl methylbutenyltricarboxylate,

COOEt·CHEt·CMe(COOEt)$_2$,

prepared from ethyl sodiomethylmalonate and ethyl α-bromobutyrate, or from ethyl sodiobutenyltricarboxylate and methyl iodide, boils at 281·5° (corr.), and on hydrolysis yields symmetrical para- and meso-ethylmethylsuccinic acids.

Ethyl ethylpropenyltricarboxylate, COOEt·CHMe·CEt(COOEt)$_2$, prepared from ethyl sodioethylmalonate and ethyl α-bromopropionate, or from ethyl sodiopropenyltricarboxylate and ethyl iodide, boils at 282·8° (corr.), and on hydrolysis yields the two symmetrical ethylmethylsuccinic acids.

Ethyl methylisobutenyltricarboxylate, $COOEt \cdot CMe_2 \cdot CMe(COOEt)_2$, is best prepared from ethyl sodiomethylmalonate and ethyl α-bromisobutyrate; it boils at 284·3° (corr.), and on hydrolysis gives trimethylsuccinic acid (m. p. 105°) and traces of higher melting acids.

Ethyl ethylbutenyltricarboxylate, $COOEt \cdot CHEt \cdot CEt(COOEt)_2$, obtained from ethyl sodioethylmalonate and ethyl α-bromobutyrate, or from ethyl sodiobutenyltricarboxylate and ethyl iodide, boils at 285·5° (corr.), and on hydrolysis gives para- and anti-diethylsuccinic acid and an acid melting at 137·5° (compare *Ber.*, **21**, 2109).

Ethyl isohexenyltricarboxylate, $COOEt \cdot CEt_2 \cdot CH(COOEt)_2$, prepared from ethyl sodiomalonate and ethyl α-bromodiethylacetate, boils at 289·3° (corr.), and on hydrolysis gives asymmetrical diethylsuccinic acid (m. p. about 86°).

Ethyl ethylisobutenyltricarboxylate, $COOEt \cdot CMe_2 \cdot CEt(COOEt)_2$, is best prepared by treating ethyl sodioethylmalonate with ethyl α-bromisobutyrate. It boils at 294·3° (corr.), and on hydrolysis gives two ethyldimethylsuccinic acids, melting at 63° and 105° respectively.

F. S. K.

Anhydride Formation and Intramolecular Change of Substituted Succinic Acids.

By C. A. Bischoff and N. Mintz (*Ber.*, **23**, 656—659).—All the substituted succinic acids examined by the authors lose water at a high temperature (200—300°), and are converted into anhydrides; in some cases the anhydride formed is not that of the original acid, but that of the geometrical or dynamical isomeride.

The monosubstituted and the asymmetrical disubstituted succinic acids undergo no change when heated in sealed tubes at 200°, but the symmetrical disubstituted acids are partially converted into the geometrical or dynamical isomerides, so that a mixture of the two is formed.

On heating with concentrated hydrochloric acid at 200° in sealed tubes, antidimethyl-, antidiethyl-, and mesobenzyl-ethylsuccinic acids are converted into the corresponding para-acids; ethyldimethylsuccinic acid (m. p. 63°) under these conditions is converted into the dynamical isomeride.

Rotatory Power of Compounds of Malic Acid with Normal Lithium and Magnesium Molybdates.

By D. Gernez (*Compt. rend.*, **110**, 529—532).—The solutions examined contained 1·1166 gram of lævogyrate malic acid, various proportions of the molybdate, and sufficient water to make the total volume up to 12 c.c. The rotatory power of the malic acid alone, in a tube 105·7 mm. long, was −0° 11′.

With lithium molybdate, the increase in rotatory power is at first practically proportional to the quantity of salt added, and attains a first maximum at −10° 8′, which corresponds with equal equivalents of the malic acid and the molybdate. On the addition of more molybdate, the rotatory power decreases, changes in sign, and increases, reaching a second maximum at +15° 36′, when the liquid contains 4 equivalents of malic acid to 9 of the molybdate. Further quantities of salt cause diminution in rotatory power and a change of sign, a third maximum being reached at −2° 22′, when the solution contains 4 equivalents of molybdate to 1 of malic acid. The continued addition of molybdate causes another change of sign, and the rotatory power increases to +8° 10′, and even then has not reached its limit.

With magnesium molybdate, the phenomena are of the same order. A first maximum is reached at −9° 40′ with equal equivalents of acid and salt. This is followed by a diminution in rotatory power, followed by a change of sign and a second maximum at +18° 14′, with 4 equivalents of acid to 9 of molybdate. Further addition of molybdate causes a second reduction, with a minimum at +1° 6′ when the liquid contains 4 equivalents of molybdate to 1 of malic acid. Beyond this point an increase in the proportion of the molybdate increases the rotatory power, which has not reached its limit even at +8° 44′ (compare Abstr., 1887, 540; 1888, 97 and 938; and 1889, 1147). C. H. B.

Physical Constants of Alkyl-derivatives of Ethyl Ethenyltricarboxylate. By C. H. Bischoff and P. Walden (*Ber.*, 23, 660—664).—In the following table (next page) are given some physical constants of various derivatives of ethyl ethenyltricarboxylate.

The atoms and groups combined to the atomic complex

$$COOEt{\cdot}C\beta_2{\cdot}C\alpha(COOEt)_2$$

are given in column 2. The molecular weight is given in column 3, the boiling point (corr.) in column 4, and the sp. gr. at 20°, reduced to a vacuum and water at 4°, in column 5. Column 6 gives the refractive index for the D-line (at 19—20°), column 7 the molecular refractive energy calculated from the experimental data by means of the formula $\frac{M(n^2 - 1)}{d(n^2 + 2)}$, and column 8 the molecular refractive energy calculated from Conrady's values (C = 2·5, H = 1·05, O′ = 1·68, O″ = 2·29). Column 9 gives the molecular refractive energy calculated from the experimental data by means of the formula $M\frac{n - 1}{d}$, and column 10 the molecular refractive energy calculated from the values C = 5, H = 1·3, O′ = 3·4, O″ = 2·8. Column 11 gives the angle of dispersion (observed with an Abbe's refractometer), and column 12 the molecular volume calculated from the experimental data.

The following table shows that, with the exception of ethyl ethenyltricarboxylate, the boiling point increases with the molecular weight; in the case of isomerides, the boiling point is influenced by the position of the alkyl radicles, and is altered by the replacement of an ethyl- by two methyl-groups.

The author's observations confirm Brühl's conclusions respecting the specific gravity and the specific and molecular refractive energy of isomeric compounds. F. S. K.

Attempts to prepare Alkyl Substituted Tricarballylic Acids. By C. A. Bischoff and A. v. Kuhlberg (*Ber.*, **23**, 664—669).—A small quantity of a thick, yellow oil boiling at 315—334° is obtained when the crude product of the action of ethyl sodioisobutenyltricarboxylate and ethyl α-bromisobutyrate is fractionated. On hydrolysis, this oil yields *tetramethyltricarballylic acid*,

$$COOH\cdot CMe_2\cdot CH(COOH)\cdot CMe_2\cdot COOH,$$

which separates from a mixture of benzene and acetone in colourless crystals melting at 156°.

When ethyl sodiobutenyltricarboxylate is treated with ethyl α-bromopropionate, an oil of the composition $C_{16}H_{30}O_8$ is formed in small quantities. F. S. K.

Preparation of Betaïnes. By E. Duvillier (*Compt. rend.*, **110**, 640—642).—Betaïnes are readily obtained with but slight admixture with secondary products by the action of alkyl iodides on zinc salts of the amido-acids in presence of zinc oxide.

4 parts of methyl iodide, 1 part of zinc amidoisovalerate, and 1 part of zinc oxide are heated in sealed tubes at 100—110°. After 16 to 18 hours, the amidovalerate and zinc oxide have disappeared; the product is boiled with water, treated with barium sulphide to remove the zinc, sulphuric acid to remove the barium, and silver hydroxide to eliminate iodine. The liquid is then treated with hydrochloric acid and platinum chloride. It yields a slightly orange-yellow platinochloride which is insoluble in alcohol, but moderately soluble in warm water, from which it separates in oblique, transparent prisms with 2 mols. H_2O or 4 mols. H_2O. The aurochloride crystallises in deep-yellow, anhydrous leaflets, moderately soluble in warm water, soluble in alcohol, insoluble in ether free from alcohol. No tetramethylammonium hydroxide is formed in the preparation of the betaïne in this way. C. H. B.

α- and β-Homobetaïne. By J. Weiss (*Arch. Pharm.* [3], **28**, 186—191).—α-Homobetaïne is best obtained by the action of methyl iodide on α-alanine in alkaline solution. The platinochloride crystallises in the monoclinic system $\breve{a} : \bar{b} : \acute{c} = 0{\cdot}8100 : 1 : 0{\cdot}6214$; $\beta = 74^\circ\ 18'\ 34''$. Mean index of refraction for sodium light, 1·6555. Brühl previously obtained α-homobetaïne by the action of trimethylamine on ethyl α-chloropropionate.

β-Homobetaïne, $OH\cdot NMe_3\cdot CH_2\cdot CH_2\cdot COOH$, is best obtained by heating β-iodopropionic acid with excess of a 33 per cent. solution of trimethylamine for six hours at 100°. The solution remains clear when cold, but after evaporation, a white, crystalline mass is obtained. This product is dissolved in water and digested with excess of silver chloride, and the chloride thus produced converted into the platinochloride. The crystalline form of this salt is monoclinic, $\breve{a} : \bar{b} : \acute{c} = 1{\cdot}3484 : 1 : 1{\cdot}0659$; $\beta = 88^\circ\ 45'\ 3''$. The aurochloride was also prepared and analysed. J. T.

Preparation of Ethylsulphonic Acid. By F. Mayer (*Ber.*, 23, 908—912).—Ethylsulphonic acid is best prepared by heating sodium ethyl sulphate (1 part) with sodium sulphite (2 parts) and water (1 part) under pressure at 110—120° for three to four hours. The liquid is separated from the sodium sulphate by filtration, evaporated to dryness, the residue extracted with a large quantity of hot alcohol, and the filtered alcoholic solution allowed to cool, whereon sodium ethylsulphonate separates in small plates or needles. The sodium salt crystallises with 1 mol. H_2O; the double salt, $4C_2H_5 \cdot SO_3Na,NaI + H_2O$, does not lose its water at 160°; the barium salt crystallises with 2 mols. H_2O; the chloride boils at 171—173°. F. S. K.

Conversion of Allylbenzene- into Propenylbenzene-derivatives, their Dispersion and Refraction. By J. F. Eykman (*Ber.*, 23, 855—864; compare this vol., p. 135).—Cubebin has the molecular formula $C_{20}H_{20}O_6$, as is shown by molecular weight determinations by Raoult's method; an optical examination of this compound showed that its dispersion is normal.

That apiole and isapiole have the same molecular formula was proved by determining the vapour-density of apiole under reduced pressure by means of the apparatus previously described (this vol., p. 101), and by determining the molecular weight of isapiole by Raoult's method; measurements of the dispersion of these two compounds seem to show that apiole is an allyl-, isapiole a propenyl-derivative.

All compounds such as safrole, methyleugenol, ethyleugenol, ethylchavibetole, &c., which contain the normal allyl-group, on prolonged boiling with alcoholic potash, are converted into the corresponding propenyl-derivatives, identical in all respects with the propenyl-derivatives obtained in other ways; methylchavicole, for example, is converted into anethoïl, safrole into isosafrole, methyleugenol into methylisoeugenol, &c.

The author has measured the dispersion of a number of allyl- and propenyl-benzene-derivatives, including those named above; his results, which are given in tabular form, show that all those compounds which contain an allyl-group have a normal dispersion, whilst in the case of those which contain the propenyl-group, both the dispersion and the refraction are abnormally high. The dispersion is almost constant in each series, but about 1½ times as great in the propenyl- as in the allyl-series. The dispersion of the alkyl-derivatives of the allylhydroxy-benzene-derivatives is less than that of the corresponding phenol, and decreases with the number of methyl-groups; no such difference is exhibited by the propenyl-benzene-compounds. The specific dispersion of the allyl-derivatives is almost constant, but that of the propenyl-compounds is the smaller the greater the specific gravity; for this reason, a comparison of the simple dispersions seems to be preferable to that of the specific dispersions. The entrance of oxygen into the molecule increases the specific gravity considerably, whilst the dispersion is only slightly influenced; a change in the position of the double binding, on the other hand, increases the dispersion considerably, but has little effect on the specific gravity. F. S K

Formation of Thiocyanates from Amido-compounds. By L. GATTERMANN and W. HAUSSKNECHT (*Ber.*, 23, 738—739).—Up to the present few compounds are known in which the thiocyanogen-group, S·CN, is directly attached to the benzene-ring. The authors have found that such compounds may be readily obtained by the action of diazo-salts on cuprous thiocyanate according to Sandmeyer's method. Unlike the latter, however, the authors recommend decomposing the diazo-salt in the cold, as follows:—

31 grams of aniline are dissolved in 100 grams of sulphuric acid and 200 grams of water, and diazotised in the usual manner. To this solution, a concentrated solution of potassium thiocyanate is added, and then gradually, a paste of cuprous thiocyanate, obtained by dissolving a mixture of 80 grams of cupric sulphate and 150 grams of ferrous sulphate in water, precipitating with 35 grams of potassium thiocyanate, and filtering. The reaction with the diazo-compound takes place in the cold, and is accelerated by stirring. After three hours, the phenyl thiocyanate is driven over with steam, and purified by rectification. The yield is very good, whereas by Billeter's method of acting on the lead salt of thiophenol with cyanagen chloride or iodide only small quantities are obtained. The compound is indeed so readily prepared that thiophenol may be most easily obtained from it by treatment with potassium hydrosulphide.

Other derivatives, such as ortho- and paratolyl- and α-naphthyl thiocyanates have been prepared by this method. Isocyanates may also be prepared in a similar manner, but the yield is not so satisfactory. H. G. C.

Preparation of Aromatic Thiocyanates. By G. THURNAUER (*Ber.*, 23, 769—772).—Paratolyl thiocyanate may be obtained in a manner similar to phenyl thiocyanate (Billeter, this Journ., 1875, 464) by passing cyanogen chloride through lead thiocresoxide suspended in alcohol. Some tolyl disulphide is also formed, but crystallises out when the oil obtained by filtering and evaporating the alcoholic solution is allowed to remain in the cold. Paratolyl thiocyanate is an oil of sweetish, unpleasant odour, which boils at 245—250° (765·5 mm.), and solidifies in a freezing mixture forming a crystalline mass. It may also be obtained by the action of cyanogen chloride on sodium thiocresoxide, if all water be carefully excluded. If cyanogen bromide and iodide be substituted for the chloride, the chief product, both with the lead and the sodium salt, is tolyl disulphide, only traces of the thiocyanate being formed.

The author has also obtained thiocyanates by Sandmeyer's method (compare previous abstract). The diazotised solution is prepared according to Sandmeyer's method, and allowed to flow into a cold solution containing 18 grams of cuprous thiocyanate, 85—90 grams of potassium thiocyanate, and 50 grams of water. After remaining for some hours the mixture is extracted with ether, and the ethereal solution washed with dilute acid and alkali, filtered, and the ether evaporated, the residual oil being purified by fractional distillation under reduced pressure.

The *paratolyl thiocyanate* prepared by this method from paratoluidine was identical with the oil above described. *Orthotolyl thiocyanate*, C_7H_7SCN, is a yellowish-red oil, boiling at 243—246°, and having an unpleasant smell. Both these compounds cause violent itching of the hands, which continues for some time after ceasing to work with them.

Contrary to the statement of Gattermann and Hausknecht (previous abstract) the author finds that a paste of cuprous thiocyanate has no action on diazotoluene either in the cold or at a higher temperature. H. G. C.

Diphenyl Carbonate. By H. ECKENROTH and J. RÜCKEL (*Ber.*, **23**, 693—701).—The reactions of phenyl carbonate, which have been previously examined by Kempff (this Journ., 1871, 341), Hentschel (*Ber.*, **17**, 1287), and Eckenroth (Abstr., 1885, 786), have been further investigated by the authors, with the following results. In preparing diphenylcarbamide from phenyl carbonate, it is unnecessary to heat the latter with aniline under pressure, as the reaction takes place equally well when the two substances are heated together in a reflux apparatus for 2—3 hours. Ortho- and para-diphenylcarbamide and dinaphthylcarbamide may be prepared in a similar manner.

Chlorine and iodine do not combine directly with phenyl carbonate, but if the latter be heated with an excess of bromine at 100°, until no more gas is evolved, a white mass remains on evaporating off the excess of bromine, which crystallises from alcohol in long, silky needles melting at 169°, and having the composition $(C_6H_4Br)_2CO_3$. It is readily soluble in benzene, chloroform, acetone, and ether, sparingly in cold light petroleum and alcohol, and insoluble in water.

It has been previously shown by Eckenroth (Abstr., 1885, 786) that diphenyl carbonate and diphenylcarbamide act on one another with formation of phenyl cyanate and phenol, and that these then again combine together to form phenyl phenylcarbamate (compare Snape, Trans., 1885, 770). The same reaction takes place if para- or orthoditolylcarbamide is substituted for diphenylcarbamide, and in these cases also the reaction is very incomplete. 8 grams of paraditolylcarbamide (obtained by boiling diphenyl carbonate with paratoluidine, washing the product with alcohol, and crystallising from the same liquid) was mixed with 7 grams of diphenyl carbonate and distilled, the distillate being allowed to remain for 14 days. The crystals formed were separated from the adhering oil, recrystallised several times from light petroleum, and thus obtained as slender, white needles melting at 115°, and agreeing in composition with the expected phenyl paratolylcarbamate $CH_3{\cdot}C_6H_4{\cdot}NH{\cdot}COOPh$.

For the preparation of phenyl orthotolylcarbamate, 8 grams of orthoditolylcarbamide (obtained in a similar manner to the para-compound) were boiled with 7 grams of phenyl carbonate in a reflux apparatus for several hours, and two-thirds of the mixture then slowly distilled over, the distillate being allowed to remain for 14 days, and treated as in the foregoing case. The phenyl orthotolylcarbamate thus obtained forms crystals which melt at 92°.

Attempts to prepare the corresponding thiocarbamates in a similar manner failed on account of the difficulty of separating the compounds formed. H. G. C.

ε-Dinitrophenol. By V. Wender (*Gazzetta*, **19**, 218—224).—The constitution of this compound, which was first prepared by Bantlin (Abstr., 1879, 237), has not yet been elucidated, but since Henriques found (Abstr., 1883, 327) that the corresponding anisoïl, when treated with ammonia, yields a nitroanisidine from which metanitroanisoil may be prepared by eliminating amidogen, it must have the constitution $[(NO_2)_2 = 2:3 \text{ or } 3:5]$. The 2 : 3 formula appears the more probable, as it explains the transformation into nitranisidine, where the nitroxyls are already in ortho-position.

The author has therefore endeavoured to prepare the 3·5-dinitrophenol by diazotising dinitranisidine $[(NO_2)_2 : NH_2 = 3:5:4]$, prepared by the nitration of paranisidine, or by the action of ammonia on the dimethyl ether obtained from the dinitroquinol $[(OH)_2 : (NO_2)_2 = 1:4:3:5]$ melting at 135°. The following compounds were prepared in the course of the experiments.

Dinitroparaphenacetide, $C_6H(NO_2)_2(OEt)\cdot NHAc$, prepared by dissolving paraphenacetide in glacial acetic acid (5 parts), cooling to 5°, and adding nitric acid (1 part, sp. gr. = 1·54). On dilution with water, the dinitrophenacetide is thrown down as a crystalline powder, which crystallises from alcohol in lustrous, silky needles, and from acetic acid in prisms. It melts at 206°, and is freely soluble in acetic acid, especially on warming, and in ether, very moderately in boiling alcohol, and very sparingly in cold alcohol. Hydrolysis does not take place on boiling it with hydrochloric acid, potash partially saponifies it in the cold, but on heating ammonia is evolved. It may also be prepared from the mononitro-derivative (melting at 104°). One of the nitroxyl-groups in this substance must occupy a meta-position relatively to the ethoxyl as in the mononitro-derivative.

Dinitrophenetidine, $C_6H(NO_2)_2(OEt)\cdot NH_2$. The preceding compound is hydrolysed by heating for 10 minutes with concentrated sulphuric acid (8 parts), the temperature not exceeding 100°. On diluting with water, the base is precipitated in red flakes which crystallise out from alcohol in thin, brownish-red prisms melting at 145°. It has feeble basic properties; the hydrochloride and sulphate may be obtained in an ethereal or acetic acid solution, but they are decomposed by cold water.

Dinitracetaniside, $C_6H_2(NO_2)_2(OMe)\cdot NHAc$, is prepared like the ethyl-compound, starting with the nitracetaniside, melting at 116°. It resembles the ethyl-derivative in many respects, forming long, slender, flat, brilliant, pale-yellowish needles which melt at 220°. It is soluble in hot acetic acid, only moderately so in boiling alcohol, very sparingly in cold alcohol, whilst it is almost insoluble in boiling water.

Dinitranisidine, $C_6H_2(NO_2)_2(OMe)\cdot NH_2$, is obtained by heating the preceding compound with concentrated sulphuric acid for 15 minutes, and diluting with water. The orange-coloured precipitate which is formed crystallises from boiling alcohol in bright-crimson needles with a bluish sheen, and melts at 182° to a red liquid. It is freely soluble in alcohol, acetic acid, and ether, and moderately in boiling water. When heated with aqueous potash, it dissolves with evolution of ammonia.

Dinitromethylquinol is formed as a secondary product of the action of ethyl nitrite on dinitranisidine. A solution of this substance (30 grams) in absolute alcohol (600 grams) is saturated with nitrous anhydride, and heated for 24 hours in a reflux apparatus. The ethyl nitrite is then distilled off, and the residue exhausted with a boiling solution of potassium carbonate, the cold solution being extracted with ether, acidified, and again treated with ether; the second extract contains the quinol, which crystallises from boiling alcohol in bright-yellow, lustrous tables, melts at 110°, and dissolves freely in hot alcohol, less so in cold; it is also soluble in acetic acid and in ether. The *barium derivative* forms lustrous, lemon-yellow needles, freely soluble in boiling water, sparingly in cold. A small proportion of this quinol is also formed when dinitranisidine is diazotised, and the resulting salt decomposed with dilute sulphuric acid.

ε-Dinitroanisoïl is the principal product of the action of ethyl nitrite on dinitranisidine (m. p. 182°); the portion insoluble in potassium carbonate crystallises from alcohol in faintly-yellowish plates which melt at 119°, and with care can be distilled without decomposition; if rapidly heated, however, it explodes. It is soluble in boiling water and in hot alcohol, less so in cold alcohol and in boiling light petroleum. It is not volatile in steam. When heated with alcoholic ammonia for 5 hours at 180°, it is converted into Bantlin's nitranisidine, melting at 75°; this yields metanitranisoïl when heated with ethyl nitrite.

ε-Dinitrophenol is obtained by heating the preceding compound with hydrochloric acid at 150° for 24 hours. The product is evaporated to dryness, extracted with a boiling solution of potash, the solution treated with ether, acidified, and again extracted with ether. The latter extract contains the dinitrophenol, which crystallises from alcohol in bright-yellow tables; it melts at 144—145°, and has an odour resembling that of metanitrophenol. It is freely soluble in ether and hot alcohol, and moderately in boiling water. The *barium derivative* is soluble in hot water, and separates out in slender, golden needles, or in groups of brownish-yellow needles, according as the solution is rapidly cooled or slowly evaporated. On heating to 150°, it becomes brownish-red, changing back to a dirty-yellow on cooling. The *potassium derivative* crystallises from water in slender, orange needles, or in thin, lustrous laminæ, containing 2 mols. H_2O, and is freely soluble in hot water and moderately in cold; when anhydrous it is of a deep-scarlet colour. By treatment with nitric acid, this dinitrophenol yields styphnic acid (m. p. 175°). It therefore appears that the phenol and anisoïl obtained are identical with Bantlin's ε-compounds.

S. B. A. A.

Constitution of Bromonitrothymol, Dinitrothymol, Dinitramidocymene, Dinitrocymene, and the Isomeric Chloro- and Bromo-thymoquinones. By G. MAZZARA (*Gazzetta*, **19**, 160—169). —When the ethyl ether of dinitrothymol is heated with alcoholic ammonia for 10 hours in a closed tube at 180—190°, and the product is freed from ammonia and crystallised from dilute alcohol, a dinitramidocymene, $C_6HPrMe(NO_2)_2\cdot NH_2$, is obtained in large, dark-yellow prismatic tables which soften at 108°, melt at 113—115°, dissolve sparingly in light petroleum and in hot water, separating out, on cooling, in small laminæ which volatilise with some difficulty in a current of steam.

According to Bantlin (Abstr., 1879, 237), only the 3·5-dinitranisoïl yields a dinitraniline when heated with alcoholic ammonia (compare Abstr., 1883, 327); the structure of the ethyl ether of dinitrothymol must therefore be—

$$[Me : NO_2 : OEt : Pr : NO_2 = 1 : 2 : 3 : 4 : 6],$$

and that of dinitramidocymene—

$$[Me : NO_2 : NH_2 : Pr : NO_2 = 1 : 2 : 3 : 4 : 6].$$

The ethyl ether of nitrobromothymol, heated with alcoholic ammonia in a sealed tube at 180—190° for 14 hours, undergoes no change; it thus behaves as a meta-derivative, and in order that the bromine should be in a meta-position with respect to the nitroxyl, the latter must be in a para-position with respect to the hydroxyl. The structure of bromonitrothymol is therefore $[Me : Br : OH : Pr : NO_2 = 1 : 2 : 3 : 4 : 6]$. This is confirmed by the fact that on nitration it yields dinitrothymol, the ethyl ether of which has been shown above to have its nitroxyls in the meta-position (relatively to each other). Further support is derived from the following considerations:—(1) the same nitrobromo-derivative is obtained by brominating nitrothymol and by nitrating parabromothymol, a result only explicable on the assumption that in the latter reaction the nitroxyl displaces the bromine; (2) that the corresponding amidobromothymol (Abstr., 1886, 1016) yields, with nitrous acid, a bromothymoquinone, which has its two oxygen-atoms in the para-position.

When dinitroamidocymene is treated with alcohol containing ethyl nitrite, the product distilled in a current of steam, pressed between filter-paper, and crystallised from dilute alcohol, a compound is obtained in rhombohedral plates which melt at 54°, and to all appearance is identical with Kraut's dinitrocymene, $[Me : Pr : (NO_2)_2 = 1 : 4 : 2 : 6]$.

Bromothymoquinone.—A bromothymoquinone melting at 48° was prepared from amidobromothymol hydrochloride, and, on reduction with sulphurous anhydride, yielded a bromothymoquinol melting at 52—53° (Abstr., 1886, 1016). The same substance is obtained by the action of potassium nitrite on amidobromothymol prepared from parabromothymol. This quinone and quinol must, from their formation, respectively have the constitutions

$$[Me : Br : O : Pr : O = 1 : 2 : 3 : 4 : 6]$$
$$\text{and } [Me : Br : OH : Pr : OH = 1 : 2 : 3 : 4 : 6].$$

Schniter (Abstr., 1887, 720) describes a bromothymoquinol (m. p. 53°) which yields a quinone melting at 45°; to the former he ascribes the constitution [Br = 5], whereas he considers chlorothymoquinol to have the structure [Cl = 2]. The formation of the same chlorobromothymoquinol, whichever of the halogens is first introduced, is thus explained by assuming that the atoms of chlorine and bromine always displace different hydrogen-atoms. Schniter principally relies on the formation of a liquid chlorothymoquinol, which yields a chlorobromothymoquinone and quinol melting at a somewhat lower temperature than the isomeric derivatives from the solid chlorothymoquinol.

The author attaches no importance to the slight difference in melting point between Schniter's bromothymoquinone and his own, and considers that the agreement of the other physical properties of these compounds, and of the melting points of the corresponding quinols, is sufficient evidence of their identity. It would, therefore, appear that Schniter's distinction between *αβ*- and *βα*-compounds is very doubtful. The author concludes that when a halogen acid acts on thymoquinone, the halogen takes the place of the hydrogen-atom next to the methyl [2]. Chlorine, however, displaces bromine from this position, leaving it to displace the atom of hydrogen next to the propyl [5], an action analogous to that of nitroxyl and bromine on thymol (compare this vol., p. 367). S. B. A. A.

Action of Chlorine on Catechol and Orthamidophenol. By T. Zincke and F. Kuster (*Ber.*, **23**, 812—831; compare Abstr., 1888, 1277, and 1889, 599).—The hexachlorohydroxypentenecarboxylic acid melting at 110°, described in a former paper, when heated at 120—140°, is found to be converted into an isomeric acid melting at 186°, which is very like the original acid in its chemical properties. When oxidised, it yields a ketone (hexachloroketopentene) melting at 92°, isomeric with that (m. p. 31°) obtained from the original acid; and this ketone, like its isomeride, is converted by treatment with alkalis into an acid, but a different one, of the formula $C_4Cl_5\cdot COOH$. The constitution of these two isomeric series is discussed at considerable length. The constitution of the members of the first series has been already determined, and the authors think that the members of the second series are not merely geometrical isomerides of the others, or derived from different hydrocarbons of the formula C_5H_6; they regard it as more probable that the isomerism is caused by a difference in the relative position of the chlorine-atoms in the five-atom carbon ring. They consequently assign the following formulæ to the compounds mentioned above (the Greek letters in brackets refer to the position of the double bond):—

	Hydroxy-acid.	Ketone.
First (*β* : *γ*) series	 $\left.\begin{array}{l}\mathrm{CCl:CCl}\\ \mathrm{\vert}\\ \mathrm{CCl_2\cdot CCl_2}\end{array}\right>\mathrm{C(OH)\cdot COOH}$ Melting at 110°.	 $\left.\begin{array}{l}\mathrm{CCl:CCl}\\ \mathrm{\vert}\\ \mathrm{CCl_2\cdot CCl_2}\end{array}\right>\mathrm{CO.}$ Melting at 31°.
Second (*γ* : *γ*) series	 $\left.\begin{array}{l}\mathrm{CCl\cdot CCl_2}\\ \Vert\\ \mathrm{CCl\cdot CCl_2}\end{array}\right>\mathrm{C(OH)\cdot COOH}$ Melting at 186°.	 $\left.\begin{array}{l}\mathrm{CCl\cdot CCl_2}\\ \Vert\\ \mathrm{CCl\cdot CCl_2}\end{array}\right>\mathrm{CO.}$ Melting at 92°.

The constitution of the β : γ-series was determined by the formation of propylideneacetic acid when the acid $C_4Cl_5·COOH$. derived from the β : γ-ketone, was reduced with nascent hydrogen. This acid was, therefore, thought to be a pentachlorobutenecarboxylic acid of the formula $CCl_2{:}CCl·CCl{:}CCl·COOH$; but since Baeyer and Russe have shown that a change in the position of double bonds takes place in the case of hydromuconic acid, the above evidence is much weakened, and the authors propose to reinvestigate the subject.

The transformation of the β : γ-hydroxy-acid into the γ : γ-isomeride is complete; but the β : γ-ketone suffers a partial transformation only, and, indeed, the γ : γ-ketone is, to some extent converted by heat into the β : γ-isomeride. An acid, $C_4Cl_5·COOH$, can be got only with difficulty from the γ : γ-ketone; it is necessary to work at 0°, and not to bring either the ketone or the acid directly into solution, as resinous matters are at once formed in an alkaline solution. The acid is altogether very unstable, and no satisfactory formula can be assigned to it. It is decomposed when gently heated, yielding carbonic anhydride and a substance C_4Cl_5H. When reduced, it yields an acid approximately of the composition $C_4H_7·COOH$, but this acid acts as a strong reducing agent, and no conclusions can be drawn as to its constitution.

With phosphorus pentachloride, the β : γ-hydroxy-acid yielded a phosphate melting at 150°. The γ : γ-acid also yielded a phosphate, $COOH·C_5Cl_6·O·PO_3H_2,2\frac{1}{2}H_2O$, melting at 170° when dried in air, at 152° when dried in a vacuum, and volatilising with decomposition at 215°. It also yields the γ : γ-ketone, the formation of which is attended by the evolution of hydrogen chloride and carbon monoxide.

A third substance, melting at 145°, was also obtained, but not in sufficient quantity to allow of its investigation.

The two ketones, when heated with phosphorus pentachloride, both gave the same γ : γ-octochloropentene, C_5Cl_8; but a high temperature was required, so that molecular transformation may have taken place.

With ammonia, the β : γ-ketone did not give an acid amide, but a substance was formed smelling like a carbamine, possibly of the formula  $\begin{array}{l}CCl{:}CCl—CO\\ \mid \qquad\qquad\quad \mid\\ CCl_2·CHCl·NH\end{array}$. The γ : γ-ketone, however, gave the amide derived from the acid ($CCl_2{:}CCl·CCl{:}CCl·COOH$) formed by the action of soda on the β : γ-ketone. This is remarkable, for we have here the γ : γ-ketone transformed into a derivative of the otherwise less stable β : γ-ketone.

Hexachlorohydroxypentenecarboxylic acid (γ : γ) is obtained by heating the isomeric acid of melting point 110° at 120—140° for about an hour; the yield is about 80 per cent. of the theoretical. The molecular weight of the new acid was determined by Raoult's method, and it was thus shown that it is a true isomeride, and not a polymeride, of the original acid. It melts at 186°, and resembles the β : γ-acid in its chemical properties. Its barium salt crystallises with 2 mols. H_2O. The methyl salt melts at 119°. With acetic chloride, it gives an *acetyl*-derivative melting, when dry, at 130°, the barium salt of which was prepared. When heated with bromine at 100°, bromopentachloroketopentene, C_5Cl_5BrO, is formed; the same substance is formed when the $\beta : \gamma$-hydroxy-acid is treated with bromine, and we have here another instance of the conversion of a $\beta : \gamma$- into a $\gamma : \gamma$-derivative. C. F. B.

Quinoneimides and Amidoquinones. By F. KEHRMANN (*Ber.*, 23, 897—907).—When chloroparadihydroxyquinone [$O_2 : (OH)_2 : Cl = 1 : 4 : 2 : 5 : 3$] is heated for a short time with aniline in alcoholic solution, it yields chlorodianilidoquinone, identical with the compound (m. p. 260—265°) obtained in like manner from metadichloroquinone by Niemeyer (Abstr., 1885, 1065). The action of free aniline on chloroparadihydroxyquinone is, therefore, the same as the action of aniline on paradihydroxyquinone (Nietzki and Schmidt, Abstr., 1889, 968); in the latter case, there is formed Hofmann's dianilidoquinone, which is, therefore, a paradianilidocompound.

When chloroparadihydroxyquinone is boiled with aniline in glacial acetic acid solution, it is converted into a compound, $C_{18}H_{13}ClN_2O_3$, isomeric with the compound melting at 260—265°. This substance crystallises in dark-green needles with a blue reflex, melts at about 240° with decomposition, and is moderately easily soluble in boiling glacial acetic acid and benzene, but only sparingly in alcohol and ether, and insoluble in water. It dissolves in concentrated sulphuric acid yielding a beautiful green solution; on diluting, the colour changes to blue, and on adding a large quantity of water, the anilide is precipitated unchanged. It is almost insoluble in alkalis, but it combines with them to form salts which are readily soluble in water with partial decomposition, but insoluble in dilute alkalis. When boiled with alcoholic potash, in which it is readily soluble, it is converted into a potassium salt, which remains, on evaporating the alcohol, in brownish-red needles; when this salt is boiled with dilute potash until the solution turns bright-red, aniline is liberated, and, on acidifying, a small quantity of a dark-green, crystalline substance is precipitated. This compound separates from boiling alcohol in small, bluish needles, has the composition $C_{12}H_8ClNO_3$, and is a chloro-derivative of a paranilidohydroxyquinone or of a paradihydroxyquinoneanilide; it is decomposed by boiling alkalis into aniline and chloroparadihydroxyquinone.

The behaviour and properties of the compound obtained by the action of aniline on chloroparadihydroxyquinone in glacial acetic acid solution show its complete analogy with the anilidohydroxyquinoneanilide and the anilidohydroxytoluquinoneanilide prepared by Zincke (Abstr., 1885, 787).

Anilidohydroxyquinoneanilide is converted into paradihydroxyquinone when heated with alkalis.

Zincke's dihydroxytoluquinone (Abstr., 1883, 1117) has probably the constitution [$O_2 : (OH)_2 : Me = 1 : 4 : 3 : 6 : 2$], as it is formed from its anilide in a manner similar to that in which the paradihydroxybenzoquinones are obtained, and the anilides of these compounds, as well as the quinones themselves, behave in like manner.

When anilidohydroxyquinoneanilide or anilidohydroxyquinone is boiled with dilute potash for several hours, paradihydroxyquinone is formed, but only in small quantities, as it is itself gradually decomposed by potash. Hofmann's dianilidoquinone also yields paradihydroxyquinone on boiling with alcoholic sulphuric acid, and chlorodianilidoquinone gives chloroparadihydroxyquinone when treated in like manner.

Tetramethyldiamidoquinone (Mylius, Abstr., 1885, 803) is best prepared by treating chloroquinone with dimethylamine in alcoholic solution; when heated to boiling with dilute potash or hydrochloric acid, it is converted into paradihydroxyquinone, but when treated with cold dilute hydrochloric acid, it is converted into *dimethylamidohydroxyquinone* [$O_2 : NMe_2 : OH = 1 : 4 : 2 : 5$].

The above experiments show that all the compounds formed by the action of bases on benzoquinone are converted into one and the same paradihydroxyquinone by substituting the anilido- or amido- by hydroxy-groups, from which it may be concluded that the anilido- or amido-groups themselves are in the para-position to one another.

It may be stated, as a general rule, that by the action of amido-compounds on quinones of the type of benzoquinone, at the most two hydrogen-atoms in the nucleus can be substituted, and these two hydrogen-atoms are in the para-position one to the other; the compounds formed are, therefore, derivatives of paradiamidoquinone, and by their decomposition with acids or alkalis, paradihydroxy-derivatives of quinone and its homologues are produced.

F. S. K.

A Higher Homologue of Cholesterin. By F. MARINO-ZUCO (*Gazzetta*, 19, 209—212).—The ethereal extract of the flowers of *Chrysanthemum cinerariæfolium*, after repeated treament with aqueous and alcoholic potash, leaves a substance which forms yellow crystals melting at 70—100°. After repeatedly crystallising this from ether placed in a freezing mixture, melting under alcohol, and again crystallising from anhydrous ether, a paraffin ($C_{17}H_{36}$?) is obtained in very thin, colourless, nacreous scales; this melts at 64°, dissolves freely in ether, benzene, and chloroform, and moderately in hot alcohol, but is almost insoluble in cold alcohol.

The portion which remains dissolved in the cold ether is purified by fractional crystallisation, until the crystals which separate melt above 150°; the ethereal solution is then evaporated, when it leaves a residue, consisting of slender needles, of a substance resembling cholesterin, but containing small quantities of fats from which it cannot be freed by boiling with alcoholic potash. The *acetyl-derivative*, $C_{28}H_{47}\cdot OAc$, prepared by boiling the crude cholesterin with acetic anhydride, crystallises from alcohol and ether in colourless, nacreous scales which melt at 223°.

The *benzoyl-derivative*, $C_{28}H_{47}\cdot OBz$, obtained by heating the cholesterin with benzoic acid at 210—240°, crystallises from ether in small, colourless needles with a silky lustre which melt with decomposition at 246°.

The pure cholesterin, $C_{28}H_{46}O$, obtained by treating either of its derivatives with alcoholic potash, forms slender, colourless needles which melt at 183°, and gives all the reactions for cholesterin, including Hesse's reaction with sulphuric acid and chloroform. It dissolves freely in ether, benzene, and chloroform, and sparingly in hot alcohol, being deposited from the latter, on cooling, in a flocculent condition. S. B. A. A.

Properties of several Anilides. By A. PICTET (*Chem. Centr.*, 1890, i, 477—478; from *Arch. sci. phys. nat. Genève*, **22**, 508—522). —By boiling the alcoholic solution of formanilide with alcoholic potash and an alkyl iodide in a reflux apparatus, the alkylformanilides are obtained. The alkylacetanilides are obtained by warming the alkylformanilides with acetic anhydride. The alkylformanilides may also be saponified, and monalkylanilines obtained. The *alkylformanilides* are colourless, oily liquids at the ordinary temperature, without odour, but are strongly refractive, and have a burning taste. When distilled under the ordinary atmospheric pressure, they suffer decomposition more or less.

Of the *alkylacetanilides*, those of methyl, ethyl, propyl, and isopropyl are crystallisable substances.

The *monoalkylanilides* are liquids—

	Boiling point.	Under pressure in mm.	Sp. gr. at 16° (water at 4°).
Methylformanilide	253°	716	1·097
Ethylformanilide	258	728	1·063
Isopropylformanilide	261–263°	720	—
Propylformanilide	267°	731	1·044
Isobutylformanilide	274	731	—
Isoamylformanilide	285–286°	728	1·044

	Melting point.	Boiling point.	Under pressure.
Methylacetanilide	101°	253°	712
Ethylacetanilide	54	258	731
Isopropylacetanilide	38	262	728
Propylacetanilide	47–48°	266	716
Isobutylacetanilide	liquid	272–273°	712
Isoamylacetanilide	liquid	287°	730

	Boiling point.	Under pressure in mm.	Sp. gr. at 18° (water at 4°).
Methylaniline	191·0°	712	0·976
Ethylaniline............	203·5	712	0·954
Isopropylaniline	207·0	731	—
Propylaniline	219·5	716	0·949
Isobutylaniline	229–230°	716	0·940
Isoamylaniline..........	252·5°	730	0·928

It is interesting to notice that the boiling points of the alkylacetanilides are exactly the same as those of the alkylformanilides, with which they correspond.

The following crystallographic determinations were also made :—Acetanilide, rhombic, 0·8481 : 2 : 2·067; methylacetanilide, rhombic, 2·530 : 1 : 2·149; ethylacetanilide, monoclinic, 1·32641 : 1 : x, β 101°56′; phenylacetanilide, rhombic, 1·277 : 1 : 2·7917. J. W. L.

Syntheses by means of Phenyl Cyanate. By R. Leuckart (*J. pr. Chem.* [2], **41**, 301—329; compare Abstr., 1885, 773, 1224).—The preparation of anilides by the action of phenyl cyanate on hydrocarbons or alkyl phenyl ethers in the presence of aluminium chloride is best conducted as follows :—Phenyl cyanate (1 part) is mixed with the well-dried hydrocarbon or phenyl ether (10 parts), and aluminium chloride gradually added; when the mixture ceases to become hotter, it is heated on the water-bath until the smell of the cyanate disappears and hydrogen chloride begins to be evolved; at this point it is poured into water and the benzene solution separated and evaporated; the residue is extracted with boiling alcohol, the solution filtered and precipitated with water; the precipitate is warmed with an alkali, filtered, washed with water, dried, and distilled. The anilide which thus distils over is recrystallised from alcohol.

Paratoluanilide, from phenyl cyanate and toluene, crystallises in lustrous needles melting at 145° (compare Fischli, Abstr., 1879, 638, and Brückner, Abstr., 1881, 95).

Xylylanilide, from phenyl cyanate and metaxylene, crystallises in needles melting at 141° (compare Ador and Meier, Abstr., 1880, 252).

Isoxylylanilide, from phenyl cyanate and paraxylene, crystallises in colourless needles melting at 140°.

β-Isodurylanilide, $C_6H_2Me_3 \cdot CO \cdot NHPh$, from phenyl cyanate and mesitylene, forms colourless needles melting at 165°, freely soluble in ether and hot alcohol.

Durylanilide, from phenyl cyanate and pseudocumene, crystallises in colourless needles melting at 178°.

Paradiphenylcarboxylanilide, $C_6H_4Ph \cdot CO \cdot NHPh$, from phenyl cyanate and diphenyl, forms colourless needles melting at 212°.

α-(?)-Naphthanilide, $C_{10}H_7 \cdot CO \cdot NHPh$, from phenyl cyanate and naphthalene, crystallises in colourless needles melting at 161°, and is probably identical with Hofmann's so-called α-naphthanilide (m. p. 160°), but the acid obtained from it by fusion with potash melts at 140°, and is, therefore, not α-naphthoic acid (m. p. 160°).

Paratolylparatoluidide, $C_6H_4Me \cdot CO \cdot NH \cdot C_6H_4Me$, obtained in like manner from paratolyl cyanate and toluene, crystallises in colourless needles melting at 158—159°.

The alkyl ethers of the phenols are conveniently prepared by dissolving the corresponding amine in alcohol, saturating with hydrogen chloride, and passing in the vapour of the alkyl nitrite; after all the nitrogen has been evolved the solution is evaporated, the residue washed with soda, dried, and distilled.

The action of phenyl cyanate on anisoïl, phenetoïl, and the naphthyl methyl ethers has been described already (Abstr., 1885, 1224).

Metamethylparamethoxybenzanilide, $MeO·C_6H_3Me·CO·NHPh$, prepared from phenyl cyanate and methyl orthocresyl ether, forms slender, lustrous, white needles melting at 147°; when fused with potash, it yields aniline and metamethylparamethoxybenzoic acid (m. p. 192°; Schall, Abstr., 1879, 792).

Metamethylorthomethoxybenzanilide, from methyl paracresyl ether and phenyl cyanate, crystallises in long, white, lustrous needles, melts at 96°, and is soluble in alcohol.

Methylpropylmethoxybenzanilide, $MeO·C_6H_2MePr·CONHPh$, from phenyl cyanate and methyl thymyl ether, crystallises in lustrous, long, white tables melting at 166°. When heated at 120—130° with strong hydrochloric acid, it yields *methylpropylmethoxybenzoic acid*, which crystallises in long, slender, lustrous needles melting at 140°; the constitution of this acid is uncertain, but it is probably identical with the acid obtained by Kobek by the methylation of parathymotic acid (Abstr., 1884, 56).

The action of phenyl cyanate on phenol has been studied by Hofmann (this Journal, 1871, 392).

Orthotolyl phenylcarbamate, $NHPh·COO·C_6H_4Me$, from phenyl cyanate and orthocresol, crystallises in long, slender, lustrous needles melting at 145° and soluble in hot alcohol.

Paratolyl phenylcarbamate forms lustrous, white leaflets, melts at 114°, and is soluble in hot alcohol.

Thymyl phenylcarbamate, $NHPh·COO·C_6H_3MePr$, from phenyl cyanate and thymol, forms lustrous, white needles melting at 104°.

The action of phenyl cyanate on α- and β-naphthol has been described before (Abstr.. 1885, 1224); the melting point of β-naphthyl phenylcarbamate is 155—156°, not 230°.

Metanitrodiphenylcarbamide, $NHPh·CO·NH·C_6H_4·NO_2$, from phenyl cyanate and metanitraniline, melts at 198·5°. *Paranitrodiphenylcarbamide* melts at 212°. *Metamidodiphenylcarbamide* crystallises in small, grey needles melting at 187·5°; it has been obtained by Lellmann and Würthner (*Annalen*, **228**, 222; compare Abstr., 1885, 977).

Phenylmetanitroparatolylcarbamide,, $NHPh·CO·NH·C_6H_3Me·NO$, from phenyl cyanate and metanitroparatoluidine, crystallises in small, lemon-yellow needles melting with decomposition at 194°.

Phenylorthamidotolylcarbamide, from phenyl cyanate and orthotolylenediamine, crystallises in colourless needles melting at 197—198°; its *hydrochloride*, *platinochloride*, and *sulphate* are described. When the hydrochloride is heated at 100°, it is decomposed into aniline and *tolylenecarbamide*, $C_6H_3Me<\begin{matrix}NH\\NH\end{matrix}>CO$, which forms slender needles, melts above 300°, and sublimes, undecomposed, in colourless leaflets. When the hydrochloride in aqueous solution is treated with potassium nitrite, *azimidotolylphenylcarbamide*, $C_6H_3Me·N_3·CONHPh$, is obtained; it forms colourless crystals melting at 159—160°; when it is treated with aqueous soda or potash, it is decomposed into phenyl cyanate and azimidotoluene (m. p. 85°), identical with Ladenburg's amidazotoluylene (m. p. 83°; this Journal, 1876, 933).

Diphenyltolylenedicarbamide, $C_6H_3Me(NPhH·CO·NH)_2$, is also obtained when phenyl cyanate acts on orthotolylenediamine—especially if the temperature is high; it is left undissolved by alcohol, and crystallises from glacial acetic acid in small, sparingly soluble needles melting at 208—209°.

Orthohydroxydiphenylcarbamide, $NHPh\cdot CO\cdot NH\cdot C_6H_4\cdot OH$, is the product of the action of phenyl cyanate on orthamidophenol in ether; it forms crystals which melt at 165—166°, and are freely soluble: its *ethyl-derivative* melts at 169—170°. When orthohydroxydiphenylcarbamide is heated above its melting point, it is decomposed into aniline and oxycarbamidophenol (m. p. 141—142°; compare Kalckhoff, Abstr., 1883, 1110, who gives m. p. 137°).

Acetylorthamidophenyl phenylcarbamate, $NHPh\cdot CO\cdot OC_6H_4\cdot NHAc$, obtained by heating acetylorthamidophenol with phenyl cyanate in toluene, forms long, pale-red, stellate needles melting at 162°.

Phthalanilphenyl phenylcarbamate, $NHPh\cdot COO\cdot C_6H_4N<\genfrac{}{}{0pt}{}{CO}{CO}>C_6H_4$, is obtained when phenyl acetate is heated with hydroxyphthalanil, $HO\cdot C_6H_4N<\genfrac{}{}{0pt}{}{CO}{CO}>C_6H_4$ (obtained by the action of phthalic anhydride on orthamidophenol); it crystallises in beautiful, colourless needles melting at 160—165°. A. G. B.

Trinitrazoxybenzenes and Trinitrazobenzenes. By H. Klinger and J. Zuurdeeg (*Annalen*, 255, 310—338).—Schmidt (*Zeit. f. Chem.*, 1869, 421) has described a trinitrazoxybenzene (m. p. 152°) which he obtained by treating azoxybenzene with a mixture of sulphuric and nitric acid; according to Petriew (*ibid.*, 870, 265) this same azoxy-compound is formed, together with a trinitroazobenzene, by heating azobenzene with concentrated nitric acid.

The authors' experiments show that Schmidt's azoxy-compound is a mixture of various substances; when azoxybenzene (20 grams) is treated with a well-cooled mixture of nitric acid of sp. gr. 1·5 (200 grams) and sulphuric acid of sp. gr. 1·8 (100 grams), and the solution kept for 24 hours, crystals are deposited. The more readily soluble crystals consist of various substances, melting below 140°, which could not be isolated; the more sparingly soluble crystals consist of a mixture of ortho- and meta-trinitrazoxybenzene which can be separated by repeated recrystallisation from benzene or acetone; the most sparingly soluble crystals melt at 207—208°, and are only formed in very small quantities.

Orthotrinitrazoxybenzene, $\overset{6}{NO_2}\cdot C_6H_4\cdot N_2O\cdot \overset{1}{C_6}H_3(NO_2)_2$ $[(NO_2)_2 = 3:4 \text{ or } 2:4]$, crystallises from acetone in well-defined, almost colourless asymmetric prisms or plates, $a:b:c = 0\cdot79919:1:1\cdot13901$, and melts at 187—188°; it is very sparingly soluble in ether, alcohol, and light petroleum, but rather more readily in hot chloroform, glacial acetic acid, acetone, nitrobenzene, and hot nitric acid. It is not acted on by dilute acids or dilute alkalis, but it dissolves in concentrated sulphuric acid yielding a yellowish solution from which, on cooling, it crystallises unchanged. On complete reduction with tin and hydrochloric acid in alcoholic solution, it yields a mixture of bases which probably consists of triamido- and orthodiamido-benzene.

Metatrinitrazoxybenzene, $\overset{5}{N}O_2\cdot C_6H_4\cdot \overset{1}{N}_2O\cdot C_6H_3(NO_2)_2$ $[(NO_2)_2 = 2:4]$, crystallises from benzene in lemon-yellow, asymmetrical prisms, $a : b : c = 0.71085 : 1 : 0.71096$, and melts at 175—176°; its behaviour with solvents is very like that of the ortho-compound, and it dissolves in concentrated sulphuric acid, yielding a yellowish solution.

Orthotrinitrazobenzene, $NO_2\cdot C_6H_4\cdot N_2\cdot C_6H_3(NO_2)_2$, separates on cooling when orthotrinitrazoxybenzene (5·5 grams) is dissolved in glacial acetic acid and treated with a solution of tin (6 grams) in hydrochloric acid; it can also be prepared by reducing the azoxy-compound with alcoholic ammonium sulphide. It crystallises from glacial acetic acid, benzene, acetone, alcohol, chloroform, and nitric acid in long, yellow needles, melts at 220°, and is much more readily soluble than the azoxy-compound. It is not changed on prolonged boiling with fuming nitric acid or with a mixture of chromic acid and nitric acid. The mother-liquors obtained in the preparation of the trinitrazo-compound contain orthonitraniline and a red substance which could not be obtained in a crystalline condition.

Metatrinitrazobenzene, $NO_2\cdot C_6H_4\cdot N_2\cdot C_6H_3(NO_2)_2$, is obtained when metanitrazoxybenzene (11 grams) is dissolved in boiling glacial acetic acid and treated with a solution of tin (8 grams) in concentrated hydrochloric acid; on cooling, the product separates in red plates or needles. It separates from benzene in crystals, melts at 172—173°, and resembles the corresponding ortho-compound in its behaviour with solvents; when boiled for several hours with a mixture of chromic acid and fuming nitric acid, it is reconverted into the azoxy-compound (m. p. 175—176°). The mother-liquors from the trinitrazo-compound contain metanitraniline (m. p. 114°) and a red substance which could not be obtained in crystals.

The ortho- and meta-trinitrazoxybenzene, described above, are both formed when (1) azobenzene, (2) orthonitrazoxybenzene, (3) paranitrazoxybenzene, (4) paranitrazobenzene (m p. 166—167°), and (5) dimetadinitrazobenzene are treated with nitric acid under suitable conditions. Janovsky and Erb (Abstr., 1885, 894) have stated that by the nitration of paranitrazobenzene there is formed a trinitrazobenzene which can also be prepared from azobenzene and from paradinitrazobenzene in like manner. The authors criticise Janovsky's results, and point out that his own statements in different journals are self-contradictory; the trinitrazobenzenes described by Janovsky are evidently mixtures of various compounds. F. S. K.

Resorcinol and Orcinol Colouring Matters. By R. Nietzki and H. Maeckler (*Ber.*, **23**, 718—726).—In continuation of their researches on the colouring matters derived from resorcinol (this vol., p. 156), the authors have re-examined the compounds obtained from the ethers of resorcinol and from orcinol (Abstr., 1881, 726; *Ber.*, **17**, 440). Weselsky and Benedikt obtained two compounds by the action of nitric acid containing nitrous acid on resorcinol monoethyl ether, to the first of which they gave the formula $C_{14}H_{11}NO_4$. The authors have been able to confirm this formula, and find that the substance is identical with the ethyl ether of resorufin previously obtained by them (*loc. cit.*). They have, however, been unable to confirm the statement that this compound is also obtained from resorcinol diethyl ether. They have also been unable to obtain the second compound mentioned by Weselsky and Benedikt, but do not doubt its existence, as the description given by them corresponds very closely with that of resazurin ethyl ether.

The "diazoresorcinol diethyl ether" obtained by Weselsky and Benedikt by the action of alcoholic hydrogen chloride on resazurin is probably a crude resorufin ethyl ether containing chlorinated impurities.

The colouring matter from orcinol was prepared according to Weselsky's directions (*Ber.*, **17**. 440), and the analysis of the substance itself and its sodium salt confirmed the formula $C_{14}H_{11}NO_3$ given by Weselsky and by Krämer (Abstr., 1884, 1341). This formula corresponds with that of resorufin, and not with that of resazurin, and, as the colour characteristics of its alkaline solution cannot be distinguished from those of the former, it must be the next higher homologue of that substance, and the authors, therefore, propose for it the name *orcirufin*. With bromine, it yields a blue colouring matter similar to that given by resorufin, and gives an *acetyl*-derivative, $C_{14}H_{10}NO_3Ac$, crystallising in orange-needles which melt at 204°. Its *silver salt* is a dark-grey precipitate, which yields *orcirufin monethyl ether*, $C_{14}H_{10}NO_3 \cdot C_2H_5$, on warming with ethyl iodide and alcohol. This crystallises from alcohol in slender, yellowish needles melting at 269°.

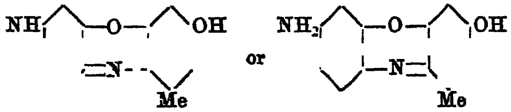
The colouring matter obtained by Liebermann (Abstr., 1875, 167) by the action of sulphuric acid containing nitrous acid on orcinol, and further examined by Krämer (Abstr., 1884, 1340), consists of impure orcirufin. This may also be obtained by warming nitroso-orcinol with orcinol in sulphuric acid solution.

Nitroso-orcinol was obtained by Krämer by evaporating orcinol with an equivalent quantity of sodium hydroxide, mixing the product with amyl nitrite and sand, and heating the whole on the water-bath. It is, however, obtained in a much purer condition and in larger quantity by cooling the mixture with ice. It crystallises from alcohol in yellow needles which melt with a slight explosion at 157°.

Action of quinonedichlorimide on resorcinol and orcinol.—In the previous communication, the authors showed that quinonechlorimide reacts with resorcinol forming resorufin. They have now investigated the action of quinonedichlorimide on both resorcinol and orcinol, but as the yield obtained from the latter is much larger, that reaction alone has as yet been closely studied.

In carrying out this synthesis, an alcoholic solution of orcinol is gradually added to a similar solution of an equimolecular proportion of quinone dichlorimide, the mixture heated for several hours on the water-bath, after which water and a slight excess of ammonia is added to the carmine-red solution. The brownish-violet precipitate is taken up with alcohol containing hydrogen chloride, and dilute sulphuric acid added. On cooling, the sulphate separates as a crystalline precipitate which is insoluble in water, but may be recrystallised from dilute hydrochloric acid, and is thus obtained in beautiful needles with a brown surface lustre. The *hydrochloride* is also insoluble in water, but soluble in dilute acid, which is probably due to the fact that the salts are decomposed by water. Neither of the salts mentioned contains a constant quantity of sulphuric or hydrochloric acid. The free base, obtained by the action of ammonia on a hot solution of the sulphate or hydrochloride, forms small, brown needles with a green, metallic lustre, and has the composition $C_{13}H_{10}N_2O_3$. The solutions of its salts have a colour and fluorescence which can hardly be distinguished from that of an alkaline solution of resorufin or orcirufin. In alcoholic solution, the orange fluorescence is very notable. Concentrated sulphuric acid dissolves the substance with a blue colour which passes into red on the addition of water; it dyes silk the colour of the base, but the fibres show no fluorescence.

From its mode of formation two formulæ are possible for this colouring matter, namely:—



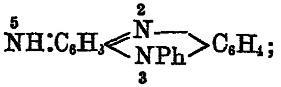
The decided basic properties of the compound, its total insolubility in alcohol, and the fact that it yields only a monacetyl-derivative, all point to the latter formula as more probable. The *monacetyl* compound, $C_{13}H_9N_2O_3Ac$, is prepared by warming the base with acetic anhydride and sodium acetate, and forms stellate groups of small, brown needles; it has neither acid nor basic properties, which also agrees with the second formula. Still further confirmation of the latter is afforded by the fact that the base may be diazotised, and then condenses with naphtholsulphonic acids to azo-colours.

The colouring matter obtained in the same manner from resorcinol shows just the same colour and fluorescence, and yields salts showing the same properties as those obtained from orcinol; it must, therefore, be the simplest member of this class of colouring matters. For these two members the authors propose the names *resorufamine* and *orcirufamine*. H. G. C.

Indulines. By O. Fischer and E. Hepp (*Ber.*, 23, 838—841).—Two compounds are formed when a mixture of amidoazobenzene (160 grams), aniline (400 grams), and aniline hydrochloride (320 grams) is heated to about 130°, and then for about ten minutes at 160°; the melt is treated with the theoretical quantity of sodium carbonate, the aniline distilled with steam, the residue boiled with 30 per cent. acetic acid (1·5 litres), and the filtered solution allowed to cool slowly. After a lapse of several days, the acetate of an induline of the composition $C_{24}H_{18}N_4$ separates from the solution as a bronze-coloured, crystalline precipitate and, on adding concentrated hydrochloric acid to the mother-liquors, the hydrochloride of an induline of the composition $C_{18}H_{13}N_3$ and the induline $C_{24}H_{18}N_4$ are precipitated together in a blue, amorphous condition. The free bases can be separated by crystallisation from hot benzene, in which the compound of higher molecular weight is the more sparingly soluble.

The new induline, $C_{18}H_{13}N_3$, crystallises from benzene in green needles, melts at 135°, and is soluble in ether, benzene, and alcohol, yielding magenta-coloured solutions; its solution in acetic acid is reddish-violet, and that in concentrated sulphuric acid bluish-violet. The *hydrochloride*, $C_{18}H_{13}N_3,HCl$, the *sulphate*, and the *nitrate*, $C_{18}H_{13}N_3,HNO_3$, are readily soluble in warm water, and impart to fibres a bluish-violet colour. When the base is heated with concentrated hydrochloric acid at 150°, it is decomposed with liberation of ammonia, yielding a new dye which has probably the composition $C_{18}H_{12}N_2O$; this compound has a brownish-red fluorescence, and its solutions are of a redder shade than those of the induline.

The induline $C_{18}H_{13}N_3$ has probably the constitution



$$\overset{5}{\mathrm{N}}\mathrm{H{:}C_6H_3}<\begin{matrix}\overset{2}{\mathrm{N}}—\!—\\ \underset{3}{\mathrm{NPh}}\end{matrix}>\mathrm{C_6H_4};$$

if it can be proved to be related to phenazine, the constitution of the indulines is practically settled, as all other indulines of the benzene series are derived from phenazine by the entrance of anilido-, phenyl-, or $NH_2{\cdot}C_6H_4{\cdot}N{\equiv}$ groups.

Paraphenylenediamine reacts very readily with all indulines; it is formed in all amidoazobenzene melts in considerable quantities, but disappears again on further heating, so that it evidently takes part in the formation of the blue indulines. When paraphenylenediamine is added to the melt, the induline formation takes place at a lower temperature, and the melt becomes blue more quickly.

Indulines are readily formed when azophenine, anilidoquinoneanilide, anilidonaphthaquinoneanil, benzeneazo-α-naphthylamine, &c., are heated with paraphenylenediamine in alcoholic solution at 150—170° in presence of paraphenylenediamine hydrochloride.

The hydrochloride of a base $C_{26}H_{20}N_4$ is formed when phenylrosinduline is heated for several hours with paraphenylenediamine (2 parts) and its hydrochloride (1½ parts) in alcoholic solution at 160°. This salt crystallises in bronze-coloured plates, is readily soluble in alcohol, and dissolves in warm water yielding a reddish-violet solution. The free *base* crystallises from hot alcohol in dark, bronze-coloured needles, melts at 247°, and dissolves in alcohol with a dirty violet coloration; it is an amidophenylrosinduline of the constitution  $\mathrm{NH_2{\cdot}C_6H_4{\cdot}}\overset{5}{\mathrm{N}}\mathrm{{:}C_6H_3}<\begin{matrix}\overset{2}{\mathrm{N}}—\!—\\ \underset{3}{\mathrm{NPh}}\end{matrix}>\mathrm{C_{10}H_6}$, as, when heated with concentrated hydrochloric acid (10 parts) and a little glacial acetic acid at 180°, it is decomposed into paraphenylenediamine and rosindon (m. p. 259°).

These experiments show that the anil-group in phenylrosinduline is replaced by the atomic complex, $NH_2{\cdot}C_6H_4{\cdot}N{\equiv}$; paraphenylenediamine has very probably an analogous action on the benzene indulines, and by the entrance of the $NH_2{\cdot}C_6H_4{\cdot}N{\equiv}$ group into the molecule, the shade becomes more decidedly blue, and the molecule more basic.

A complete account of these experiments will shortly be published in the *Annalen*. F. S. K.

Benzylphosphines and their Derivatives. By E. A. Letts and R. F. Blake (*Trans. Roy. Soc. Edin.*, 35, 527—628; compare also this vol., p. 492). The authors prepared monobenzylphosphine by Hofmann's method (heating 4 grams of zinc oxide, 16 grams of phosphonium iodide, and 12 grams of benzyl chloride in a sealed tube for six hours), but found that better results were obtained at 120° than at 160°. In the treatment of the products, precautions were taken to exclude the air. It was found impossible to satisfactorily purify the monobenzylphosphine by fractional distillation, but this was effected by its conversion into the hydriodide. When pure, it is a highly refractive liquid which fumes strongly when exposed to the air, becoming very hot and often inflaming spontaneously. Its *hydrobromide* is obtained by saturating a benzene solution of the base with hydrobromic acid, or by dissolving the phosphine in the fuming acid, and crystallises in scales insoluble in benzene. This salt is very deliquescent, and decomposes rapidly in contact with water, instantly with potash. The *hydrochloride* forms colourless scales, the *platinochloride* a bulky, yellow precipitate. When slowly oxidised by exposure to a limited quantity of air, the phosphine yields *benzylphosphinous, benzylphosphinic*, and phosphoric acids, the first-named in by far the largest proportion. Benzylphosphinous acid is a syrupy liquid which refuses to crystallise. It is fairly soluble in water, but separates from a strong solution in oily drops. It is easily soluble in alcohol and ether. Most of its salts are easily soluble. The *barium salt*, $(C_7H_7{\cdot}PHO_2)_2Ba + 4H_2O$, forms a granular, crystalline mass; the *calcium*, with $\frac{1}{3}H_2O$, *magnesium*, with $5H_2O$, *zinc*, and *lead*, with $\frac{1}{2}H_2O$, salts are all colourless and crystalline; the *cadmium salt* is flocculent and white. When heated, benzylphosphinous acid is decomposed into monobenzylphosphine and benzylphosphinic acid, probably according to the equation $3C_7H_7{\cdot}PH_2O_2 = 2C_7H_7{\cdot}PH_2O_3 + C_7H_7{\cdot}PH_2$. Bromine acts on benzylphosphinous acid, but the reaction seems to be very complicated.

Monobenzylphosphinic acid, $C_7H_7{\cdot}H_2PO_3$, is best obtained by the action of benzyl alcohol on a mixture of phosphorus and phosphorus iodide. It is a colourless, crystalline bibasic acid melting at 169—169·5° (corr.), and soluble in water and alcohol. Its salts mostly crystallise readily. The *barium salt*, $C_7H_7{\cdot}BaPO_3 + 2H_2O$, crystallises in thin plates much less soluble in hot than cold water: 100 c.c. water at 9·7° dissolve 1·807 grams at 100°, 0·4305 gram of the hydrated salt. The *hydrogen barium salt* $(C_7H_7{\cdot}PHO_3)_2Ba + 3H_2O$, is crystalline and very soluble. The normal *calcium*, *lead*, and *magnesium* salts are all crystalline, and contain 1 mol. H_2O, which they only lose at 200°. The *cadmium* and *zinc* salts contain 1 mol. H_2O, which they lose at 110°. The *sodium*, *potassium*, and *ammonium* salts are crystalline and very soluble; the *silver* salt forms an unstable, white precipitate. When moderately heated (at 200—230°), the acid forms a *pyro-acid* $(C_7H_7)_2H_2P_2O_5$, yielding a *barium salt* crystallising in long needles. When heated rapidly, the normal acid decomposes, yielding metaphosphoric acid and probably toluene. When heated with phosphorous acid, benzylphosphinic acid gives off hydrogen phosphide and monobenzylphosphine, the reaction appearing to take place principally according to the equation $3H_3PO_3 + C_7H_7{\cdot}H_2PO_3 = 3H_3PO_4 + C_7H_7{\cdot}PH_2$.

When sulphur is warmed with monobenzylphosphine, hydrogen sulphide is evolved, and *pyrobenzylthiophosphinic* acid, $(C_7H_7)_2H_2P_2S_5$, is formed, which is a viscous mass, and when boiled with water, yields the thiophosphinic acid, $C_7H_7{\cdot}PS(OH)_2$, the latter forming a crystalline *barium* salt. A crystalline salt, $(C_7H_7)_2P_2S_3O_2Ba + 2H_2O$, was also obtained. Bromine acts with explosive violence on benzylphosphine, but if the action is moderated, monobenzylphosphine hydrobromide is formed. By the action of carbon bisulphide on the phosphine, two crystalline compounds were obtained. but their formulæ have not been established. Sulphuric acid appears to form with the phosphine an unstable crystalline sulphate, but this substance could not be obtained pure. When a mixture of the phosphine and chloracetic acid is heated in sealed tubes at 120°, acetic chloride and benzylphosphinic acid are formed. Bromacetic acid and ethyl chlorocarbonate both act very violently on the phosphine, but the products have not yet been isolated.

The products of Hofmann's sealed tube reaction undoubtedly contain besides mono-benzylphosphine, *di-* and *tribenzylphosphines* and *tetrabenzylphosphonium iodide.* Although they have not been able to obtain *dibenzylphosphine* in an absolutely pure state, the authors have established the fact that it is a liquid which cannot be distilled without decomposition into the mono- and tribenzylphosphines. It combines with hydriodic acid and probably other hydracids to form crystalline compounds decomposed by water. *Tribenzylphosphine* is a solid, crystalline substance of high boiling point, possibly volatile in a vacuum with little or no decomposition. It unites with hydracids to form salts which are decomposed by water, and combines energetically with benzyl iodide to form tetrabenzylphosphonium iodide. It oxidises, on exposure to air, to tribenzylphosphine oxide, which the authors have shown (*loc. cit.*) to be identical with Hofmann's dibenzylphosphine.

Numerous salts and double salts of tetrabenzylphosphonium are described.

Besides those already mentioned, the authors obtained from the sealed tube products a crystalline substance of very low boiling point ("crystalline oil"), seemingly of the formula $(C_7H_7)_2HPO$, and an "insoluble crystalline body" for which analysis seems to indicate the formula $(C_7H_7)_3PO_2$, but these formulæ are still somewhat uncertain.

Dibenzylphosphinic acid, $(C_7H_7)_2HPO_2$, was obtained amongst the products of Hofmann's sealed tube reaction, but whether formed during the reaction or during the subsequent treatment, the authors were unable to determine. It is also formed by the action of benzyl alcohol on a mixture of phosphorus and phosphorus iodide, and by fusing tribenzylphosphine oxide with caustic potash. It is fairly soluble in hot alcohol, almost insoluble in water. It crystallises in iridescent, micaceous plates which melt at 192°. At a higher temperature it decomposes, but also partly volatilises unchanged. It forms characteristic salts. The *barium* salt, $[(C_7H_7)_2PO_2]_2Ba + 8H_2O$, and the *calcium* salt, with $8H_2O$, crystallise in thin plates, the *magnesium* salt, with $3H_2O$, in long, colourless needles. The *cadmium* salt forms a white, amorphous precipitate, the *copper salt* a blue, amorphous powder, the *silver* salt colourless needles which blacken slightly on drying. The *sodium*, *potassium*, and *ammonium* salts crystallise with 7 mols. H_2O in easily soluble crystals. Phosphorus pentachloride reacts strongly with the dibenzyl acid, but no organic compound other than benzyl chloride could be isolated, and the decomposition appears to be complete. When dibenzylphosphinic acid is heated, it is partly distilled, partly decomposed, some tribenzylphosphine oxide being formed.

When benzyl alcohol is allowed to act on a mixture of phosphorus and phosphorus iodide, all the oxidation products above described are formed, the proportions of the various products varying according to the conditions of the experiment. L. T. T.

Action of Ethyl Acetoacetate on Cinnamaldehyde. By P. Biginelli (*Gazzetta*, 19, 212—214).

—Hantzsch (Abstr., 1883, 82) found that the action of ethyl acetoacetate on certain aldehydes in presence of alcoholic ammonia resulted in the formation of compounds of the formula  $NH<\begin{matrix}CMe:C(COOEt)\\CMe:C(COOEt)\end{matrix}>CHR$ (compare Schiff and Puliti, Abstr., 1883, 1151). If a similar action were to take place in presence of compound ammonias, the action of ethylenediamine on cinnamaldehyde should give rise to a substance composed of two nuclei of the above form, united by ethylene through the nitrogen-atoms.

The reaction, however, does not take place in this way. When cinnamaldehyde (13·2 grams), ethyl acetoacetate (26 grams), ethylenediamine (3 grams), and absolute alcohol (10 grams) are heated for an hour in a reflux apparatus, the product, after cooling, draining, and washing with 80 per cent. alcohol, crystallises from alcohol in groups of long, silky needles which melt at 160—161° and have the composition $C_{21}H_{26}O_6$. This substance is soluble in alcohol and most ordinary solvents except water. It dissolves in acetic acid without undergoing any change. It acquires a rose colour by the action of concentrated sulphuric acid, in which it afterwards dissolves forming a greenish-yellow solution. It is decomposed by potash with the formation of a compound resembling benzoic acid in appearance and properties, but melting at 130—131°. The bromine-derivative melts at about 80°.

Methylamine or aniline may be substituted for ethylenediamine in the reaction between cinnamaldehyde and ethyl acetoacetate without affecting the composition of the product; it would, therefore, appear that ethylenediamine merely provides an alkaline menstruum in which the other substances can react.

With ethylenediamine and ethyl acetoacetate, benzaldehyde gives a crystalline compound containing no nitrogen; propaldehyde, on the other hand, yields azotised products. S. B. A. A.

Aromatic Alkyl Ketones; their Oxidation by Potassium Permanganate. By A. Claus (*J. pr. Chem.* [2], **41**, 396—414; compare Abstr., 1885, 1136; 1886, 462, 463; 1887, 253).—Aromatic alkyl ketones can only be oxidised by potassium permanganate to ketonic acids when the benzene nucleus contains a side-group in the ortho-position to the ketone-group; and when this oxidation takes place, an α-ketonic acid is always obtained, independently of the number of carbon atoms in the alkyl-group and of this being primary or secondary.

Paratolyl methyl ketone (Abstr., 1886, 462) boils at 222° (uncorr.), not 220°, and is still liquid at − 20°; its sp. gr. is 1·013 at 13°; it is slightly volatile with steam, and gives no crystalline compound with alkaline sulphites. If the action of the aluminium chloride is prolonged, a thick, yellow oil boiling above 300° is formed; it seems to be a condensation-product.

Paratolyl dibromomethyl ketone, obtained by adding bromine to a solution of the ketone in carbon bisulphide, crystallises in beautiful, colourless leaflets, which are sparingly soluble in alcohol; it melts at 97° (uncorr.), and does not sublime; it yields toluic and terephthalic acids when oxidised, but no ketonic acid. When this dibromo-derivative is treated with alcoholic potash, it yields *tolyl ketone aldehyde*, $C_6H_4Me·CO·CHO$, or a polymeride thereof; this substance crystallises in nodular aggregates which melt at 170° (uncorr.) and sublime in colourless needles.

Paratolyl methyl acetoxime, $C_6H_4Me·CMe{:}N·OH$, crystallises in colourless, six-sided tables melting at 88° and insoluble in water, but soluble in alcohol, ether, and chloroform. *Paratolyl methyl ketone phenylhydrazide* crystallises in lustrous, colourless prisms melting at 95° (uncorr).

Paratolyl methyl pinacone, $C_6H_4Me·CMe(OH)·CMe(OH)·C_6H_4Me$, is prepared by adding sodium amalgam (5 per cent.) in small quantities to a solution of the ketone in 70 per cent. alcohol (10 vols.); when the solution has become colourless, it is acidified with dilute sulphuric acid and mixed with much water; the pinacone separates as a yellow oil which crystallises from alcohol in large, hexagonal tables, melts at 90° (uncorr.), and is soluble in ether and chloroform. When the pinacone is reduced with potash and zinc, *paratolyl methyl carbinol*, $C_6H_4Me·CHMe·OH$, a yellow oil boiling above 300°, is obtained.

When paratolyl methyl ketone is warmed with sulphuric acid, it undergoes condensation forming a *phorone*, $C_{27}H_{28}O$, which crystallises in lustrous, colourless needles melting at 168°; it is insoluble in water, sublimes easily, and burns with a bright, luminous flame. This substance is under investigation.

Tritolylbenzene, $C_6H_3(C_7H_7)_3$, is obtained when dry hydrogen chloride is passed into paratolyl methyl ketone daily for two weeks; the brown mass is washed with alcohol and crystallised from chloroform, from which the tritolylbenzene crystallises in white needles, whilst from alcohol and acetone, it crystallises in leaflets; both forms melt at 171° (uncorr.) and decompose at 220°, but do not sublime.

Tribromotritolylbenzene crystallises in colourless, felted needles which melt at 212° (uncorr.). *Trinitrotritolylbenzene* separates from the usual solvents as a crystalline powder; it begins to decompose at 160°, and does not melt.

Benzenetribenzoic acid, $C_6H_3(C_6H_4{\cdot}COOH)_3$, is obtained by heating tritolylbenzene with dilute nitric acid of sp. gr. 1·1 (5—6 parts) at 160—180° in a sealed tube. It separates from alcohol as a nearly colourless, crystalline powder sparingly soluble in ether and chloroform, insoluble in water; it sublimes in needles, without melting, at 280°. The *normal*, *monacid*, and *diacid potassium* salts and the *normal ammonium* salt were obtained.

Ortho-xylyl methyl ketone is a mobile, colourless, strongly refractive, oily liquid; it boils at 243° (uncorr.), and is soluble in the usual solvents, except water. Its *oxime* crystallises from ether in colourless, lustrous, flat needles and prisms melting at 89—90° (uncorr.). Its *phenylhydrazide* forms colourless crystals melting at 113° (uncorr.).

Ortho-xylyl methyl carbinol, obtained by reducing the ketone with zinc-dust in alcoholic potash, is a clear, yellowish liquid of pleasant odour, and boils between 255° and 260° (uncorr.). When reduced with hydriodic acid, it yields 1 : 2-dimethyl-4-ethylbenzene.

When ortho-xylyl methyl ketone is oxidised with potassium permanganate, it yields only metaparadimethylbenzoic acid (paraxylic acid; m. p. 163°). When it is treated with dry hydrogen chloride, the compound $C_{20}H_{22}O$ is obtained; this crystallises in nearly colourless needles, melts at 113° (uncorr.), and is soluble in ether and sparingly in alcohol, but insoluble in water. In one experiment, a small quantity of a second substance, melting at 173° (uncorr.), was obtained. Attempts to bring about a condensation of the ketone by phosphoric anhydride led to the formation of metaparadimethylbenzoic acid (m. p. 163°).

Ortho-cymyl methyl ketone is a liquid boiling at 256—260° (uncorr.); it yields 4-methylisophthalic acid when oxidised, but no ketonic acid.

A. G. B.

Anisaldehyde and Succinic Acid. By R. FITTIG and J. POLITIS. (*Annalen*, **255**, 293—309; compare this vol., pp. 583—594).—*Anisylisocrotonic acid*, $OMe{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}CH_2{\cdot}COOH$, is formed, together with dianisylpentolic acid and dianisyltetrylene, when anisaldehyde is heated at 120° for 30 to 40 hours with sodium succinate and acetic anhydride. The dark-brown product is treated with sodium carbonate, the alkaline solution extracted with ether, filtered from the impure dianisyltetrylene, and acidified strongly with hydrochloric acid, whereon anisylisocrotonic acid and dianisylpentolic acid are precipitated, and can be easily separated by treating the mixture with hot water, in which the former alone is soluble.

Anisylisocrotonic acid separates from water in colourless plates, melts at 106·5°, and is readily soluble in ether, alcohol, and chloroform, and moderately easily in hot water, but only sparingly in carbon bisulphide, and very sparingly in cold water. It is isomeric with the paramethoxyphenylcrotonic acid obtained by Perkin (Trans., 1877, 411) from anisaldehyde and propionic acid. The *barium* salt, $(C_{11}H_{11}O_3)_2Ba + 3H_2O$, crystallises from hot water in plates, and is only moderately easily soluble in cold water; the *calcium* salt, with $2H_2O$, crystallises from water in needles, and is more sparingly soluble than the barium salt; the *silver* salt, $C_{11}H_{11}O_3Ag$, is only sparingly soluble in boiling water. The acid is not reduced by sodium amalgam; it combines with concentrated hydrobromic acid at 0°, yielding a crystalline compound which is very unstable.

Anisylbromobutyrolactone,  $\mathrm{OMe{\cdot}C_6H_4{\cdot}CH}<\begin{matrix}\mathrm{CHBr{\cdot}CH_2}\\ \mathrm{O\text{———}CO}\end{matrix}$, can be prepared by treating anisylisocrotonic acid with bromine (1 mol.) in cold carbon bisulphide solution, and keeping the crystalline dibromo-acid, $C_{11}H_{13}Br_2O_3$, thus produced for a few days; as soon as the evolution of hydrogen bromide is at an end, the lactone is recrystallised from chloroform or glacial acetic acid, from which it separates in well-defined, monosymmetric crystals, $a : b : c = 1{\cdot}6554 : 1 : 0{\cdot}5997$, $\beta = 85° 56'$, melting at 118·5°.

Anisylbutyrolactone,  $\mathrm{OMe{\cdot}C_6H_4{\cdot}CH}<\begin{matrix}\mathrm{CH_2{\cdot}CH_2}\\ \mathrm{O\text{—}CO}\end{matrix}$, prepared by reducing the preceding compound with sodium amalgam in cold alcoholic glacial acetic acid solution, crystallises from boiling water in plates, melts at 53·5°, and is readily soluble in ether, carbon bisulphide, and chloroform, but only very sparingly in light petroleum, and insoluble in sodium carbonate; it has a slight aromatic odour, and is only very slightly volatile with steam.

Barium anisylhydroxybutyrate is obtained when the lactone is boiled with a solution of barium hydroxide; it is a brittle, amorphous compound moderately easily soluble in water and alcohol. When an aqueous solution of the barium salt is acidified, extracted with ether, and the ethereal solution evaporated, the hydroxy-acid remains as a solid, colourless mass; it melts at about 80°, probably with decomposition, and is completely reconverted into the lactone on warming with dilute hydrochloric acid.

Dianisylpentolic acid, $OMe{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}C(COOH){:}CH{\cdot}C_6H_4{\cdot}OMe$ (see above), crystallises from glacial acetic acid in long, yellow needles, melts at 160°, and is almost insoluble in water and only very sparingly soluble in carbon bisulphide, but moderately easily in alcohol, ether, chloroform, and benzene. The *barium* salt $(C_{19}H_{17}O_4)_2Ba + 2H_2O$ crystallises from hot, dilute alcohol in colourless plates, and is almost insoluble in water; the anhydrous salt is yellow. The *calcium* salt, with $3H_2O$, resembles the barium salt; the *silver* salt, $C_{19}H_{17}O_4Ag$, is almost insoluble in water. Dianisylpentolic acid does not combine with concentrated hydrobromic acid at 0°; when treated with bromine (2 mols.) in chloroform solution, hydrogen bromide is evolved, and a compound of the composition $C_{19}H_{17}Br_3O_4$ is obtained. This substance melts at 140° with decomposition, and is doubtless a brominated lactone.

Dianisylpentylenic acid,

$$OMe{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}CH(COOH){\cdot}CH_2{\cdot}C_6H_4{\cdot}OMe,$$

is obtained by reducing the pentolic acid with sodium amalgam in alkaline solution. It crystallises from benzene with 1 mol. of benzene, and from carbon bisulphide in colourless needles melting at 111°; it is readily soluble in alcohol, ether, and benzene, but only sparingly in carbon bisulphide, light petroleum, and water. The *calcium* salt, $(C_{19}H_{19}O_4)_2Ca + 2H_2O$, is almost insoluble in water, and is not easily obtained in crystals; the *silver* salt, $C_{19}H_{19}O_4Ag$, is almost insoluble in water.

Dianisylbromopentalactone,

$$\mathrm{OMe{\cdot}C_6H_4{\cdot}CH}<\substack{\mathrm{CHBr}\\ \mathrm{O{-}CO}}>\mathrm{CH{\cdot}CH_2{\cdot}C_6H_4{\cdot}OMe},$$

is obtained by treating dianisylpentylenic acid with bromine in cold carbon bisulphide solution, and dissolving the impure dianisyldibromovaleric acid, $C_{19}H_{20}Br_2O_4$, thus produced, in glacial acetic acid. It crystallises in colourless needles, melts at 136°, and is insoluble in cold alkaline carbonates.

Dianisylpentalactone,

$$\mathrm{OMe{\cdot}C_6H_4{\cdot}CH}<\substack{\mathrm{CH_2{-}}\\ \mathrm{O{\cdot}CO}}>\mathrm{CH{\cdot}CH_2{\cdot}C_6H_4{\cdot}OMe},$$

prepared by treating the bromo-lactone with sodium amalgam in acetic acid solution, separates from acetic acid in small, prismatic crystals, melts at 83°, and is readily soluble in ether, chloroform, and carbon bisulphide, but insoluble in sodium carbonate.

Barium dianisylhydroxyvalerate is obtained as a gummy mass by boiling the lactone with baryta-water; when decomposed with acids, it yields the hydroxy-acid as a colourless, crystalline compound.

Dianisyltetrylene, $OMe{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}CH{:}CH{\cdot}C_6H_4{\cdot}OMe$, is obtained in a pure condition by washing the impure residue referred to above with warm water; it separates from benzene in colourless crystals with a violet fluorescence, and is almost insoluble in water, alcohol, and ether, and only sparingly soluble in carbon bisulphide, but more readily in glacial acetic acid, chloroform, and benzene. It sinters together at 225°, and does not melt completely until 235—238°. This compound can also be obtained by distilling dianisylpentolic acid with lime; when boiled with potassium permanganate, it yields anisic acid. The *tetrabromide*, $C_{18}H_{18}Br_4O_2$, is a colourless, crystalline compound very sparingly soluble in carbon bisulphide, more readily in chloroform; it is decomposed by boiling chloroform, or when heated alone, with evolution of hydrogen bromide. F. S. K.

Action of Ethyl Sodacetoacetate on Tribromodinitrobenzene. By C. L. JACKSON and G. D. MOORE (*Amer. Chem. J.*, **12**, 164—181; compare Abstr., 1889, 781).—Details are first given of a slightly improved method of preparing tribromodinitrobenzene from aniline, by means of which a nearly quantitative yield was obtained.

Ethyl bromodinitrophenylacetoacetate,

$$C_6H_2Br(NO_2)_2{\cdot}CH(COMe){\cdot}COOEt,$$

was prepared by adding an alcoholic solution of ethyl sodacetoacetate (about 4 mols.) to a solution of tribromodinitrobenzene (1 mol.) in benzene. The mixture was heated for an hour on the steam-bath, and then mixed with water; the reddish benzene solution which was precipitated was removed from the dark-red aqueous solution, and the latter was made slightly acid with sulphuric acid in order to decompose the sodium salt of the new substance. This separated as a yellowish oil which was extracted with ether, and left, after evaporation of the ether, a dark, reddish-brown oil, which solidified to a mass of crystals. These were freed from adhering red oil by washing with alcohol, and were then recrystallised from this solvent. A further quantity was obtained from the benzene solution, but the average yield was only about 50 per cent. of the theoretical; probably much of the substance remained dissolved in the red oil. From the analogous reaction of tribromodinitrobenzene with ethyl sodiomalonate (compare this vol., p. 377), it is shown that ethyl bromodinitrophenylacetoacetate must have the formula given above, and not $C_6HBr(NO_2)_2:C(COMe)\cdot COOEt$. It is yellow, and crystallises in acute rhombohedra, or in prisms which show a tendency to twin. It melts at 96°, and dissolves in most solvents except water and light petroleum; hot alcohol is the best solvent. It has marked acid properties, giving red solutions with aqueous ammonia, soda, or potash; the sodium salt was obtained as a brick-red, amorphous mass; salts of the heavy metals formed yellow or reddish precipitates.

Bromodinitrobenzyl methyl ketone, $C_6H_2Br(NO_2)_2\cdot CH_2\cdot COMe$, was prepared by boiling ethyl bromodinitrophenylacetoacetate for an hour in a reflux apparatus with sulphuric acid (of sp. gr. 1·44 and boiling point 132°), and purifying the white precipitate which separated on cooling by crystallisation from alcohol. It can also be prepared, although less advantageously, by heating the ethereal salt at 130—150° with hydrochloric acid in a sealed tube. No bromodinitrophenylacetic acid is formed. The ketone crystallises from alcohol in white, rectangular plates or in tufts of needles, melts at 112—113°, and is soluble in the usual solvents, water and light petroleum excepted. It has well-marked acid properties, and gives with aqueous soda or ammonia a red solution, the colour of which is intensified by the addition of alcohol.

Anilidodinitrobenzyl methyl ketone, $NHPh\cdot C_6H_2(NO_2)_2\cdot CH_2\cdot COMe$, was prepared by warming a mixture of aniline (2 mols.) with bromodinitrobenzyl methyl ketone (1 mol.), washing the product with water, and crystallising from alcohol. It forms bright-yellow groups of curved needles melting at 131°, and dissolves in most solvents except light petroleum; its aqueous solution has a yellow colour. It has somewhat feeble acid properties, and gives with soda a brownish-red solution, but only if alcohol is present; the sodium salt was obtained as a brownish-black mass; its alcoholic solution is much browner than that of the other salts mentioned in this paper.

Anilidodinitrobenzyl methyl ketone hydrazone,

$$NHPh\cdot C_6H_2(NO_2)_2\cdot CH_2\cdot CMe:N_2HPh,$$

was made by warming anilidodinitrobenzyl methyl ketone with excess of phenylhydrazine. A tarry mass was obtained which was crystallised from alcohol, washed free from excess of phenylhydrazine with very dilute hydrochloric acid, and boiled with alcohol, enough benzene being then added to effect solution; on cooling, crystals were deposited, and were purified by recrystallisation. It forms reddish-brown scales (resembling officinal ferric citrate) which melt at 140°, and dissolve in many solvents, but not to any extent in light petroleum, water, or ether. It has no acid properties. C. F. B.

Lactam-formation in the Fatty Series; Identity of Citraconanil and Pyranilpyroïnlactone. By R. Anschütz (*Ber.*, 23, 887—896).—β-Anilidopyrotartaric acid is best prepared by treating the additive compound of ethyl acetoacetate and hydrogen cyanide with aniline in ethereal solution, and keeping for three to four weeks at the ordinary temperature (compare Schiller-Wechsler, Abstr., 1885, 900); the ether is then separated and the product treated with concentrated sulphuric acid. 85 grams of ethyl anilidopyrotartramate is obtained in this way from 100 grams of ethyl acetoacetate, and the ethereal salt, on hydrolysis, yields β-anilidopyrotartaric acid, which separates from water in anhydrous, prismatic crystals, or in crystals containing 1 mol. H_2O, according to the conditions under which crystallisation takes place. When the acid is heated at 180° in sealed tubes, or distilled under a pressure of 12 mm., it is converted into citraconanil (m. p. 98°) which is identical with Reissert's pyranilpyroïnlactone in all respects. When the citraconanil, obtained in this way, is dissolved in warm baryta-water, it is converted into mesaconanilic acid.

When β-anilidopyrotartaric acid is treated with acetic chloride, it is converted into a compound melting at 136°, which seems to be the anhydride. F. S. K.

Benzylsuccinic Acid and its Homologues. By C. A. Bischoff and N. Mintz (*Ber.*, 23, 653—656).—*Ethyl benzylethenyltricarboxylate*, $COOEt\cdot CH_2\cdot C(C_7H_7)(COOEt)_2$, can be prepared from ethyl sodioethenyltricarboxylate and benzyl chloride; it boils at 336·3° (corr.) (at 230—238°; 38 mm.), and, on hydrolysis, yields benzylethenyltricarboxylic acid which melts at 168·5° with evolution of gas, being converted into benzylsuccinic acid (m. p. 161°).

Ethyl benzylpropenyltricarboxylate,

$$COOEt\cdot CHMe\cdot C(C_7H_7)(COOEt)_2,$$

prepared from ethyl sodiopropenyltricarboxylate and benzyl chloride, boils at 337·8° (corr.) and, on hydrolysis, yields a mixture of benzylmethylsuccinic acid (m. p. about 135°) and benzylpropenyltricarboxylic acid. Benzylmethylsuccinic anhydride, prepared by distilling the acid, is a crystalline compound melting at 110°.

Ethyl benzylbutenyltricarboxylate, $COOEt\cdot CHEt\cdot C(C_7H_7)(COOEt)_2$, prepared from ethyl sodiobutenyltricarboxylate in like manner, boils at 336·1° (corr.), and, on hydrolysis, gives symmetrical parabenzylethylsuccinic acid (m. p. 157·5°) and symmetrical mesobenzylethylsuccinic acid (m. p. 123·5°).

Ethyl benzylisobutenyltricarboxylate,

$$COOEt\cdot CMe_2\cdot C(C_7H_7)(COOEt)_2,$$

prepared from ethyl sodioisobutenyltricarboxylate and benzyl chloride, boils at 336·6° (corr.), and on hydrolysis yields benzyldimethylethenyltricarboxylate together with small quantities of benzyldimethylsuccinic acid (m. p. 153—155°) and an acid of lower melting point, probably the dynamical isomeride. F. S. K.

Benzaldehyde and Pyrotartaric Acid. By R. Fittig and L. Liebmann (*Annalen*, **255**, 257—275; compare this vol. pp. 583—594, and Penfield, Abstr., 1883, 473).—Two isomeric methylphenylparaconic acids are formed when benzaldehyde is heated with sodium pyrotartrate and acetic anhydride for 20 hours at 100°. The product is treated with warm water, the solution rendered alkaline with soda, extracted with ether to free it from benzaldehyde and resinous products, then concentrated by evaporation, and strongly acidified. The precipitated acids are separated, dried, dissolved in chloroform, and the insoluble pyrotartaric acid separated by filtration; the chloroform solution is then evaporated, the residue digested with hot carbon bisulphide, which removes traces of impurities, and then recrystallised from 80 per cent. alcohol, in which the α-acid is more sparingly soluble than the β-compound.

α-Methylphenylparaconic acid,  $\mathrm{CO}<\begin{array}{l}\mathrm{O}\text{——}\mathrm{CHPh}\\ \qquad\qquad\ \ | \\ \mathrm{CHMe{\cdot}CH{\cdot}COOH}\end{array}$, forms monoclinic crystals, $a : b : c = 1·080 : 1 : 1·082$, $\beta = 65° 26'$, and melts at 177°. The *barium* salt, $(C_{12}H_{11}O_4)_2Ba + H_2O$, is prepared by treating an aqueous solution of the acid with barium carbonate in the cold. It forms small crystals, and is moderately easily soluble in water. The *calcium* salt, with H_2O, resembles the barium salt. The free acid is not acted on by fuming hydrobromic acid, as stated by Penfield. On distillation, α-methylphenylparaconic acid gives benzaldehyde, phenylbutylene, α-methylphenylisocrotonic acid, methylnaphthol, and traces of a lactone, but a considerable quantity of the acid passes over unchanged; the distillation-products are separated as follows:—The distillate is rendered alkaline with sodium carbonate, the neutral compounds extracted with ether, the residual solution acidified, and the precipitated acids extracted with ether; the acid mixture is then distilled with water, whereon α-methylphenylisocrotonic acid passes over, whilst the unchanged paraconic acid remains.

α-Methylphenylisocrotonic acid, CHPh:CH·CHMe·COOH, crystallises from boiling water in large, indented plates, melts at 110·5°, and is readily soluble in alcohol, ether, and carbon bisulphide. The *barium* salt, $(C_{11}H_{11}O_2)_2Ba + H_2O$, is very readily soluble in cold water, from which it separates in colourless needles. When the acid is treated with concentrated hydrobromic acid at 0°, it yields an oil, which is probably impure phenylbromohydrotiglic acid, as it dissolves in cold sodium carbonate, and, on warming, the solution becomes turbid owing to the separation of an oily lactone.

Methylnaphthol is obtained by repeatedly shaking the ethereal extract (see above) with dilute soda, saturating the alkaline solution with carbonic anhydride, and recrystallising the precipitated methylnaphthol from hot water. It crystallises in long yellow needles, melts at 89°, and is very sparingly soluble in water. It gives with ferric chloride a colourless precipitate which, on keeping, gradually turns yellow, and with a solution of bleaching powder, a very characteristic green precipitate which quickly turns yellow. When distilled with zinc-dust, it yields β-methylnaphthalene (m. p. 37—38°) identical with the compound obtained from β-methylphenylparaconic acid (see below) in like manner.

β-Methylphenylparaconic acid,  $CO<\begin{matrix}O—CHPh\\ CH_2·CMe·COOH\end{matrix}$, separates from dilute alcohol in monoclinic crystals, $a : b : c = 1·278 : 1 : 1·2345$, $\beta = 82° 15'$, and melts at 124·5°. The *barium* salt, prepared in the cold, separates from water in anhydrous crystals. The *calcium* salt ($+ 2H_2O$) crystallises in needles and is readily soluble in water. The *silver* salt is readily soluble in warm water, and is very stable.

Barium β-methylphenylitamalate, $C_{12}H_{12}O_6Ba$, prepared by boiling the lactone acid with baryta-water, crystallises from water, in which it is moderately easily soluble, in small plates. The *calcium* salt, with H_2O, resembles the barium salt. The *silver* salt ($C_{12}H_{12}O_6Ag_2$) is amorphous and less stable than the corresponding salt of the lactone acid.

β-Methylphenylparaconic acid combines with concentrated hydrobromic acid at 0°, yielding a crystalline compound which melts at 149° with decomposition, and has the composition $C_{12}H_{13}BrO_4$; this compound is doubtless identical with the bromo-acid described by Penfield (*loc. cit.*), who erroneously considered it to be a derivative of the α-lactone acid; when warmed with water, it is decomposed with evolution of carbonic anhydride, yielding β-methylphenylparaconic acid and β-methylphenylisocrotonic acid. When β-methylphenylparaconic acid is distilled, it yields phenylbutylene, β-methylphenylisocrotonic acid, benzaldehyde, a methylnaphthol, and small quantities of a lactone, but a considerable quantity of the acid passes over unchanged.

β-Methylphenylisocrotonic acid, $CHPh{:}CMe·CH_2·COOH$, crystallises from hot water in colourless plates, melts at 112—113°, and is readily soluble in alcohol, ether, benzene, and carbon bisulphide, but only sparingly in boiling water. The *barium* salt, $(C_{11}H_{11}O_2)_2Ba$, crystallises from water, in which it is moderately easily soluble, in slender, anhydrous needles.

Phenylbromisovaleric acid, $CHPhBr·CHMe·CH_2·COOH$, was obtained as an oil by treating the preceding compound with concentrated hydrobromic acid at 0°; it dissolves in cold sodium carbonate, but, on warming, the solution becomes turbid owing to the separation of *phenylisovalerolactone*,  $CO<\begin{matrix}O—CHPh\\ CH_2·CHMe\end{matrix}$.

Barium phenylhydroxyvalerate, $(C_{11}H_{13}O_3)_2Ba$, is obtained as a syrup when the lactone is boiled with baryta-water.

β-Methyl-α-naphthol, $C_{11}H_{10}O$, crystallises from boiling water in colourless needles, melts at 92°, and is readily volatile with steam; it gives the same reaction with ferric chloride and with a solution of bleaching powder as the methylnaphthol obtained from α-methylphenylparaconic acid. When distilled with zinc-dust, it yields meth naphthalene (m. p. 37—38°) identical with the compound (m. p. 32·5°) described by Schulze (Abstr., 1884, 1185).

Phenylbutylene, $C_{10}H_{12}$, is a colourless oil boiling at 181° (thermometer entirely in vapour); it combines with bromine yielding a yellowish. oily dibromide, $C_{10}H_{12}Br_2$. This hydrocarbon is probably identical with the compound prepared from benzaldehyde and isobutyric acid (Perkin, Trans., 1877, 660), and also with that obtained from phenylhydroxypivalinic acid by Fittig and Jayne (Abstr., 1883, 471; 1885, 663). F. S. K.

Salicylaldehyde and Pyrotartaric Acid. By R. FITTIG and H. C. BROWN (*Annalen*, **255**, 285—292; compare preceding abstract).—*Coumarinpropionic acid*,  $C_6H_4<\begin{array}{l}\text{O—CO}\\ \text{CH:C·CHMe·COOH}\end{array}$, is formed, together with orthohydroxyphenylmethylisocrotonic acid (see below), when salicylaldehyde is heated at 120° for 20 to 30 hours with sodium pyrotartrate and acetic anhydride. The mixture is treated with water, the products extracted with ether, and submitted to distillation with steam in order to get rid of the salicylaldehyde. The residual solution is evaporated to dryness to expel the acetic acid, dissolved in warm sodium carbonate, the filtered solution acidified with hydrochloric acid, and the precipitated acids extracted with ether; after evaporating the ether, an oil remains from which the coumarinpropionic acid gradually separates in crystals, whilst the hydroxyphenylmethylisocrotonic acid remains in a liquid condition.

Coumarinpropionic acid crystallises from boiling water in colourless plates, melts at 171°, and is very readily soluble in chloroform, but only sparingly in ether and cold water, and almost insoluble in benzene. The *barium* salt, $(C_{12}H_9O_4)_2Ba + 3H_2O$, is obtained by boiling an aqueous solution of the acid with barium carbonate; it forms colourless crystals, and is readily soluble in water. The *calcium* salt, with $5H_2O$, is a crystalline compound readily soluble in water. The *silver* salt, $C_{12}H_9O_4Ag$, is moderately easily soluble in water, and very stable.

Ethylcoumarin,  $C_6H_4<\begin{array}{l}\text{O—CO}\\ \text{CH:CEt}\end{array}$, is formed, with evolution of carbonic anhydride, when coumarinpropionic acid is distilled; it melts at 70—71°, and is identical with the butyrocoumarin prepared by Perkin (Trans., 1881, 439) from salicylaldehyde and butyric acid.

Orthohydroxyphenyldimethylsuccinic acid,

$$OH·C_6H_4·CH_2·CH(COOH)·CHMe·COOH,$$

is obtained when coumarinpropionic acid is reduced with sodium amalgam in warm aqueous solution, the solution being kept as neutral as possible; it crystallises well from water, and melts at 145—150°, being converted into the anhydride (or lactone). It is readily soluble in water, alcohol, ether, and chloroform, but only sparingly in carbon bisulphide and benzene, and almost insoluble in light petroleum. The *anhydride* (or *lactone*), $C_{12}H_{12}O_4$, is formed when the acid is heated at 120°; it is gradually decomposed by water. The *barium* salt,

$C_{12}H_{12}O_5Ba$, prepared by neutralising the acid with barium carbonate, is amorphous, and is very readily soluble in water, but insoluble in alcohol; the *calcium* salt, $C_{12}H_{12}O_5Ca$, and the *silver* salt, $C_{12}H_{12}O_5Ag_2$, are also amorphous.

Orthohydroxyphenylmethylisocrotonic acid, $C_{11}H_{12}O_3$, is obtained in a pure condition by means of the crystalline barium salt. It separates from carbon bisulphide and from a mixture of benzene and light petroleum in large plates, melts at 73°, and is very readily soluble in chloroform and benzene, but only moderately easily in carbon bisulphide, and almost insoluble in light petroleum; when treated with a little water, it deliquesces to a colourless oil, but does not dissolve to any appreciable extent. The *barium* salt, $(C_{11}H_{11}O_3)_2Ba + 4H_2O$, crystallises in needles, and is very readily soluble in water, but insoluble in alcohol. The *calcium* salt, $(C_{11}H_{11}O_3)_2Ca$, is a syrup, very readily soluble in both water and alcohol. The *silver* salt, $C_{11}H_{11}O_3Ag$, is only sparingly soluble in, and is decomposed by, boiling water.

F. S. K.

Acids Obtained by Heating Metahydrazobenzoic Acid with Stannous Chloride. By R. KUSSEROW (*Ber.*, **23**, 912—918).—When metahydrazobenzoic acid (1 mol.) is warmed for a long time with stannous chloride (1 mol.) in aqueous solution, it is almost completely converted into diamidodiphenic acid, which passes into solution, but a small quantity of an insoluble substance containing tin remains. When this residue is boiled with sodium carbonate, and the filtered solution allowed to cool, a sparingly soluble sodium salt separates in colourless needles, and the mother liquors contain the sodium salt of another acid. The acid obtained from 300 grams of nitrobenzoic acid yields 35 grams of the mixed sodium salts.

The *acid* $C_{14}H_{12}N_2O_4$ separates in lemon-yellow needles when a solution of the sparingly soluble sodium salt is decomposed with hydrogen sulphide; it melts above 290°, and is almost insoluble in water and alcohol. The *sodium* salt, $C_{14}H_{11}N_2O_4Na + 4H_2O$, loses its water at 180°, and is moderately easily soluble in hot, but only sparingly in cold water. The *potassium* salt crystallises in colourless needles, and seems to be rather more readily soluble than the sodium salt. The *barium* salt, $(C_{14}H_{11}N_2O_4)_2Ba + 2H_2O$, crystallises in yellowish, microscopic needles, loses its water, and becomes colourless at 200°, and is almost insoluble in water. The *silver* salt is almost insoluble in hot water, and darkens when exposed to light in a moist condition. The *hydrochloride*, $C_{14}H_{12}N_2O_4,HCl$, *hydrobromide*, and *hydriodide* crystallise in colourless, microscopic needles, and are decomposed by water. The *sulphate*, $(C_{14}H_{12}N_2O_4)_2,H_2SO_4$, crystallises in small, colourless needles, and is decomposed by boiling water. The acid is not changed on prolonged boiling with soda or by concentrated hydriodic acid at 170°. The *diazo*-compound is a light-brown, unstable, crystalline powder which is decomposed on warming with water or alcohol. The *hydrazine*-derivative, prepared by reducing the diazo-compound with stannous chloride, is a colourless, amorphous substance very sparingly soluble in boiling water, and insoluble in alcohol.

The *acid* $C_{14}H_{10}N_2O_3$ is obtained when the mother liquors from the sparingly soluble sodium salt (see above) are evaporated, and the crystalline sodium salt decomposed with hydrochloric acid; it crystallises from hot water in needles, and does not melt when heated on platinum foil. The *barium* salt, $(C_{14}H_9N_2O_3)_2Ba + 9H_2O$?, crystallises in needles, and is very sparingly soluble in water. The *silver* salt is very sparingly soluble in water, and darkens when exposed to light in a moist condition. The salts are not decomposed by hydrogen sulphide, and their solutions show a blue fluorescence. The *hydrochloride*, $C_{14}H_{10}N_2O_3,HCl$, crystallises in microscopic needles, and is decomposed by water. The *diazo*-compound seems to be moderately stable.

F. S. K.

Sulphonic Derivatives of Parapropylmetachlorotoluene. By G. CARRARA (*Gazzetta*, **19**, 169—175).

—The following experiments were made with a view of preparing the thiosulpho- and thiochloro-derivatives of cymene by fusing the chlorosulphonic acids with potassium sulphide.

Chlorocymene prepared from thymol and phosphoric chloride by Fileti and Crosa's method is converted into the sulphonic acid by Paterno and Canzoneri's method. Chlorhydrin sulphate (48·5 grams) is gradually added to chlorocymene (70 grams), and heated on the water-bath until no more hydrogen chloride is evolved, the residue, which consists of a yellowish oil and a white crystalline mass, is treated with 98 per cent. alcohol, by which the former is completely dissolved out. The insoluble part crystallises from 98—99 per cent. alcohol or from ether in prisms which melt at 64°, and volatilise with partial decomposition at 197°. It is insoluble in water or in a 20 per cent. solution of potash, only very sparingly soluble in cold alcohol, and moderately in absolute alcohol and ether. It has the composition $C_{10}H_{12}Cl_2SO_2$. On neutralising the aqueous extract mentioned above with barium carbonate, and submitting the barium compounds to fractional crystallisation, a salt which has the composition $(C_{10}H_{12}Cl{\cdot}SO_3)_2Ba + 3Aq$ is obtained as a uniform mixture of oblique prisms and rhomboidal tables. It is soluble in dilute alcohol, and very sparingly in water. The lead salt forms lustrous, nacreous plates containing 3 mols. H_2O. It is soluble in dilute alcohol, and very sparingly in water. The silver salt forms white prisms containing ½ mol. H_2O. On exposure to light, they are first turned red, and subsequently blackened. It is soluble in water.

Chlorocymenesulphonic acid, $C_{10}H_{12}Cl{\cdot}SO_3H + 3Aq$.—On decomposing the lead or barium salts, separating the metals, and evaporating the residual solutions to dryness, the acid is obtained as a crystalline mass consisting of small, white prisms. If the solution is concentrated to a syrup, and left for a few days at a temperature of about 4°, it separates out in large, colourless, transparent, oblique prisms. It becomes anhydrous when exposed over sulphuric acid in a vacuum, but again takes up the 3 mols. H_2O on exposure to the air for a short time. It melts at 24° when hydrated, and at 79° when anhydrous; it turns brown when heated above 110°. It is freely soluble in water, alcohol, ether, benzene, and hot carbon bisulphide.

Nitro-derivative.—The silver salt of this compound is obtained by evaporating a mixture of the sulphonic acid with nitric acid (sp. gr. = 1·38) to dryness three times in succession, heating with water to expel the nitric acid, neutralising with silver carbonate, and fractionally crystallising. The portion which separates out first contains lustrous, yellow needles of silver nitrochlorocymenesulphonate, $C_{10}H_{11}(NO_2)Cl·SO_3Ag + H_2O$. S. B. A. A.

Preparation of Sulphones. By R. OTTO and A. RÖSSING (*Ber.*, 23, 752—759).—It has previously been shown by R. and W. Otto (Abstr., 1888, 282) that the mono-haloïd substitution-products of ketones are readily converted by the action of the salts of sulphinic acids into sulphoneketones, according to the equation

$$CH_2Cl·CO·CH_3 + SO_2PhNa = NaCl + SO_2Ph·CH_2·CO·CH_3.$$

If the monobromo-derivative of the phenylsulphonacetone thus obtained be further treated with sodium benzenesulphinate, it is converted into sodium chloride and symmetrical diphenylsulphonacetone, $SO_2Ph·CH_2·CO·CH_2·SO_2Ph$.

The authors have endeavoured to find other methods of preparing sulphoneketones, but obtained only negative results from the action of chloracetone on methylphenylsulphone, of benzenesulphonic chloride on acetone, and of benzenesulphonic acid and acetone in presence of phosphoric anhydride, and of acetic chloride and chloracetone on ethyl sodiophenylsulphonacetate. From ethyl chloracetate and sodium benzenesulphonate, phenylsulphonacetic acid was obtained, the acetyl-group being eliminated as acetic acid.

Positive results were, however, obtained by replacing hydrogen in ketones by a mercaptan residue, and oxidising the compound thus formed with potassium permanganate. Chloracetone and sodium phenylmercaptide act readily on one another in alcoholic solution at 100°, according to the equation—

$$COMe·CH_2·Cl + SPhNa = NaCl + COMe·CH_2·SPh.$$

The oily product, after mixing with a little benzene, is well shaken with a 3 per cent. solution of permanganate; dilute sulphuric acid being occasionally added, until the solution remains permanently red. After removing the permanganate by alcohol, the solution is extracted with ether, and the semi-crystalline mass recrystallised from alcohol. The compound thus prepared is identical with the phenylsulphonacetone previously prepared by R. and W. Otto. The aqueous solution, after extraction with ether, contains acetic and benzenesulphonic acids, which are products of the further oxidation of phenylsulphonacetone.

Ethyl thiophenylacetoacetate, $SPh·CHAc·COOEt$, obtained from sodium phenylmercaptide and ethyl chloracetoacetate, on oxidation, gives carbonic anhydride, acetic acid, and phenyl bisulphide.

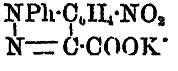
Dichlorhydrin is acted on by sodium phenylmercaptide with formation of a disulphone, $OH·CH(CH_2·SPh)_2$, which is oxidised by potassium permanganate to *symmetrical diphenylsulphonisopropyl alcohol*, $OH·CH(CH_2·SO_2Ph)_2$, a yellow oil insoluble in water, but readily soluble in alcohol and ether. Its *benzoate*, $C_{22}H_{20}OS_2O_6$,

crystallises from alcohol in needles melting at 149—150°. The corresponding ketone, $CO(CH_2\cdot SO_2\cdot Ph)_2$, cannot be obtained by further oxidation, as it then splits up into acetic acid and benzenesulphonic acid.
H. G. C.

Replacement of the Sodium in Ethyl Sodiophenylsulphoneacetate by Alkyls. By A. Michael (*Ber.*, **23**, 669—671).—The author has repeated some of the experiments on the synthesis of homologues of ethyl phenylsulphoneacetate which were previously carried out conjointly with Palmer and Comey (Abstr., 1884, 319; 1885, 986), as his results were called into question by Otto and Rössing (Abstr., 1889, 994); he points out that they were unable to obtain ethyl α-phenylsulphonebutyrate, for the simple reason that they used alcohol containing water, and in doing so neglected to follow his directions.
F. S. K.

Analogy of Ketonic Acids to Sulphonecarboxylic Acids. By A. Rössing (*J. pr. Chem.* [2], **41**, 369—396).—The action of various substances, whose behaviour with ethyl acetoacetate (as a typical ketonic acid) is known, on phenylsulphonacetic acid, ethyl sodiophenylsulphonacetate, and sodium benzenesulphinate was tried. The author summarises the results of his experiments as follows:—(1) β-Sulphonecarboxylic acids ($R\cdot SO_2\cdot CH_2\cdot COOH$) are not split up into other acids by the action of alkalis. (2) The sodium in ethyl sodiophenylsulphonacetate cannot be displaced by acid radicles. Substituted ethereal salts, containing an acetyl- and a sulphone-group, united to the same carbon-atom, cannot be obtained by acting on sodium benzenesulphinate with ethyl mono- or di-chloracetoacetate. (3) The action of iodine on ethyl sodiophenylsulphonacetate in the presence of water in alcoholic solution produces only iodomethylphenylsulphone, and not an ethyl diphenylsulphonesuccinate, nor can a diphenylsulphonesuccinic acid be obtained by the action of sodium benzenesulphinate on mono- or di-bromosuccinic acid. (4) Ethyl chloroxalate decomposes benzene sulphinate, forming carbonic anhydride, phenyl benzenethiosulphonate, and diethyl oxalate; a little ethyl phenylketonesulphonate is formed at the same time. (5) Nitrous acid acts on phenylsulphonacetic acid, forming a *compound*, $(PhSO_2)_2NHO$, which crystallises in leaflets and melts at 98—99° without decomposition; it is not identical with the substance of the same formula obtained by Königs (Abstr., 1878, 573), and contains no hydroxyl-group. (6) Concentrated nitric acid acts on phenyl-sulphonacetic acid, producing *phenylnitrososulphone*, $PhSO_2NO$, which forms white, vitreous crystals melting at 156—157°, and soluble in hot alcohol, benzene, ether, and glacial acetic acid.
A. G. B.

Indazole-derivatives. By H. Strassmann (*Ber.*, **23**, 714—718).—The author has further examined the reactions of the remarkable compound obtained by Victor Meyer by the action of alkalis on the substance obtained from diazobenzene chloride and ethyl dinitrophenylacetate, to which the provisional constitutional formula



$$\begin{array}{l} NPh\cdot C_6H_4\cdot NO_2 \\ |\qquad\ | \\ N{=}C\cdot COOK \end{array}$$

has been assigned (Abstr., 1889, 516). The compound in question cannot be reduced by any of the usual means; but the conclusion that it does not contain a nitro-group cannot be drawn, as the compound from which it is obtained, and which undoubtedly contains nitro-groups, is equally stable towards the same reagents.

When the methyl salt of the indazole-compound is heated with hydroxylamine hydrochloride and ethyl alcohol in a sealed tube at 160—180° for eight hours, it is converted into a substance which crystallises in orange rhombohedra or yellow needles, and melts at 158°; this was found, however, to consist, not of an oxime, but simply of the ethyl salt. It may also be prepared by substituting hydrochloric acid for hydroxylamine hydrochloride.

Fuming nitric acid acts on the above methyl salt with formation of a mononitro-compound, $C_{15}H_{10}N_2O_4{\cdot}NO_2$, which crystallises from acetic acid in white needles melting at 281°. It dissolves with difficulty in ammonia, yields a yellow, flocculent silver salt, and is readily reduced by zinc and hydrochloric acid, forming an amido-compound which, on the addition of alkali, separates in grey flocks, soluble in concentrated acids. The *hydrochloride* forms small, white plates, and gives with platinous chloride and hydrochloric acid a yellow, micro-crystalline precipitate. The nitrate and sulphate are also white and crystalline.

The compound is quite as stable towards fuming sulphuric acid, which converts it into a sulphonic acid, very sparingly soluble in alcohol, and crystallises from that liquid in slender needles which, on heating, carbonise without melting.

As the compound does not split up when subjected to the action of the strongest reagents, the author has endeavoured to throw some light on its constitution by examining the action of amyl nitrite on ethyl dinitrophenylacetate. The compound obtained agreed in composition with none of the substances which might be expected to be formed in the reaction, and requires further investigation.

H. G. C.

Some new Diphenyl-derivatives By E. TÄUBER (*Ber.*, 23, 794—798).—*Metadinitrobenzidine*, $NH_2{\cdot}C_6H_3(NO_2){\cdot}C_6H_3(NH_2){\cdot}NO_2$ $[(NH_2)_2 : (NO_2)_2 = 4 : 4' : 2 : 6']$, was prepared by dissolving benzidine sulphate in sulphuric acid, and adding potassium nitrate in such quantity as to furnish enough nitric acid for the formation of a dinitro-derivative. The liquid was then poured into water, filtered from a slight precipitate which formed, and saturated with soda or ammonia. The precipitated nitro-compound was collected, dissolved in dilute hydrochloric acid, and, after boiling the solution with animal charcoal, reprecipitated by ammonia, and crystallised repeatedly from alcohol. It melts at 214°, and dissolves in dilute mineral acids, and to some extent in water.

Metadiamidobenzidine, $[(NH_2)_4 = 4 : 4' : 2 : 6']$, was obtained as a hydrochloride by reducing the above dinitro-compound with tin and hydrochloric acid, and removing the tin with hydrogen sulphide. By decomposing the purified hydrochloride with excess of strong aqueous ammonia, the base itself was obtained in small plates melting at 165°. It does not react with orthodiketones, and yields brown colouring matters with nitrous acid and with diazochlorides; hence it is a *meta*-compound. The author prefers the formula $[(NH_2)_4 = 4 : 4' : 2 : 6']$ to $[4 : 4' : 2 : 2']$ for this substance, because it does not give a diamido-carbazol when heated with hydrochloric acid under pressure, as a compound with the latter constitution would be expected to do

Metanitrobenzidine, $NO_2{\cdot}C_6H_3(NH_2){\cdot}C_6H_4{\cdot}NH_2$ $[(NH_2)_2 : NO_2 = 4 : 4' : 2]$, was prepared in a similar manner to the dinitro-compound, half the quantity of potassium nitrate being used. On cooling the solution, yellowish metanitrobenzidine hydrogen sulphate,

$$C_{12}H_{11}N_3O_2,H_2SO_4 + \tfrac{1}{2}H_2O,$$

crystallised out, and was purified by recrystallisation from water. When decomposed by ammonia, it yielded the free nitro-base as an oil, which soon solidified to a red, crystalline mass melting at 143°.

Metamidobenzidine $[(NH_2)_3 : NO_2 = 4 : 4' : 2]$—The hydrochloride of this base was obtained by reducing the nitro-compound with tin and hydrochloric acid. This salt was decomposed by ammonia, and the solution, on being allowed to evaporate spontaneously, deposited the base in long, colourless needles melting at 134°. The brown colouring matters which it yields with nitrous acid and with diazochlorides show that it is a *meta*-compound.

As regards the azo-colouring matters which the above substances yield, it appears that the introduction of one nitro-group in the meta-position with respect to an amido-group weakens the affinity of the dye for the cotton-fibre, whilst the second nitro-group in the meta-position destroys it altogether. C. F. B.

Derivatives of Stilbene and Isostilbene. By V. Redzko (*J. Russ. Chem. Soc.*, 21. 421—430).—In order to find whether the two tolane dichlorides, $C_{14}H_{10}Cl_2$ (α- and β-), are chemically isomeric or only physically, the author has subjected diphenyldichlorethylene, $CPh_2{:}CCl_2$, to the action of hydriodic acid and red phosphorus. On heating a mixture of 2 grams of the dichloride (boiling at 316.5° corr.) with 1 gram of red phosphorus and 30 c.c. of strong hydriodic acid for 20 hours at 170—190°, a mixture of hydrocarbons was obtained, consisting chiefly of diphenylethane and the lower homologues of benzene, the last being products of decomposition of dibenzyl. On changing the conditions of reduction, dibenzyl was obtained. On saturating a solution of tolane in chloroform with chlorine, tolane tetrachloride was obtained

Phosphorus pentachloride was cooled in a retort, and benzoïn added to it; the more volatile products of the violent reaction were removed by distillation, and the residue extracted with ether. In this way, a mixture of chlorobenzile, $C_{14}H_{10}OCl_3$, with α-tolane dichloride was obtained. Chlorobenzile was found to melt at 61—62°. The author has doubts as to whether β-tolane dichloride has the same symmetrical formula as the α-compound. B. B.

Action of Ammonium Formate on Ketones. By R. Leuckart (*J. pr. Chem.*, [2], 41, 330—340; compare Abstr., 1885, 1215; 1886, 1023; 1887, 376; 1889, 883, 1003).—When ammonium formate ($2\frac{1}{2}$ parts) is heated with benzile (1 part) for five hours at 215—220°, the reaction mixture treated with water and crystallised from alcohol, colourless needles or leaflets of benzilam (m. p. 113°) are obtained (70 per cent. of the benzile used); this formation confirms Japp's formula for benzilam (Abstr., 1884, 313). A small quantity of lophine is obtained at the same time.

When ammonium formate is heated with benzoïn at 230°, ditolane-azotide (m. p. 245°; Japp, Trans., 1886, 828) is obtained, and if phenanthraquinone is substituted for benzoïn, diphenanthrylene-azotide (*ibid.*) is formed.

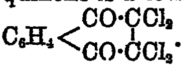
Ammonium formate simply reduces anthraquinone without forming any additive product.

Acetone was heated with ammonium formate for 4—5 hours in a sealed tube at 210°, and the oil formed mixed with soda and distilled with steam. The colourless distillate was acidified with hydrochloric acid, evaporated, mixed with soda, and shaken with ether; the ether was evaporated, and the residual oil distilled, when the following fractions were obtained:—(1) $C_8H_{15}N$, a colourless, strongly refractive, mobile oil, distilling at 155—156°; it is a strong base, and gives coloured precipitates with solutions of metallic salts; its *hydrochloride* and *platinochloride* were obtained. The yield of this fraction is about 9 per cent. of the acetone. (2) $C_{10}H_{19}N$, a yellow oil which gradually becomes brown; it distils between 195° and 200°, is less soluble in water than the first fraction, and is a strong base. It gives coloured precipitates with solutions of metallic salts. (3) $C_{10}H_{19}N$, a yellowish-brown oil, quite insoluble in water and strongly basic. It distils between 260° and 270°.

All these oils have a peculiar, numbing smell, and are undoubtedly closely allied to the pyridine bases. A. G. B.

Tetrachloro-α-diketohydronaphthalene and its Decomposition-products: Orthotrichloracrylbenzoic Acid and Phthalylchloracetic Acid. By T. Zincke and T. Cooksey (*Annalen*, 255, 356—392).

—It has been shown by Zincke and Frölich (Abstr., 1887, 955) that the dichloro-α-naphthachloroquinone obtained by Claus (Abstr., 1886, 714) is, in reality, a ketochloride-derivative of hydronaphthalene, analogously constituted to the compounds prepared from amido-β-naphthol; it was also shown by Zincke and Kegel (Abstr., 1888, 709) that when Claus' dichloro-α-naphthachloroquinone is treated with alcoholic potash, it is converted into an acid identical with the compound obtained from hexachlorodiketohydronaphthalene; this probably has the constitution $CCl_2{:}CCl{\cdot}CO{\cdot}C_6H_4{\cdot}COOH$. The experiments described below prove that this acid has this constitution; it follows, therefore, that Claus' dichloro-α-naphthachloroquinone is a tetrachloro-α-diketohydronaphthalene of the constitution



$$C_6H_4<\begin{matrix}CO{\cdot}CCl_2\\ |\\ CO{\cdot}CCl_2\end{matrix}.$$

Tetrachloro-α-diketohydronaphthalene, prepared by Claus' method (*loc. cit.*), melts at 117°, and is much more stable than the isomeric compounds.

Orthotrichloracrylbenzoic acid, $CCl_2:CCl\cdot CO\cdot C_6H_4\cdot COOH$, crystallises in needles or prisms and melts at 126—127°; the metallic salts cannot be obtained owing to their instability. The *methyl* salt, $C_{11}H_7Cl_3O_3$, crystallises from dilute alcohol in well-defined, colourless prisms, melting at 47—48°. The acid is completely decomposed by water at 140—150°, yielding, besides resinous products, a neutral compound, which crystallises in reddish-brown needles, melts at 270°, and is free from chlorine. It is gradually decomposed by cold alkalis, yielding phthalic acid and trichlorethylene, and when treated with aniline in the cold it is converted into phthalanil (m. p. 203°).

Orthopentachloropropionylbenzoic acid, $CCl_3\cdot CCl_2\cdot CO\cdot C_6H_4\cdot COOH$, is formed when orthotrichloracrylbenzoic acid is heated at 140—150° with manganese dioxide and concentrated hydrochloric acid. It crystallises from glacial acetic acid in prisms, melts at 185—186°, and is moderately easily soluble in alcohol and glacial acetic acid, but almost insoluble in water. It is not acted on by concentrated sulphuric acid at 100°, but when heated alone, it is decomposed into pentachlorethane and phthalic anhydride, which sublimes. It dissolves unchanged in sodium carbonate, but it is immediately decomposed by alkalis yielding phthalic acid and pentachlorethane. The *methyl* salt, $C_{11}H_7Cl_5O_3$, crystallises from dilute alcohol in needles, melts at 78—79°, and is readily soluble in methyl and ethyl alcohol.

Phthalylchloracetic acid,  $CO<^{O\,—}_{C_6H_4}>C:CCl\cdot COOH$, is produced, together with small quantities of an isomeric acid, chloracetophenonecarboxylic acid, and a compound melting at 104—105°, when orthotrichloracrylbenzoic acid is treated with concentrated sulphuric acid at the ordinary temperature. The solution is poured into water, the precipitate separated by filtration, dissolved in sodium acetate, and the boiling solution acidified with hydrochloric acid, whereupon the phthalylchloracetic acid and its isomeride are precipitated in crystals (and can be separated by crystallising from a mixture of benzene and acetic acid), while the chloracetophenonecarboxylic acid remains in the solution and can be isolated by extracting with ether. Phthalylchloracetic acid separates from a mixture of benzene and acetic acid in slender, silky needles, melts at 233—234° with previous softening, and is readily soluble in alcohol and glacial acetic acid, but only sparingly in acetone and benzene, and almost insoluble in light petroleum. It is gradually decomposed by cold sodium carbonate, and quickly by soda, yielding a yellow, resinous compound, but it dissolves unchanged in cold sodium acetate, and, even on boiling, it is only slowly decomposed. When warmed for a long time with concentrated sulphuric acid, it is converted into a neutral substance, probably tribenzoylenebenzene, which melts at 180°; it is readily oxidised by nitric acid of sp. gr. 1·4, with formation of phthalic acid.

The *anilide* of chloracetophenonecarboxylic acid,

$$NHPh\cdot CO\cdot C_6H_4\cdot CO\cdot CH_2Cl,$$

is formed, with evolution of carbonic anhydride, when phthalylchloracetic acid is warmed with aniline in alcoholic solution; it separates from hot alcohol in colourless crystals, melts at 175—176° with decomposition, and is insoluble in water.

Dichloromethylenephthalyl, $CO<\begin{matrix}O\,—\\C_6H_4\end{matrix}>C:Cl_2$, is easily obtained, together with the tetrachloro-compound (see below), by passing chlorine into glacial acetic acid containing phthalylchloracetic acid in suspension until the acid has completely dissolved. It crystallises from hot alcohol in long, slender needles, melts at 128—129°, and is readily soluble in benzene, glacial acetic acid, and light petroleum. When treated with cold alcoholic potash, it is converted into dichloracetophenonecarboxylic acid, identical with the compound obtained by Zincke and Gerland from dichlorodiketohydrindene: when dichloracetophenonecarboxylic acid is warmed with concentrated sulphuric acid, it is reconverted into dichloromethylenephthalyl.

Tetrachloromethylphthalide (tetrachloromethylenephthalyl),

$$CO<\begin{matrix}O\,—\\C_6H_4\end{matrix}>CCl{\cdot}CCl_3,$$

crystallises from dilute alcohol in well-defined, colourless prisms, melts at 93—94°, and is readily soluble in alcohol, glacial acetic acid, and benzene; it is decomposed by alcoholic potash into chloroform and phthalic acid.

The acid $C_{10}H_5ClO_4$, isomeric with phthalylchloracetic acid, is obtained when the mother liquors from the phthalylchloracetic acid (see above) are evaporated to dryness and the residue extracted with hot benzene, in which it is more readily soluble than phthalylchloracetic acid. It crystallises in slender needles, melts at 215—216° with previous softening, and resembles the isomeride in its properties and reactions; when dissolved in cold, concentrated sulphuric acid, it is gradually converted into phthalylchloracetic acid.

Chloracetophenonecarboxylic acid, $COOH{\cdot}C_6H_4{\cdot}CO{\cdot}CH_2Cl$, crystallises from a mixture of ether and light petroleum in thick, colourless needles, melts at 118—119°, and is moderately easily soluble in alcohol, ether, glacial acetic acid, and benzene, but almost insoluble in light petroleum. The *methyl* salt, $C_{10}H_9O.Cl$, crystallises from dilute alcohol in colourless needles melting at 78—79°. When the acid is treated with chlorine in sodium carbonate solution, it is converted into trichloracetophenonecarboxylic acid (m. p. 142°), the *methyl* salt of which crystallises in colourless needles and melts at 127—128°.

A direct comparison of the acid obtained from hexachloroketohydronaphthalene with the orthotrichloracrylbenzoic acid described above proved the identity of the two compounds; the methyl salts of the two acids were also proved to be identical. F. S. K.

Dichloro-α-naphthaquinone Dichloride. By A. Claus (*J. pr. Chem.*, [2], **41**, 285—291).—In this paper the author replies to a paper of Zincke and Cooksey (preceding abstract), in which they are at variance with him as to the constitution and nomenclature of some naphthaquinone-derivatives. A. G. B.

Azimido-compounds. By T. ZINCKE and C. CAMPBELL (*Annalen*, 255, 339—356; compare Zincke and Arzberger, Abstr., 1889, 501). —When amido-β-naphthylphenylamine is treated with acetic acid and sodium nitrite, it yields a tertiary azimide, which has quite different properties from the compound of the same composition which is obtained by the oxidation of benzeneazo-β-naphthylamine. The two substances are therefore isomeric, and each belongs to a distinct class of compounds, which may be named *azimides* and *pseudoazimides* respectively. The azimides contain the atomic complex, $\begin{smallmatrix}-\mathrm{N}\\-\mathrm{NX}\end{smallmatrix}>\mathrm{N}$, and are obtained by the action of nitrous acid on orthodiamines or their derivatives; they contain a hydrogen-atom in combination with nitrogen, which can be displaced by metals, acid radicles, and alkyl-groups, and they can be easily converted into tertiary bases and ammonium hydroxides, or their derivatives. The pseudoazimides contain the atomic complex, $\begin{smallmatrix}-\mathrm{N}\\|\\-\mathrm{N}\end{smallmatrix}>\mathrm{NX}$, and are formed by the oxidation of the orthamidodiazo-compounds and by the decomposition of the diazoimides obtained from the latter; they have not a basic character.

Phenylazimidonaphthalene, $C_{10}H_6<\begin{smallmatrix}-\mathrm{N}\\\mathrm{NPh}\end{smallmatrix}>\mathrm{N}$, is obtained when α-amido-β-naphthylphenylamine, or the hydrochloride thereof, is gradually treated with sodium nitrite in cold glacial acetic acid solution. It can also be prepared by treating amidophenylnaphthylamine with excess of amyl nitrite in well-cooled glacial acetic acid solution, and then evaporating to dryness on the water-bath. It crystallises from hot alcohol in colourless needles, and from glacial acetic acid in prisms, melts at 149—150°, and is almost insoluble in water; it is only very sparingly soluble in concentrated hydrochloric acid, and it does not form a platinochloride. The *methiodide*, $C_{17}H_{14}N_3I$, prepared by heating the base with methyl iodide at 100°, crystallises from hot dilute alcohol in colourless needles, melts at 196° with liberation of methyl iodide, and is only sparingly soluble in alcohol, water, and glacial acetic acid; it combines with iodine yielding a *periodide*, which crystallises in reddish-brown needles melting at 127°. The *methochloride*, $C_{17}H_{14}N_3Cl$, prepared by treating the methiodide with silver chloride, is readily soluble in water and alcohol, and crystallises from the last-named solvent in small, colourless needles melting at 183° with decomposition. The *platinochloride*, $(C_{17}H_{14}N_3Cl)_2PtCl_4$, crystallises in small, yellow plates, melts at about 250—251°, and is only sparingly soluble in hot alcohol and glacial acetic acid, and almost insoluble in water. The *compound* $C_{17}H_{14}N_3Cl,ICl$, prepared from the iodide by Zincke and Lawson's method (Abstr., 1887, 730—731), crystallises in broad, yellow needles or plates, and melts at 138—139°. The *hydroxide*, $C_{17}H_{14}N_3{\cdot}OH$, can only be obtained in solution, and it decomposes when its solutions are evaporated; it has a strongly alkaline reaction and an intensely bitter taste, and it decomposes salts of ammonia, iron, and aluminium.

Ethylphenylnaphthaleneazammonium iodide, $C_{16}H_{11}N_3,EtI$, prepared by heating phenylazimidonaphthalene with ethyl iodide at 100° for 5—6 hours, crystallises in colourless needles, melts at 192° with decomposition, and is moderately easily soluble in hot alcohol, but only sparingly in water. The *periodide* crystallises in brown plates and melts at 113°. The *ethochloride*, $C_{10}H_{11}N_3$,EtCl, obtained by treating the iodide with silver chloride, crystallises in almost colourless needles, melts at 212° with decomposition, and is readily soluble in water and alcohol, but only sparingly in ether. The *platinochloride*, $(C_{18}H_{16}N_3Cl)_2PtCl_4$, crystallises from hot alcohol, in which it is only sparingly soluble, in golden plates, melts at about 264°, and is almost insoluble in water. The *chloriodo*-additive compound forms large, dark-yellow plates melting at 174—176°.

When amidophenylnaphthylamine hydrochloride is treated with amyl nitrite in cold glacial acetic acid solution, the chloro-compound (m. p. 172—173°) previously described by Zincke and Lawson (*loc. cit.*) is obtained.

A compound of the composition $C_{16}H_8N_4O_2$, or $C_{16}H_{10}N_4O_2$, separates in crystals when nitrous acid (prepared from arsenic trioxide and nitric acid) is passed into a well-cooled glacial acetic acid solution of amidophenylnaphthylamine. It crystallises in golden needles, melts at 207—208°, and is readily soluble in hot glacial acetic acid and hot benzene, but only sparingly in hot alcohol; it dissolves in concentrated sulphuric acid yielding a colourless solution, does not give Liebermann's nitroso-reaction, and does not combine with alkyl iodides. When reduced with stannous chloride in warm alcoholic solution, it is converted into a base of the composition $C_{16}H_{12}N_4$; this compound crystallises in colourless needles or plates, melts at 193—194°, and is readily soluble in alcohol, glacial acetic acid, and chloroform, the solutions showing a slight fluorescence. The *hydrochloride*, $C_{16}H_{12}N_4$,HCl, crystallises in colourless needles or plates. The *acetyl*-derivative, $C_{16}H_{11}N_4Ac$, crystallises from hot alcohol, in which it is only sparingly soluble, in colourless needles, melts at 260—261°, and is readily soluble in glacial acetic acid. The *diacetyl*-derivative, $C_{16}H_{10}N_4Ac_2$, is obtained, together with the monacetyl-derivative, by boiling the base for a long time with acetic anhydride and sodium acetate; it crystallises from dilute alcohol in plates, melts at 176—177°, and is readily soluble in glacial acetic acid.

When the hydrochloride of the base (m. p. 193—194°) is suspended in alcohol and treated with a little glacial acetic acid and sodium nitrite, it is converted into a deep-red substance which is almost insoluble in all ordinary solvents, and is reconverted into the base when warmed with a dilute alcoholic solution of stannous chloride.

A compound of the composition $C_{23}H_{16}N_4$ is formed when the base (m. p. 193—194°) is heated with benzaldehyde for a few hours at 130—140°; it crystallises in yellow needles, melts at 137—139°, and is readily soluble in benzene, but only sparingly in light petroleum.

Pseudophenylazimidonaphthalene,  $C_{10}H_6{<}\overset{N}{\underset{N}{|}}{>}NPh$, prepared by the method previously described by Zincke (Abstr., 1886, 244), melts at 107—108°, and is chiefly characterised by its chemical indifference; molecular weight determinations by Raoult's method in glacial acetic acid solution gave results in accordance with the molecular formula $C_{16}H_{11}N_3$. F. S. K.

Amidochrysene. By R. Abegg (*Ber.*, 23, 792—793).—Mononitrochrysene cannot be reduced by the usual agents; hydriodic acid, however, effects the desired result. Pure nitrochrysene, mixed with a little red phosphorus, was gently boiled with hydriodic acid until the original brown colour had changed to grey. The grey powder, evidently the hydriodide of a base, was washed and dried, dissolved in hot alcohol, filtered from unaltered red phosphorus, and treated with concentrated alcoholic potash; the free base, $C_{18}H_{11}\cdot NH_2$, being less soluble in alcohol than its hydriodide, then separated out. It melts at 201—203°, its colour is brown or yellowish-brown, and it dissolves in benzene, nitrobenzene, ether, alcohol, and acetic acid. Its platinochloride, $(C_{18}H_{13}N)_2,H_2PtCl_6$, was obtained as a yellow, crystalline precipitate, which oxidises and turns green when warmed.

Terpenes from the Oil of Pinus abies. By W. Kouriloff (*J. Russ. Chem. Soc.*, 21, 357—367).—Resin from the fir tree (*Pinus abies*) was distilled with steam and the oil subjected to fractional distillation and purification from oxygen compounds. It contains an inactive terpene and a detro-rotatory isoterpene. The author has carefully determined their physical properties, and compares them with optically isomeric compounds obtained previously by Flavitzky (Abstr., 1887, 968).

	Inactive terpene.	Dextro-terpene.	Dextro-isoterpene.	Lævo-isoterpene.
Boiling point	157°	156°	178·3°	176·7°
Spec. rot. power $[\alpha_D]$..	0	+27·5°	+57·6°	47·5°
Density at 0°	0·8748	0·8764	0·8627	0·8627
Density at 20°	0·8589	0·8600	0·8480	0·8529
Coeff. of dilat.........	0·00093	0·00095	0·00089	0·00087
Mol. refrac. $P\frac{A-1}{d}$	71·48	71·24	73·28	73·28

B. B.

Dextrorotatory Terpene from Pinus cembra. By F. Flavitzky (*J. Russ. Chem. Soc.*, 21, 367—375).—A large quantity of the needles of the Siberian cedar (*Pinus cembra*, L.) was subjected to distillation with steam and the oil obtained fractionated and purified. The dextrorotatory terpene hitherto obtained by the author from Russian turpentine had a rotatory power of $[\alpha]_D = +32·45°$ only, whereas the corresponding lævorotatory terpene from French turpentine was found to have a rotatory power of $[\alpha]_D = -43·36°$. Fractionation of the cedar-oil yielded a terpene boiling at 156° (corr.) and having a specific rotatory power $[\alpha]_D = +45·04°$. The density is 0·8746 at 0° and 0·8585 at 20°. Coefficient of dilatation = 0·00094°, molecular refractive power $P\frac{A-1}{d} = 71·55$. Analogous values are given for some of its derivatives. The terpene in question is optically isomeric with that from French turpentine, the value of $[\alpha]_D$, found by Flavitzky, being $= -43·36°$, whereas Bouchardat and Lafont

(Abstr., 1886, 475), after allowing the same terpene to remain in contact with glacial acetic acid for six months, found $[\alpha]_D = -44.95°$. The two terpenes are therefore optically isomeric, boiling at 156°, and having a specific rotatory power of $[\alpha] = +45°$ and $-45°$. Both isomerides seem to behave differently towards a solution of 1 per cent. of sulphuric acid in glacial acetic acid, the action on the lævorotatory compound being more energetic. B. B.

Camphoric Acids. By E. JUNGFLEISCH (*Compt. rend.*, **110**, 790—793).—The solubility of ordinary dextrogyrate camphoric acid is practically identical with that of the lævogyrate acid from feverfew camphor, but very different from that of the lævogyrate acid obtained by heating the dextrogyrate acid in presence of water.

When lævogyrate camphoric acid is heated in presence of water, it yields an optically inactive acid, *paracamphoric acid*, which is very similar to mesocamphoric acid. but which can be split up into a lævogyrate acid similar to the original acid and a dextrogyrate acid similar to that obtained from dextrocamphoric acid under like conditions, but with an equal rotatory power of opposite sign. The dextrogyrate and lævogyrate acids obtained in this way, when mixed in equivalent proportions, yield an inactive acid with properties recalling those of the mesocamphoric acids. C. H. B.

Camphorates of the α-Borneols. By A. HALLER (*Compt. rend.*, **110**, 580—583).—The various active and inactive camphoric acids and camphols can yield 72 ethereal salts, 48 of which will be acid salts and 24 normal salt, some of the latter being active and some racemic. The products described in this paper were obtained from dextrocamphoric acid and the α-borneols.

Dextro-α-borneol (2 mols.) and dextrocamphoric anhydride (1 mol.) were heated in sealed tubes at 210—215° for 48 hours. The product was extracted with a mixture of ether and light petroleum and the solution washed with an aqueous solution of sodium carbonate in order to remove the acid ethereal salt. The ether was then distilled off and the residue crystallised from alcohol. The product was insoluble in water and alkalis, but dissolved in ether, benzene, and light petroleum. It had the composition $C_8H_{14}(COO{\cdot}C_{10}H_{17})_2$, but contained at least two substances which could be separated by fractional crystallisation, the extreme melting points being 102° and 128°, and the extreme molecular rotatory powers $[\alpha]_D = +30.83$ and $+52.08$.

The dextrogyrate acid salt is obtained by acidifying the alkaline wash water of the previous operation. It dissolves in alcohol and ether, but is only slightly soluble in light petroleum, from which it crystallises in hard, white nodules melting at 176—178°: molecular rotatory power $[\alpha]_D = +31°$ to $+40°$. When treated with acetic chloride, it yields camphoric anhydride and a chlorine compound which is doubtless borneol chloride. It is only slightly soluble in cold alkalis and alkaline carbonates, but dissolves readily on heating and gelatinises on cooling. If the gelatinous mass is dried and crystallised from alcohol, *sodium borneol camphorate*,

$$COONa{\cdot}C_8H_{14}{\cdot}COO{\cdot}C_{10}H_{17},$$

is obtained in white, crystalline leaflets, which have an alkaline reaction and are decomposed by carbonic acid. With copper salts, its solution gives a blue precipitate which readily splits up into cupric oxide and hydrogen borneol camphorate.

Similar products are obtained in the same way from lævo-α-borneol and dextrocamphoric anhydride. The normal salt crystallises in slender needles melting at 122°. The acid salt dissolves in alcohol, ether, and benzene, but is only slightly soluble in light petroleum; it melts at 164—168° and its molecular rotatory power is $[\alpha]_D = -17°$ to $-25°$. Like its isomeride, it dissolves in alkalis and alkaline carbonates and the solution gelatinises on cooling, has an alkaline reaction, and is decomposed by carbonic anhydride.

If the camphols and camphoric acid are heated at 140°, no normal ethereal salts are obtained.

From these facts it follows (1) that complete etherification of camphoric acid is only obtained at a comparatively high temperature, and when the anhydride is used; (2) in the operation, isomerides are formed owing to alteration of the camphoric acid; (3) in the acid ethereal salts, the acid function resembles that of the phenols rather than that of a true acid. C. H. B.

Phenolsulphonic Acids from Camphor. By P. CAZENEUVE *Compt. rend.*, **110**, 719—722).—The action of concentrated sulphuric acid on camphor yields sulphonic derivatives in small quantities only. If monochlorocamphor is mixed with five times its weight of concentrated sulphuric acid, a reaction takes place at 30° with slow evolution of hydrogen chloride, sulphurous anhydride, and some methyl chloride; at the ordinary temperature, the reaction takes place much more slowly. At least four products are formed and can be separated by fractional crystallisation after neutralisation with barium carbonate. All are sulphonic derivatives and have a phenolic function, which is indicated by the blue or violet coloration produced with ferric chloride, and the formation of acetyl-derivatives.

One has the composition $SO_2{\cdot}C_9H_{12}O(OH)_2$ and contains a phenolic hydroxyl, an alcoholic hydroxyl (secondary), and the ketonic group of the camphor, but no acid hydroxyl. The second has the composition $HSO_3{\cdot}C_{10}H_{16}O{\cdot}OH$ and contains one acid and one phenolic hydroxyl. The third contains three sulphonic acid groups and at least one phenolic hydroxyl, and has the formula $(HSO_3)_3{\cdot}C_{10}H_{18}O_5{\cdot}OH$, but the exact number of phenolic or alcoholic hydroxyls and the existence or non-existence of a ketonic group have still to be ascertained. The fourth compound contains one or several hydroxyl-groups and one or several phenolic groups, but is very difficult to purify, and its composition has not yet been definitely ascertained.

The author regards these results as conclusive proof of the presence of a benzene nucleus in the terebene-group. The formation of phenols by the combination of the hydroxyl of sulphuric acid with a benzenoïd nucleus has not been observed before. C. H. B.

Constituents of Quassia amara, L., and Picraena excelsa, Linds. By F. MASSUTE (*Arch. Pharm.* [3], 28, 147—171).—The coarsely-powdered drug *Quassia amara* was digested three times with 50 to 60 per cent. alcohol, the liquids mixed and treated with a little freshly-burnt magnesia, a little acetic acid added if necessary to produce a slight acid reaction, and the solution filtered, after which the alcohol was expelled at the lowest possible temperature. The aqueous solution thus obtained was warmed gently in an open dish, and the water was replenished from time to time, so as to get rid of all alcohol. On cooling, the separated resin was removed, and the liquid repeatedly shaken up with chloroform. From the separated chloroform solution, the chloroform was distilled off, and the residue treated with a mixture of absolute alcohol and ether; this was evaporated and the residue was dissolved in absolute ether, which, on slow evaporation, gave crystals of quassiin, which further treatment with ether and alcohol rendered quite pure. This process insures the isolation of the bitter principle actually existing in the plants, and avoids the formation of decomposition-products. Repeated recrystallisation of the product led to the separation of four compounds differing in their solubilities and melting points. The melting points were 210° to 211°, 215° to 217°, 221° to 226°, and 239° to 242°. The first and last compounds could not be further examined owing to the lack of material; but the former agrees with the quassiin obtained by first boiling the wood with water as in Christensen's extraction method, and in crystalline form and melting point is the same as that observed by Wiggers, and by Oliveri and Denaro. Quassiin, melting point 215° to 217°, on analysis gave $C_{35}H_{46}O_{10}$. and that with melting point 221° to 226° gave $C_{37}H_{50}O_{10}$. The bitter principle picrasmin, obtained as above from *Picraena excelsa*, melted at 206° to 208° and was a mixture of two varieties melting at 204° and at 209—212° respectively. Some commercial crystalline material was purified, and the two varieties were readily isolated; that melting at 204° was found to have the formula $C_{35}H_{46}O_{10}$ whilst the other gave $C_{36}H_{48}O_{10}$. It is probable that quassiin and picrasmin are not identical but form two series of homologous compounds. To elucidate this point, some of the decomposition-products of picrasmin were studied. Hydrochloric acid in a closed tube with picrasmin produced *picrasmic acid;* the barium salt of this acid was analysed and showed the acid to be bibasic; its formation may be thus represented $C_{31}H_{40}O_6(COOMe)_2 + 2HCl = C_{31}H_{40}O_6(COOH)_2 + 2MeCl$. Zeisel's reaction, in which picrasmin is treated with fuming hydriodic acid in a current of carbonic anhydride, shows that three methoxyl-groups are present, but only two of these were attached to carboxyl, as shown by treatment with hydrochloric acid. Quassiinic acid, $C_{30}H_{38}O_{10}$, obtained by Oliveri and Denaro, and picrasmic acid, $C_{33}H_{42}O_{10} + 5H_2O$, obtained by the author, strengthen the view of the non-identity of quassiin and picrasmin.

J. T.

Action of Acids on Litmus. By J. E. MARSH (*Chem. News*, **61**, 2).—Attention is drawn to the fact that concentrated and Nordhausen sulphuric acids, glacial acetic acid, dry propionic, butyric, and valeric acids do not redden dry litmus paper; it is therefore inferred that the conversion of blue into red litmus requires the presence of water.

The reddening of litmus by strong nitric acid is attributed to the decomposition of the organic matter with the liberation of water.

D. A. L.

Preparation and Properties of certain Pyrrolidone-derivatives. By O. Kühling (*Ber.*, 23, 708—713).—In addition to the compounds described in his previous paper (Abstr., 1889, 1211), the author has now succeeded in obtaining certain new pyrrolidone-derivatives by the action of ethylamine on the cyanhydrin of ethyl levulinate, and has also prepared the amide of 2-methylpyrrolidone-2-carboxylic acid. The latter is formed by adding 2-methylpyrrilidone-2-carbonitrile to well-cooled sulphuric acid, allowing the mixture to remain for a few hours, then pouring it into water, neutralising with sodium carbonate, and evaporating to dryness. The residue is extracted with alcohol, and the inorganic matter removed by repeated evaporation to dryness and extraction with alcohol. The amide,  $\genfrac{}{}{0pt}{}{CH_2\cdot CH_2}{CO-NH}>CMe\cdot CONH_2$, forms white, crystalline crusts, consisting of stellate aggregates of slender needles which melt at 161°, and are very soluble in water, less so in alcohol, and insoluble in ether. The corresponding acid and its salts could not be obtained in the crystalline form.

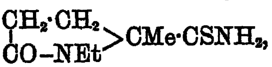
The action of ethylamine on the cyanhydrin of ethyl levulinate was allowed to take place under the same conditions as that of aniline (*loc. cit.*), and the resulting nitrile, which could only be obtained as an oil, added to cooled concentrated sulphuric acid. The 1-*ethyl-2-methylpyrrolidone-2-carboxylamide*,  $\genfrac{}{}{0pt}{}{CH_2\cdot CH_2}{CO-NEt}>CMe\cdot CONH_2$, thus formed was separated and purified in the manner described above. It crystallises from alcohol in needles or prisms which melt at 183°, and dissolve readily in water and alcohol, but not in ether.

1-*Ethyl-2-methylpyrrolidone-2-carboxylic acid*,

$$\genfrac{}{}{0pt}{}{CH_2\cdot CH_2}{CO-NEt}>CMe\cdot COOH,$$

is best prepared by boiling the pure amide with a slight excess of caustic potash solution, and after concentrating the solution, adding the requisite quantity of acid. The liquid is again evaporated, and the residue extracted with alcohol, the evaporation and extraction repeated several times, and the acid finally crystallised from benzene. It forms stellate aggregates of vitreous needles, and sometimes, on slow evaporation, separates in long, dendritic crystals. It melts at 123°, and is very readily soluble in water and alcohol, less so in hot benzene, and still less in ether. The *salts* of the acid could not be obtained crystalline.

1-*Ethyl-2-methylpyrrolidone-2-carbothioxylamide*,



$$\genfrac{}{}{0pt}{}{CH_2\cdot CH_2}{CO-NEt}>CMe\cdot CSNH_2,$$

is obtained by passing hydrogen sulphide through an alcoholic solution of the above nitrile, to which a little ammonia has been added. It crystallises from alcohol in short, white, lustrous prisms which melt with decomposition at 176°.

The *amidoxime* of this series is obtained by boiling the foregoing thiamide with equivalent quantities of hydroxylamine hydrochloride and sodium carbonate; it crystallises from water in slender needles or small plates, which are readily soluble in water and alcohol.

From the results shown in this and the previous paper, it appears that the stability and power of crystallisation of the nitriles, amides, and acids are greatest in the compounds derived from aniline, and least in those derived from ammonia, those derived from ethylamine occupying an intermediate position. H. G. C.

Pyridines: their Relation to Quinoline, Isoquinoline, and the Alkaloids. By A. Edinger (*J. pr. Chem.* [2], **41**, 341—359).—The author has sought to arrive at the constitution of the bases obtained by the action of moist silver oxide and of alkaline hydroxides on alkylpyridyl halogen-compounds, by comparing their more stable and more easily purified double compounds.

When benzylpyridyl platinochloride, $(C_5NH_4\cdot C_7H_7)_2,H_2PtCl_6$, is precipitated in aqueous solution, it is anhydrous and melts at 221° (uncorr.); but when it is precipitated in alcoholic solution, it melts at 199° (uncorr.), and contains ½ mol. alcohol of crystallisation. Both forms are slender needles, and are insoluble in water and alcohol.

When benzylpyridyl chloride is treated with silver oxide and water under ether, the aqueous solution of the base obtained gives an anhydrous platinochloride melting at 220° (uncorr.), and identical with the above. A dark-red, crystalline carbonate was obtained when the aqueous solution of the base was saturated with carbonic anhydride and evaporated. The hydrochloric acid solution of the base is not precipitated by ammonia.

When the saponification is performed with potassium or sodium hydroxide, the platinochloride is most easily obtained from an alcoholic solution; it then melts at 199° and contains ½ mol. alcohol of crystallisation. The platinochloride obtained from aqueous solution darkens without melting at 290°, and contains 12 mols. H_2O. The base gives no carbonate, and is precipitated by ammonia.

The paper concludes with some remarks on the constitution of pyridine, quinoline, and isoquinoline. A. G. B.

Pyridine-derivatives from Propaldehyde-ammonia, and Propaldehyde. By E. Dürkopf and H. Götsch (*Ber.*, **23**, 685—693).—When a mixture of propaldehyde-ammonia and propaldehyde, in the proportion of 1 mol. of the former to 2 mols of the latter, is heated in a sealed tube for six hours at 205—210°, a reddish-brown oil is formed, consisting chiefly of bases belonging to the pyridine-group. The reaction which here takes place is of a character similar to that occurring between aldehyde-ammonia and paraldehyde under similar conditions (Abstr., 1887, 1314). The secondary bases were separated from the crude oil by treatment with potassium nitrite in hydrochloric acid solution, and the residual mixture of tertiary bases separated by

20 fractionations into two chief fractions boiling at 197—199° and 219—221° respectively.

The first-named fraction, after being purified by conversion into the mercury double salt, yielded a colourless base, boiling at 198—199° (corr.) under 763·5 mm. pressure, and agreeing in almost all its properties with the parvoline obtained by Waage and Hoppe (Abstr., 1884, 172; 1889, 120); it has, however, a feeble, not unpleasant odour, the coneïne-like smell observed by Waage and Hoppe being probably due to an admixture of secondary bases. The crystallographic examination of the *platinochloride*, $C_9H_{13}N,H_2PtCl_6$, agrees well with that of Waage's parvoline platinochloride; it forms fairly large, monoclinic crystals melting at 189°, readily soluble in hot, sparingly in cold water. The two bases must, therefore, be identical. The *aurochloride*, $C_9H_{13}N,HAuCl_4$, and the *mercury double salt*, $C_9H_{13}N,HCl,3HgCl_2$, described by Hoppe as oils, were both obtained crystalline, and melt at 81—82° and 117—119° respectively.

On very moderate oxidation with potassium permanganate, the base yielded an acid which could not be obtained free from potash, but which, from the analysis of its platinochloride, must be a dimethyl- or ethyl-pyridinemonocarboxylic acid. It melts at 150—151°, and its *platinochloride*, which crystallises with 1 mol. EtOH, separates from alcohol in slender needles which are very soluble in water and gradually decompose at 260°.

By the further action of potassium permanganate, parvoline yields a methylpyridinedicarboxylic acid, which is also formed in small quantity in the preparation of the foregoing acid; hence the latter must be a dimethylpyridinecarboxylic acid, and the parvoline itself a dimethylethylpyridine. As the methylpyridinedicarboxylic acid here obtained is identical with that formed by the oxidation of Dürkopf and Schlaugk's parvoline, it is probable that the side-chains occupy the 2 : 3 : 5 positions, which is confirmed by the fact that on complete oxidation of Waage's parvoline with warm potassium permanganate, carbodinicotinic acid, $C_5NH_2(COOH)_3$, is obtained. It forms hard, spherical, crystalline aggregates, melts at 318°, and forms an acid silver salt which crystallises in rosette-like aggregates of small plates.

These facts show that Waage's parvoline agrees in almost all its properties and reactions with the parvoline previously obtained by the authors from propaldehyde-ammonia and paraldehyde. The latter differs from Waage's base only in its boiling point (188°) and in the crystallographic properties of its *platinochloride*. The lower boiling point may have been caused by some impurity, or may be different according to the different methods of preparation (compare β-picoline). A fresh preparation of the *platinochloride* gave crystals agreeing in properties with those of Waage; but as the crystals previously measured were no longer in existence, the possibility of dimorphism is not excluded. A further proof of their identity is found in the fact that Dürkopf and Schlaugk's base gives on reduction a parpevoline identical with that described below.

The secondary base, isolated from the crude oil by means of its nitroso-compound, is a colourless, mobile liquid, which boils at 176—177°, and has a penetrating odour resembling that of decaying hay. It has a sp. gr. of 0·8474 at 20° (water at 4° = 1), and a molecular volume of 143·3. The analysis shows its formula to be $C_9H_{19}N$, which has been confirmed by a determination of its vapour-density. It is identical with the hydro-base obtained by the reduction of both Waage's and Dürkopf and Schlaugk's base, and is, therefore, a parpevoline. It forms a hygroscopic *hydrochloride* and *hydriodide*, whilst platinum chloride, gold chloride, and picric acid give oily precipitates. The *cadmioiodide*, $(C_9H_{19}N,HI)_2CdI_2$, crystallises in white, sparingly soluble needles which melt at 120—130°.

The fraction of the original oil boiling at 219—221° was purified by conversion into the platinochloride, and forms a colourless oil which boils at 216—217° (uncorr.), is unaltered in air or light, and has likewise the composition of a parvoline, $C_9H_{13}N$. Its *platinochloride*, $C_9H_{13}N,H_2PtCl_6$, forms yellow, sparingly soluble needles or prisms, which do not melt at 270°; the *aurochloride*, $C_9H_{13}N,HAuCl_4$, crystallises in slender, lemon-yellow needles melting at 138—140°, and the *mercurochloride* separates from water containing hydrochloric acid in long, lustrous spangles, or well-developed crystals, probably belonging to the monoclinic system. The base, on oxidation, yields acids which are being further examined. H. G. C.

Action of Quinoline on Copper Sulphate. By E. Borsbach (*Ber.*, **23**, 924—925).—The basic salt which is precipitated when a concentrated solution of copper sulphate is shaken with quinoline has the composition $2CuSO_4,3Cu(OH)_2 + 4H_2O$, and not $3C_9H_7N,2CuSO_4 + H_2O$, as stated by Lachowicz (*Monatsh.*, **10**, 884). F. S. K.

Action of Phenylhydrazine on Ethyl Thiacetoacetate. By K. Buchka and C. Sprague (*Ber.*, **23**, 847—855; compare this vol., p. 28).—*Thiophenylmethylpyrazolone*,  $\left[\begin{matrix}NPh\cdot CO\\ | \\ N:CMe\end{matrix}\!\!>CH\right]_2S$, is formed when a glacial acetic acid solution of phenylhydrazine (2 mols.) is gradually added to a cold glacial acetic acid solution of ethyl thioacetoacetate (1 mol.); on keeping, the base separates in yellow crystals, and can be purified by converting it into the crystalline hydrochloride. It can also be prepared by gradually adding a chloroform solution of sulphur dichloride to a well-cooled chloroform solution of phenylmethylpyrazolone, and decomposing the salt which is produced. It crystallises from alcohol, benzene, or acetic acid in small, colourless plates; the crystals in all cases retain some of the solvent, which is slowly given off on exposure to air, but quickly at 100°. It decomposes at about 183°, but without melting; it is soluble in alkalis and in baryta-water, and it forms stable salts with strong acids. The *hydrochloride*, $C_{20}H_{18}N_4SO_2,HCl$, separates from alcohol in colourless crystals containing 1 mol. of alcohol. When the base is warmed with excess of phenylhydrazine, it is converted into phenylmethylpyrazoloneketophenylhydrazone, small quantities of di-phenylmethylpyrazolone being also formed. It is, doubtless, identical with the compound prepared by Michaelis and Philips (this vol., p. 582) by treating phenylhydrazine with ethyl thioacetoacetate in cold glacial acetic acid, and to which they assigned provisionally the composition $C_{20}H_{22}O_4N_4S$. F. S. K.

Brominated Derivatives of 1-Phenylpyrazole. By L. BALBIANO (*Gazzetta*, 19, 128—134).—1-Phenylpyrazole is obtained by heating a solution of epichlorhydrin (50 grams) in benzene (150 grams) with phenylhydrazine (120 grams) for eight to nine hours, and distilling off the benzene. The residue is mixed with sulphuric acid (400 grams containing 10 per cent. acid), distilled in a current of steam, and the ethereal extract of the distillate freed from ether and redistilled. The yield is 58 per cent.

1-*Phenylbromopyrazole*, $C_3N_2H_2BrPh$. is prepared by adding a solution of bromine (11·1 parts) in concentrated acetic acid (20 parts) to a very cold solution of 1-phenylpyrazole (10 parts) in acetic acid (10 parts), allowing the mixture to remain for an hour, and precipitating with water. The yield is theoretical. It crystallises from boiling 95 per cent. alcohol in large, white, lustrous needles, melts at 80·5—81° (corr.), and boils at 293—296° with partial decomposition. It dissolves in alcohol, ether, benzene, and chloroform, especially when warmed, but it is insoluble in water. It has feeble basic properties, and dissolves in concentrated sulphuric, hydrochloric, and acetic acids, but it is reprecipitated unaltered on diluting the solution. Hydroxyl cannot be substituted for the bromine in this compound by the action of potassium hydroxide, nor can a hydrocarbon radicle be introduced by Fittig's or by Friedel and Craft's method. It has also been ascertained that only one of the three possible isomeric 1-phenylbromopyrazoles is formed by the above process, and that the substitution of bromine for the hydrogen-atom takes place without any intermediate additive product being formed.

The *platinochloride*, $(C_3N_2H_2BrPh)_2,H_2PtCl_6,1\frac{1}{2}H_2O$, forms minute-pointed, orange-coloured prisms which decompose at 160—170° without melting. It is decomposed by water and slowly on exposure to the air.

1-*Phenyldibromopyrazole*, $C_3N_2HBr_2Ph$, is obtained by adding bromine (14·5 grams) dissolved in acetic acid (15 grams) to a solution of 1-phenylbromopyrazole (20 grams) in acetic acid (170—180 grams), and precipitating with water after the lapse of a few hours. The yield is about 93 per cent. The dibromo-derivative crystallises from alcohol in large, soft, white, lustrous, flattened needles, melts at 83·5—84° (corr.), dissolves in hot alcohol and benzene, sparingly in cold alcohol and is insoluble in water. It is more feebly basic than the monobrominated derivative, dissolving in concentrated sulphuric acid, but only sparingly in fuming hydrochloric acid and in glacial acetic acid. On mixing hydrochloric solutions of 1-phenyldibromopyrazole and of platinic chloride, a platinochloride is obtained in minute, bright-yellow needles which decompose on drying in the air.

1-*Phenyltribromopyrazole*, $C_3N_2Br_3Ph$, is prepared by boiling a solution of either the mono- or the dibromo-derivative in acetic acid or chloroform with the theoretical amount of bromine. It crystallises from alcohol in groups of slender, silky, colourless needles, melts at

106·5—107 (corr.), and is moderately soluble in alcohol, ether, and chloroform when heated, but only very sparingly in the cold. It is insoluble in water, dissolves with difficulty in concentrated sulphuric acid, and is almost insoluble in fuming hydrochloric acid.

S. B. A. A.

Action of Acid Chlorides on 1-Phenylpyrazole. By L. Balbiano (*Gazzetta*, **19**, 134—141).—1-*Phenylacetylpyrazole*, $C_3N_2H_2AcPh$, is obtained by heating 1-phenylpyrazole (10 grams) and acetic chloride (40 grams) at 140—150° for eight hours in a sealed tube. The product is freed from acetic chloride by distillation, nearly neutralised with a hot solution of sodium carbonate, and extracted with water; on cooling, phenylacetylpyrazole separates out. It crystallises from dilute alcohol in small, opaque, white needles, which melt at 121·5—122·5° (corr.) to a faintly-yellowish liquid. It is soluble in methyl alcohol and in ethyl alcohol, especially on warming, only moderately in hot water, and very sparingly in cold. It is not sensibly altered by boiling for an hour with a 25 per cent. solution of potassium hydroxide. The ketonic nature of this compound is evident from the formation of an oxime and a hydrazone.

1-*Phenylacetylpyrazoleoxime*, $C_3N_2H_2Ph{\cdot}CMe{:}NOH$, is obtained by boiling a solution of phenylacetylpyrazole (1 mol.) and of hydroxylamine hydrochloride (1 mol.) in methyl alcohol with an aqueous solution of sodium carbonate (1 mol.) for four or five hours. The product is filtered, evaporated on the water bath, and the residue extracted with boiling alcohol. On cooling, the oxime crystallises out in spherical groups, consisting of minute, white needles; it softens at 105°, and melts at 129—131° to a yellowish liquid; on resolidifying, it forms a glassy, transparent mass. It is soluble in alcohol, especially on warming, very moderately so in hot water, and very sparingly in cold water. It dissolves in concentrated hydrochloric acid, and on boiling the solution, it is split up into phenylacetylpyrazole and hydroxylamine hydrochloride.

1-*Phenylacetylpyrazolephenylhydrazone*, $C_3N_2H_2Ph{\cdot}CMe{:}N_2HPh$, is prepared by mixing a hot alcoholic solution of phenylacetylpyrazole (1 mol.) with a hot, aqueous solution of phenylhydrazine hydrochloride (1 mol.) and sodium acetate (1 mol.). It crystallises from boiling alcohol acidified with acetic acid in small, slender, yellowish needles which dissolve in hot alcohol, and melt with decomposition at 142—144°. On boiling with hydrochloric acid, it splits up into phenylacetylpyrazole and phenylhydrazine hydrochloride.

1-*Phenylbenzoylpyrazole*, $C_3N_2H_2BzPh$, is prepared by heating phenylpyrazole (10 grams) and benzoic chloride (40 grams) in a sealed tube at 240—250° for 10 hours. The product is made slightly alkaline with aqueous sodium carbonate, filtered hot, and extracted with hot alcohol. On cooling, phenylbenzoylpyrazole crystallises out in slender, lustrous, white needles which melt at 122—123 (corr.). It is soluble in hot alcohol, very moderately so in hot water, and very sparingly in cold water. The ketonic nature of this compound is likewise shown by the formation of an oxime and a hydrazone.

1-*Phenylbenzoylpyrazolephenylhydrazone*, $C_3N_2H_2Ph{\cdot}CPh{:}N_2HPh$, is prepared like the corresponding acetyl-derivative; it crystallises from alcohol in small, yellowish-white needles, melts with decomposition at 138—140°, and dissolves in hot alcohol, but not in water. On boiling with hydrochloric acid, it is split up into 1-phenylbenzoylpyrazole and phenylhydrazine.

1-*Phenylbenzoylpyrazoleoxime*, $C_3N_2H_2Ph{\cdot}CPh{:}NOH$, prepared like the corresponding acetyl-derivative, crystallises from alcohol in lustrous, nacreous laminæ, softens at 148°, and melts at 152—154°. It dissolves in alcohol, but is almost insoluble in cold water. Prolonged boiling with hydrochloric acid splits it up into 1-phenylbenzoylpyrazole and hydroxylamine.

The experiments described confirm the analogy between pyrroline and pyrazole-derivatives. S. B. A. A.

Two Pyrazolebenzoic Acids. By L. BALBIANO (*Gazzetta*, **19**, 119—128; compare Abstr., 1887, 1054; 1889, 1215). *Parapyrazolebenzoic acid*, $C_3N_2H_3{\cdot}C_6H_4{\cdot}COOH$ [$C_3N_2H_3 : COOH = 4 : 1$], is obtained when paratolylpyrazole (6 grams) is dissolved in a dilute solution of potassium hydroxide, and gradually added to a solution of potassium permanganate (12 grams) in water (200 c.c.). As soon as the liquid is decolorised, the unaltered pyrazole is distilled off in a current of steam, the residue filtered, precipitated with dilute sulphuric acid, washed, and thoroughly dried. The acid crystallises from absolute alcohol in small, faintly-yellowish needles, and melts at 264—265° (corr.) to a reddish-yellow liquid. It is almost insoluble in cold water, dissolves very sparingly in warm water or cold alcohol, and only moderately in warm alcohol, ether, or acetic acid It dissolves in concentrated sulphuric acid and in fuming hydrochloric acid, being precipitated again unaltered on diluting the solution. The hydrochloric solution gives no precipitate with a concentrated acid solution of platinic chloride. Its boiling alcoholic solution, after treatment with sodium and with sulphuric acid, gives no coloration either with potassium dichromate or with ferric chloride.

The *ethyl salt* is obtained by adding twice its volume of absolute alcohol to the hydrochloric solution of the acid, saturating with dry hydrogen chloride, and after some time expelling the excess of alcohol and hydrochloric acid, saturating the residue with sodium carbonate, and extracting with ether. The ethyl salt crystallises from hot alcohol in yellowish-white needles, or in shining, unctuous plates; it melts at 61—62° (corr.), and dissolves in alcohol and in ether, especially on warming. It does not take up hydrogen when its alcoholic solution is treated with sodium, &c., but the acid (m. p. = 264°) is reproduced.

The *sodium salt*, $C_{10}H_7N_2O_2Na$, crystallises from dilute alcohol in small, white, anhydrous needles, grouped together in spherical masses, which are very soluble in cold water, but less so in dilute alcohol.

The *barium salt* forms small, anhydrous, white, unctuous laminæ having a silky lustre, it is moderately soluble in hot water, less so in cold. With calcium chloride and zinc sulphate, the sodium salt also gives precipitates soluble in hot water, whilst the precipitates with lead acetate, mercuric chloride, silver nitrate, and copper sulphate are insoluble.

Orthopyrazolebenzoic acid, $C_3H_3N_2{\cdot}C_6H_4{\cdot}COOH$ [$C_3N_2H_3 : COOH = 2 : 1$], is obtained by the oxidation of orthotolylpyrazole in the way already described for the para-compound. It crystallises from boiling 50 per cent. alcohol in large, bright-yellow, prismatic needles, which have a vitreous lustre and melt at 138 5—139° (corr.) to a bright yellow liquid. It is soluble in warm water, alcohol, and ether, and sparingly in cold water, it dissolves in fuming hydrochloric acid, but no precipitate is obtained on diluting the solution, or on adding platinic chloride; it likewise dissolves in concentrated sulphuric acid. It does not take up hydrogen when its boiling alcoholic solution is treated with sodium, &c.

The *ethyl salt* is obtained by digesting a solution of the acid in 95 per cent. alcohol with one-third its volume of concentrated sulphuric acid for three to four hours at 50—60°. After remaining for some time, the solution is diluted with water, saturated with sodium carbonate, and the oil which separates out is extracted with ether. When pure, it is a yellow oily liquid, which boils at 308—310° (in vapour) and remains liquid at $-10°$. It is soluble in alcohol and ether, but not in water; it does not take up hydrogen on treating its alcoholic solution with sodium, but the free acid is reproduced. The *barium salt* forms crystalline incrustations, consisting of superposed flattened prisms, the crystals are hard, anhydrous, and readily soluble in water. The *sodium salt* is very soluble in water, and the solution gives with silver nitrate and with mercuric chloride a deposit of small, white crystals soluble in hot water, but no precipitate with either calcium chloride, copper sulphate, lead acetate, or zinc sulphate.

From the above experiments, it appears that bisubstituted phenols in which one hydrogen-atom is displaced by a carbazotic nucleus behave similarly to other bisubstituted phenols, the para-compounds having higher melting points than the ortho-compound, &c. The author considers that the inability of the pyrazole in these compounds to form pyrazoline by hydrogenation indicates that this property is dependent upon the position and character of the other substituting radicle.

S. B. A. A.

Oxidation of Orthophenylenediamine. By O. FISCHER and E. HEPP (*Ber.*, **23**, 841—847; compare Abstr., 1889, 409).—Diamidophenazine hydrochloride has the composition $C_{12}H_{10}N_4,HCl + 3H_2O$, and not $C_{24}H_{18}N_6O,2HCl + 5H_2O$, as stated by Wiesinger (Abstr., 1884, 1322). The *sulphate*, $(C_{12}H_{10}N_4)_2,H_2SO_4 + 3H_2O$, forms crystals very like those of anhydrous chromic acid; Wiesinger's formula for this compound is also incorrect.

Diformyldiamidophenazine, $C_{14}H_{10}N_4O_2$, prepared by boiling the diamido-compound for several hours with sodium formate and concentrated formic acid, is a reddish-yellow compound, very sparingly soluble in water, alcohol, benzene, ether, &c.

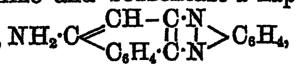
A quinoxaline of the composition $C_{26}H_{16}N_4$ is formed when an alcoholic solution of diamidophenazine is boiled with benzile for 1½ hours, glacial acetic acid then added, and the mixture boiled again for an hour. It crystallises from toluene in shining, reddish-brown plates, decomposes when heated, and dissolves in concentrated

sulphuric acid yielding a deep blue solution, the colour of which disappears on adding water. The formation of this quinoxaline proves that diamidophenazine is an orthodiamido-compound, so that it has the constitution $C_6H_4<\overset{N}{\underset{N}{|}}>C_6H_2(NH_2)_2$ $[(NH_2)_2 = 2 : 3]$.

Dihydroxyphenazine, $C_{12}H_8N_2O_2$, is formed, with liberation of ammonia, when diamidophenazine is heated at 200° with concentrated hydrochloric acid; the reddish-brown, crystalline salt obtained in this way is decomposed with dilute soda, and the base purified by converting it into the sulphate. It crystallises from dilute alcohol in reddish-yellow needles with ½ mol. H_2O, and loses its water at 100°, but only very slowly. The *sulphate*, $(C_{12}H_8N_2O_2)_2,H_2SO_4 + 2H_2O$, crystallises well from dilute sulphuric acid. The *diacetyl*-derivative. $C_{16}H_{12}N_2O_4$, crystallises from hot benzene in yellowish plates, melts at 230°, and is only a feeble base.

The compound obtained by Hübner and Frerichs (this Journal, 1876, ii, 309; and Abstr., 1878, 143) by treating orthophenylenediamine with cyanogen iodide, is diamidophenazine, and has not, therefore, the composition $C_{14}H_{12}N_4$.

The *hydrochloride*, $C_{16}H_{11}N_3,HCl$, separates, on cooling, in red crystals, when orthophenylenediamine (1 mol.) is heated with benzeneazo-α-naphthylamine hydrochloride (1 mol) and alcohol (10 parts) at 160°; it crystallises from hot alcoholic hydrochloric acid in slender, garnet-red needles, and dissolves in warm water with an orange-red coloration, but is gradually decomposed when the solution is boiled. The free *base*, $C_{16}H_{11}N_3$, crystallises from boiling alcohol in shining plates or slender, yellow needles, melts at 264°, and is insoluble in water and alkalis, and only sparingly soluble in benzene, ether, and cold alcohol, the solutions showing a yellowish-green fluorescence; it dissolves in concentrated hydrochloric acid and in sulphuric acid with a green coloration. The *platinochloride*, $(C_{16}H_{11}N_3)_2,H_2PtCl_6$, crystallises in slender, red needles, and is only sparingly soluble. The *aurochloride*, $C_{16}H_{11}N_3,HAuCl_4$, crystallises in yellowish-red plates, and is rather sparingly soluble in water and alcohol. The *acetyl*-derivative, $C_{18}H_{13}N_3O$, separates from glacial acetic acid as a light yellow, crystalline powder, and is very sparingly soluble in acetic anhydride.



When the compound $C_{16}H_{11}N_3$ described above is heated for some hours at 180—200° with concentrated hydrochloric acid, it is decomposed into ammonia, and the hydrochloride of a base of the composition $C_{16}H_{10}N_2O$. This *base* crystallises from alcohol in reddish needles; it has also the properties of a phenol, and dissolves in hot dilute soda, yielding a reddish-yellow solution from which it is precipitated on the addition of dilute acetic acid. When distilled with zinc-dust, it yields naphthaphenazine (m. p. 142°), so that the compound obtained from orthophenylenediamine and benzeneazo-α-naphthylamine is *α-amido-α-naphthaphenazine*, $NH_2\cdot C\ll\begin{matrix} CH-C\cdot N \\ \quad\ \| \quad | \\ C_6H_4\cdot C\cdot N \end{matrix}>C_6H_4$, analogously constituted to the eurhodine, $C_{17}H_{13}N_3$, obtained by Witt from orthamidoazotoluene and α-naphthylamine.

F. S. K.

Nitro- and Chloro-derivative of β-Methyl-δ-hydroxyquinazoline. By H. DEHOFF (*J. pr. Chem.* [2]. 41, 368).—*Nitro-β-methyl-δ-hydroxyquinazoline*,

$NO_2{\cdot}C_6H_3{<}{\begin{smallmatrix}C(OH)\\N{:}CMe\end{smallmatrix}}{\gg}N$, is obtained by adding anhydracetylorthamidobenzamide to red fuming nitric acid; it crystallises from alcohol as a yellow powder; it is an acid. Its *methyl-derivative* forms short, almost colourless needles melting at 165°.

When anhydracetylorthamidobenzamide is heated with phosphorus pentachloride at 170°, a substance $C_9H_4Cl_4N_2$ is obtained; this crystallises from alcohol in slender, white, felted needles, and melts at 124—125°. With potash, it yields a compound, $C_9H_6Cl_3N_2O$, which crystallises in yellow prisms melting at 206—207°. The *ethyl-compound* of this last substance crystallises in lustrous, white needles melting at 75°. A. G. B.

γ-Coniceïne, Conyrine, and Inactive Coniïne. By E. LELLMANN and W. O. MÜLLER (*Ber.*, 23, 680—684).—The coniceine previously described by Lellmann (Abstr., 1889, 901) has proved to be identical with the γ-coniceine obtained by Hofmann from coniine, bromine, and soda (Abstr., 1885, 562), the difference in the boiling points of 20° previously noticed being due to a slight impurity present in Lellmann's base; the latter, when purified by means of the stannochloride, boils like γ-coniceine at 173°. A direct comparison of specimens obtained by both methods also afforded complete proof of their identity.

In the previous paper it was left undecided which of the following formulæ represents γ-coniceine,

$CH_2{<}{\begin{smallmatrix}CH_2{\cdot}CH\\CH_2{\cdot}NH\end{smallmatrix}}{\gg}C{\cdot}CH_2{\cdot}CH_2Me$, or

$CH_2{<}{\begin{smallmatrix}CH_2{\cdot}CH_2\\CH_2{\cdot}NH\end{smallmatrix}}{>}C{:}CH{\cdot}CH_2Me$.

A compound of the first constitution should, on dehydrogenisation, readily yield propylpyridine, whereas the formation of this base could hardly be explained by the second formula. The authors therefore distilled the stannochloride of γ-coniceïne with zinc-dust, and purified the crude distillate by dissolving it in hydrochloric acid, extracting the non-basic portions with ether, adding excess of alkali, and distilling in a current of steam. The distillate was again dissolved in hydrochloric acid, and a little sodium nitrite added, and any nitrosamine formed removed by ether, the solution being then again made alkaline and distilled. In order to identify the base, it was converted into the platinochloride, the crystallographic examination of which gave results agreeing with those obtained by Ladenburg for propylpyridine platinochloride (*Annalen*, 247, 20). The melting point was, however, found to be 172°, whereas Ladenburg found 159—160°. The authors, therefore, prepared a specimen of the platinochloride by Ladenburg's method, and found in this case also the melting point 172°. As this compound was investigated with great care by Ladenburg, the platinochloride must exist in two isomeric forms of different melting point, which, however, differ only very slightly in their crystallographic properties. The properties of the free base agree well with those given by Ladenburg and Hofmann for propylpyridine, and there can, therefore, be no doubt as to its identity with this compound, from which it follows that γ-coniceïne has the first of the formulæ given above. This result also renders it probable that the secondary piperideïne bases obtained by Ladenburg in a similar manner from α-methyl-, α-ethyl-, and α-isopropylpiperidine have a corresponding constitution.

γ-Coniceïne appears to be also formed, together with conyrine, by the distillation of coniïne hydrochloride with zinc-dust.

When γ-coniceïne is reduced with tin and hydrochloric acid, it is readily converted into inactive coniïne. Its boiling point was found to be 165—166°, whilst its hydrochloride melted at 213°, whereas Ladenburg found the melting point to be 202—203°. It appears that the treatment with tin and hydrochloric acid exerts a purifying influence on the base, as dextro-coniine hydrochloride, for which the authors, in agreement with Ladenburg, found the melting point 218°, after treatment with these reagents melted at 221°. H. G. C.

By-product from the Synthesis of Cocaïne. By C. LIEBERMANN and F. GIESEL (*Ber.*, **23**, 926—929).—A direct comparison of the compounds of the base described by the authors as methylcocaïne (this vol., p. 647) with those of Einhorn and Marquardt's dextrorotatory cocaïne (this vol., p. 646) has shown that the two bases are very probably identical. The nitrates of both compounds have the same solubility in water, namely, 1·55 in 100 at 20°. Dextrorotatory cocaïne, purified by means of the nitrate, melts at about 43—47°; the hydrochlorides of the two bases also melt within about 3° of one another.

Dextrorotatory benzoylecgonine hydrochloride, prepared from dextrorotatory cocaïne, is identical with the compound prepared from "methylcocaïne;" both substances form rhombic crystals $a : b : c = 0·8361 : 1 : 0·5184$.

The nitrates of dextrorotatory benzoylecgonine and "methylcocaïne" are equally soluble in water (about 1·1 in 100 at 19°). The methyl-derivative of "methylcocaïne" melts at the same temperature (115°) as the methyl-derivative of dextrorotatory ecgonine, and both have the same rotatory power. F. S. K.

Aricine. By H. MOISSAN and E. LANDRIN (*Compt. rend.*, **110**, 469—471).—The alkaloïd which was discovered by Pelletier and Coriol was obtained from the bark known as *Arica* or *Cusco quinquina*. The bark used by the authors contained 3·0 to 3·5 per cent. of the alkaloïd, a proportion much larger than that found by previous investigators. It was roughly powdered, mixed with 10 per cent. of lime and 10 per cent. of sodium hydroxide solution of 40°, and the mixture partially dried on a water-bath. It was then exhausted with ether, and the ethereal solution mixed with dilute sulphuric acid, which precipitated aricine sulphate. The sulphate was dissolved in boiling water, and the alkaloid precipitated with ammonia and purified by repeated recrystallisation from alcohol. It has the composition $C_{23}H_{26}N_2O_4$, as stated by Gerhardt and by Hesse, melts at 188—189°, and is insoluble in water, but dissolves in alcohol (1 part in 100 at 15°, and 9 parts in 100 of the boiling solvent), and in ether (3 parts in 100 at 15°).

Its rotatory power in alcoholic solution is $[\alpha]_D = -58° 18'$, and in ethereal solution $[\alpha]_D = -92° 30'$. Contrary to the usual statements, the hydrochloride is optically active, its rotatory power having a sign opposite to that of the bases, $[\alpha]_D = +14° 30'$ in an alcoholic solution.

Aricine is distinguished from its isomeride cusconine by its melting point and rotatory power. The quantity of bark used was so great that 2 kilos. of aricine were obtained. The product was identical in properties with the aricine isolated by Pelletier. C. H. B.

Action of Resorcinol on Egg Albumin. By J. ANDEER (*Chem. Centr.*, 1890, i, 324; from *Arch. path. Anat*, **119**, 191—192).—If a drop of egg albumin is allowed to fall into a saturated solution of resorcinol, the drop of albumin, at first transparent, becomes gradually opaque, and finally white like a hailstone. It gradually falls through the liquid, lengthens itself out to a band, becomes broader and broader, finally reaching the bottom. It has the appearance of a bacteriological culture. If the liquid is now shaken, it falls to the finest powder, and is so disseminated in the froth that it appears to have dissolved. The same effects are produced however dilute the egg albumin may be. J. W. L.

Reactions of Albumoses and Peptone. By R. NEUMEISTER *Zeit. Biol.*, **26**, 324—347).—The various reactions (biuret reaction, precipitation by nitric and other acids, and by ammonium sulphate and other salts) of the products of proteolysis are described and compared with one another (compare Abstr., 1888, 509, 516). Statements made by other observers in relation to their delicacy and applicability are reviewed and criticised.

The term *tryptophan* is suggested for the substance which is formed during pancreatic digestion from proteids, and which gives a reddish-violet coloration with bromine. W. D. H.

Proteïnchrome and Proteïnchromogen. By E. STADELMANN (*Zeit. Biol.*, **26**, 491—526).—It has been known since the researches of Gmelin, Bernard, and others of the earlier physiologists that on tryptic digestion a substance is formed from proteïds which gives with chlorine, or better with bromine (not with iodine), a reddish-violet coloration. Other methods of decomposing proteïds, such as putrefaction, barium hydroxide, and strong (5 per cent.) sulphuric acid, give rise to many substances, among which this hitherto unnamed material is to be found. It is not formed during gastric digestion. Krukenberg (*Verhandl. physik. med. Ges. Würzburg*, **18**) and Hemala (*Chem. Unters. wiss. Med.*, von C. F. W. Krukenberg, Heft 2) have previously investigated this substance, and Nencki (this Journal, 1875, 479) considered that it was probably identical with naphthylamine, a view which Hemala showed to be untenable. Neumeister (preceding abstract) has recently suggested the name tryptophan for it; the name here suggested is that of *proteïnchromogen* for the original substance, and of *proteïnchrome* for the coloured material formed on the addition of chlorine or bromine.

Proteïnchromogen dialyses through parchment paper, will not dissolve in ether or chloroform, is non-volatile, and is destroyed at 100°. It is precipitable by silver nitrate, and causes reduction of this salt in the cold. The pigment itself (proteinchrome) is soluble in the digestion fluid, and is soluble in ether and in chloroform, the solutions showing a well-marked absorption-band at D. The halogens appear to be in a state of chemical combination with the organic radicle. Impure nitric acid destroys it. Many of these facts were previously described by Krukenberg, who considers that the substance is not a proteid, but a member of the indigo-group.

Proteinchromogen is stated by Neumeister to be soluble in amyl alcohol, and can thus be isolated. In the present research, amyl alcohol was not found to be at all a suitable reagent to employ for this purpose. In fact no method was found which would satisfactorily separate it from peptone, with which, in diffusibility and many of its reactions, it agrees closely, and from the amido-acids. The preparation of proteïnchrome by the use of 90 per cent. alcohol (for full details the original memoir must be consulted) met with better success. Its colour and other reactions show that it is not identical with naphthylamine. When dissolved in ether, it shows a well-marked absorption-band in the green (68—93); when dissolved in alcohol, the band does not appear until after the addition of sodium hydroxide; after treatment with various reagents, and in different solvents, the spectroscopic appearances differ, the measurements being given in detail.

Elementary analysis of several specimens gave the following percentage results:—

N.	Br.	S.	C.	H.	O.
10·99—11·92	19·77—23·16	2·95—3·77	48·12—51·34	4·45—5·28	8·03—12·00

From these numbers it is calculated that the percentage composition of proteïnchromogen is: C, 61·02; H, 6 89; N, 13·68; S, 4·69; and O, 13 71.

Proteinchromogen is not formed from anti-products of digestion, but only from the hemi-group (hemi-peptone). It is thus a substance which must be classed with leucine, tyrosine, and similar materials formed during pancreatic digestion. Its reactions and general composition seem to point to its being a proteid, or a substance allied to a proteid; its high percentage of sulphur quite excludes the view that it belongs to the indigo-group.

W. D. H.

Melanin. By J. Brandl and L. Pfeiffer (*Zeit. Biol.*, **26**, 348—376).—The pigment of melanotic tumours has been previously investigated by Berdez and Nencki (Abstr., 1888, 976), and by Morner (Abstr., 1887, 168). In the present research, the material was obtained from a patient who died of melano-sarcoma of the liver. Details of the clinical history of the case and autopsy are briefly given.

The pigment was separated from the proteïds of the tumour by the method of Berdez and Nencki, and was found to be insoluble in most reagents; concentrated mineral acids dissolve it slowly in the cold, more quickly when warmed; iron is then found in the acid, showing that it has decomposed the pigment. In concentrated alkalis in the cold it is almost insoluble; on the application of heat, it dissolves with the formation of a sulphide of the alkali. Dilute potassium hydroxide (1 per cent.) dissolves it slightly, forming a dark-red solution. It is precipitated from this solution by a solution of magnesium sulphate, or of barium chloride, or by neutralisation.

Specimens of the pigment submitted to elementary analysis gave percentage results which may be compared with the results of previous observers in the following table:—

	Nencki and Berdez.			Morner.		Brandl and Pfeiffer.
	Phymatorusin.	Hippomelanin.		Insoluble in acetic acid.	Soluble in acetic acid.	
		a.	*b.*			
C....	53·48	53·6	55·61	55 72	—	53·87
H....	4 03	3·88	3·82	6·00	—	4·20
N....	10·55	10·48	10 87	12 30	—	10·56
S....	10·67	2·84	2·81	7·97	5·90	3·63
Fe...	—	—	—	0·07	0·21	0 52
O....	21·27	29·20	26·89	17·94	—	27 25

The preparations made in the present research were, after removal of the iron, found to be free from ash.

In agreement with Mörner, and in opposition to Berdez and Nencki, it is considered probable that melanin originates from hæmoglobin; during the course of the disease, as the tumour grew in size, the number of red corpuscles and the percentage of hæmoglobin in the blood fell steadily.

The urine of patients suffering from melanotic disease contains, as a rule, a dark pigment, or a chromogen (melanogen) which is converted into the pigment by oxidation. Many observers have considered that this pigment is the same as that occurring in the tumours. The quantity of urine available for research in the present case was too small to make a thorough and systematic analysis. It, however, became dark-brown or black on exposure to the air, or by oxidising in other ways. With bromine-water, a minimal quantity of a brownish-black precipitate was obtained. Zeller has stated that this substance, which he calls bromomelanin, contains 16 6 per cent. of bromine (*Langenbeck's Arch. klin. Chirurg.*, **29**, 245). An amyl alcohol solution of the pigment separated from the urine gave two absorption-bands in the yellow-green and blue-green regions of the spectrum respectively, and, on ignition, yielded an ash that contained iron.

W. D. H.

Neurokeratin. By W. KÜHNE and R. H. CHITTENDEN (*Zeit. Biol*, **26**, 291—323).—Neurokeratin, the supporting framework of nervous tissue, may be separated from other constituents of that tissue by its extreme insolubility in various reagents; it is also unaffected by the gastric and pancreatic ferments.

In the present research, the tissue was in some cases submitted to artificial digestion before, in other cases after, the lecithin and cholesterin were removed by protracted extractions with alcohol and ether. Five specimens were thus prepared and subjected to elementary analysis, and the mean percentage result compared with those similarly obtained from keratin (prepared from hair) are as follows:—

	C	H.	N.	S.	O.
Keratin	49·45	6·52	16·81	4·02	23·20
Neurokeratin	56·99	7·54	13·15	1·87	20·45

A few estimations were made of the quantity of neurokeratin in various parts of the nervous system by weighing the residue of a weighed amount of the tissue after treatment with numerous reagents in which the albumin, cholesterin, lecithin, nuclein, and other constituents of that tissue are soluble. The percentage amounts found were as follows:—

1. Nerve (brachial plexus)	0·316
2. Cerebellar cortex	0·312
3. White matter of cerebrum	2·243
4. White matter of corpus callosum	2·902
5. Cerebral cortex	0·327
6. Nerve (brachial and sciatic)	0·601
7. White matter of corpus callosum	2·572

The most noteworthy point in connection with these analyses is the remarkably high percentage of neurokeratin in white matter.

Liver and kidney treated in the same way only gave an imponderable residue.

The paper concludes with an account of the microscopic appearances of neurokeratin in the nerve-fibres before and after they had been treated with the various reagents used. W. D. H.

Physiological Chemistry.

Living Motors and the Theory of Heat. By R. LEZÉ (*Ann. Agron.*, **16**, 30—38).—The author draws a comparison between the useful effect of the food supplied to a working horse and that of the food consumed by heat engines, based on the following figures. The albuminoïds of food are estimated to furnish 4,000 calories per kilogram on combustion; fats, 10,000 calories per kilo.; carbohydrates and woody fibre, 4.000 calories per kilo. Taking a horse weighing 700 kilos., and consuming per diem 7 kilos. lucerne hay, 10·5 kilos. maize, 3·9 kilos. bran, and 7 kilos. straw, the calorific value of the food will be (leaving the straw out of account)—

		calories.
From albuminoïds................	2·807 × 4,000 =	11,228
„ fatty matter................	1·092 × 10,000 =	10,920
„ carbohydrates and woody fibre	14·000 × 4,000 =	56,000
		78,148

There is thus expended on the horse 80,000 calories per diem, the same amount as is furnished by complete combustion of 10 kilos. of carbon. Such a horse will accomplish 2,700,000 kilogrammetres of work per day of 10 hours; and, admitting 1 kilo. of carbon per steam horse power per hour, the 10 kilos. of carbon burnt under a steam-engine will do the same. In the steam-engine, as in the horse, this is only one-thirteenth of the theoretical equivalent, namely, 80,000 × 425 = 34,000,000 kilogrammetres. But with heat-engines there is the prospect of indefinite improvement in the duty, whereas there is no such prospect in the case of animals. Pursuing the comparison, the heat-engine works at an elevated temperature, the horse not above 38°, and its weight is only one-sixth to one-eighth that of the horse. Supposing the horse to lose 15,700 calories per day by radiation, there remains 58,950 disposed of in other ways, since the work accomplished only requires 6,350. This quantity of 58,950 calories is partly used up in the phenomena of life and partly represented by unburnt fuel in the excretions. The heat corresponding with the carbonic anhydride expired, accounts for but a small part, about 4,400 calories. The combustion of the fuel is much less complete in the animal than in our furnaces; the reactions are more complex—more difficult to follow; the animal mechanism is so organised that the falls of temperature are hardly sensible, and the equilibrium soon restored. In the heat-engine, the consumption of fuel is directly proportional to the work done, whereas the animal consumes fuel when doing no work. J. M. H. M.

The Difference between Arterial and Venous Blood in different Blood-vessels. By F. Krüger (*Zeit. Biol.*, 26, 452—490).—Previous researches on this subject are first epitomised. In the present research, the experiments were made exclusively on cats; the results obtained being as follow:—

1. The amount of dry residue and of hæmoglobin in the blood of the carotid artery and jugular vein is the same.

2. After the slightest passive congestion has occurred in any vascular area, both dry residue and hæmoglobin are increased in the blood drawn from that region.

3. The percentage of hæmoglobin and of solid residue in the blood of the afferent and efferent vessels of the liver is usually different, but no constant relation exists between the two.

4. The blood of the larger mesenteric vein is poorer in both total

solids and hæmoglobin than that of the portal vein and of the splenic vein.

5. The blood of the splenic vein is generally richer in hæmoglobin and in solid residue than that of the arterial blood. There are occasional exceptions to this rule. The amount of fibrin in arterial and venous blood is approximately equal. The specific gravity of the defibrinated blood is sometimes higher in the splenic vein, sometimes in the artery. The specific gravity of the serum is, on the contrary, always higher in the artery than the vein; the same is true for the solid residue.

6. Hæmoglobin appears to be both formed and destroyed in the spleen.

7. The blood of the renal vein is poorer in both hæmoglobin and solid residue than the arterial blood. The amount of fibrin is also less in the blood from the kidneys than in arterial blood. The dry residue and specific gravity of both defibrinated blood and of the serum of the venous blood from the kidney is always smaller than in that from arterial blood. There appears to be little doubt that blood pigment is destroyed in the kidneys.

The hæmoglobin estimations were made by means of Hüfner's spectrophotometer. W. D. H.

The Permeability of the Red Corpuscles in relation to their Isotonic Coefficients. By H. J. HAMBURGER (*Zeit. Biol.*, **26**, 414—433).—When defibrinated blood is mixed with salt solutions of different concentration, and the corpuscles allowed to subside, it is found that there is for each salt a certain concentration when no hæmoglobin is dissolved out from the red corpuscles, while a saline solution of less concentration becomes tinged with the pigment. The mean of these two limits was found to give numbers identical with the isotonic coefficients of H. de Vries (*Pringsheim's Jahr. wiss. Botanik*, **14**, Heft 4).

The salt solutions in which the corpuscles lose their pigment are, in water-attracting power, far inferior to the serum in which they are contained. It is, therefore, necessary to add at least 50 per cent. of water, after admixture with the defibrinated blood, before the corpuscles allow their pigment to be removed. The salt solutions which have the same water-attracting power as the serum are designated isotonic, with one higher than that of the serum, hyperisotonic, with one lower, hypisotonic.

The present experiments were performed on the blood of the ox, horse, and pig; and the substances investigated were solutions of potassium nitrate, magnesium sulphate, sodium chloride, sodium sulphate, cane-sugar, dextrose, and diluted serum: the results obtained may be summed up as follows:—

1. That the blood corpuscles of defibrinated blood are exceedingly permeable by salts.

2. That after the addition of isotonic, hyperisotonic, and hypisotonic solutions of salts, sugar, and serum to defibrinated blood (which is diluted with water before the admixture), a passing out of certain constituents of the corpuscles into the surrounding medium occurs;

this takes place in such a manner that the water-attracting power of neither undergoes any change, or in other words in isotonic proportions.
W. D. H.

Blood of the Aplysiæ. By L. Cuénot (*Compt. rend.*, **110**, 724—725).—The blood from the heart of *Aplysia depilans* has a distinct rose colour, due to the presence of 0·636 per cent. of an albuminoïd which is precipitated by alcohol acids, mercuric chloride, and the usual reagents. Its colour has no relation to the presence of oxygen, and it seems improbable that it plays any part in respiration. When the blood is dialysed, or exposed for a long time to air, it decomposes spontaneously, part of the albuminoid remaining in solution and part separating in a white, flocculent form. This albuminoïd is distinct from hæmocyanin and may be called *hæmorhodin*. If the blood is concentrated in a vacuum and heated, it becomes opalescent at 58°, and seems to coagulate completely at about 70°.

The blood of *Aplysia punctata* is quite different, and contains 1·77 per cent. of a perfectly colourless hæmocyanin which is not affected by air and coagulates at about 76°. This albuminoid probably plays no part in the absorption of oxygen.
C. H. B.

Presence in Chyle of a Ferment which destroys Sugar. By R. Lépine *Compt. rend.*, **110**, 742—745).—The removal of the pancreas of a dog was followed by intense diabetes, the ratio of sugar to urea rapidly increasing and becoming as high as 233 : 100. The injection of chyle into the jugular vein caused a very marked reduction in the amount of sugar, the ratio of sugar to urea, four hours afterwards, being 24 : 100. After a time, however, the diabetes returned. A similar, but smaller, reduction in the quantity of sugar was caused by the intravenous injection of malt diastase. The addition of chyle to a 1 per cent. solution of glucose kept at 38° caused a decided reduction of the amount of glucose in the liquid.

From these facts, the author concludes that the chyle contains a ferment which destroys glucose, and that one of the functions of the pancreas is to provide the body with this ferment, and thus prevent the abnormal accumulation of glucose. Diabetes seems to be a consequence of an insufficient supply of the ferment.
C. H. B.

The Formation and Fate of Glycogen. By W. Prausnitz (*Zeit. Biol.*, **26**, 377—413).—The experiments described were made on hens; a period of four days' hunger was found sufficient to reduce the quantity of glycogen in the body to a *minimum*. As starch was found to be almost indigestible, the animals were then fed on a known quantity of cane-sugar, and killed a certain number of hours after feeding. The amount of cane-sugar which remained unaltered, or of dextrose into which it had been converted, in the alimentary canal was then ascertained; this amount subtracted from the dose given, gave the amount absorbed; the amount of glycogen in the whole body was then ascertained.

An example of one of the numerous experiments performed may be taken as a sample of the data found.

Experiment 7.—After four days' hunger, the hen lost 14·17 per cent. of its original weight. It was then fed with 24·35 gram of cane-sugar, and killed 48 hours afterwards.

No sugar was found in the stomach contents: the fæces contained 1·5 gram, the animal had in its liver 0·022 gram of glycogen; the rest of the body, 0·484 gram of glycogen. The total glycogen (0·506 gram) corresponds to 0·534 gram of cane-sugar. 22 85 grams of sugar had therefore been absorbed, and of this 2·33 per cent. was found in the form of glycogen. The relation of glycogen to total body-weight (excluding feathers and intestinal contents) was 0 048 : 100. The relation of the hepatic glycogen to that in the rest of the body was 1 : 22.

This experiment, on being compared with others of a similar kind, but differing from it in the length of time intervening between the feeding and the killing of the animal, shows certain results which are represented in the form of curves, and which may be briefly stated as follows:—The amount of total glycogen in the body, in the liver, and in the muscles, runs closely parallel to one another; the maximum of glycogen formation as evidenced by the quantity found after death occurs 20 hours after feeding; the curves rise to this point, and then fall. This is is somewhat later than is stated by previous observers, and is certainly not coincident with the maximum of bile-formation.

Some observers consider that the liver is the exclusive seat of the formation of glycogen; and that glycogen in the muscles and elsewhere is derived from the liver; other physiologists maintain that other cells besides liver cells may have a glycogenic function. In the present research it was found that the blood contains no trace of glycogen, so that if that substance is transported from the liver, it must pass in some soluble form. It is, however, considered probable that the liver is not the only seat of glycogenesis.

The paper concludes with the results of a few experiments on what happens to the glycogen of muscles after death. It is maintained in opposition to Böhm (*Pflüger's Archiv*, **23**, 44), that the muscle glycogen rapidly disappears after death. W. D. H.

Absorption of Different Fats from the Alimentary Canal. By L. Arnschink (*Zeit. Biol.*, **26**, 434—451).—It is very generally believed that fats with a high melting point are not so digestible as those which are liquid at the body temperature. The object of the present research was to put this question to the test of accurate experiment, feeding a dog with a weighed quantity of a fat, and ascertaining the amount which is not absorbed, by analysing the fæces.

The following table gives succinctly the principal facts found:—

Fat given.		Composition.		Melting point of fat.	Fæces.				Amount of fat not absorbed. Per cent.
		Olein per cent.	Solid fats per cent.		Neutral fat per cent.	Fatty acids per cent.	Soaps per cent.	Total fatty matter in the day. Grams.	
	grms.			°					
Stearin..	20	0	100	60	93·0	0	7·0	18·2	91·0
,, ..	20	0	100	60	94·8	0	5·2	17·2	86·2
Pig's fat.	100	52	48	34	26·6	19·8	58·6	2·8	2·8
Mutton suet.	100	30	70	49	41·2	51·4	7·4	7·4	7·4
Goose fat	50	71	29	25	36·7	55·4	7·9	1·2	2·5
Olive oil.	50	72	28	0	52·6	23·3	24·0	1·1	2·3
Mixture of stearin and almond oil	20	54	46	55	60·6	19·4	20·0	2·2	10·6

This clearly shows that the melting point and the amount of fat absorbed vary in the way already supposed. The bearing of this on diet in cases of stomach disease is pointed out. W. D. H.

Behaviour of Sulphur in the Organism, and the Detection of Thiosulphuric acid in Urine. By W. Presch (*Chem. Centr.*, 1890, i, 405—406; from *Arch. path. Anat.*, 119, 148—167).—The author has used Salkowski's method for the detection of thiosulphuric acid in urine, which depends on the fact that if the substance is distilled with hydrochloric acid, free sulphur collects in the condenser, whilst hydrogen sulphide is evolved. When applying this test, the urine was tested for hydrogen sulphide first, and in its absence, any formation of hydrogen sulphide may be attributed to the presence of thiosulphuric acid. Another delicate test is to precipitate any thiosulphuric acid as silver thiosulphate; the latter is decomposed on heating into silver sulphate and sulphide, the former being then tested for. The author could not detect the least trace of thiosulphuric acid in any healthy urine. Experimenting on himself on the effect of taking sulphur in the form of flowers of sulphur, he found that 73·5 per cent. was excreted as sulphuric acid, and that the remainder is absorbed for the formation of organic sulphur compounds. J. W. L.

Composition of the Milk of the Bottle-nose Whale. By P. F. Frankland and F. J. Hambly (*Chem. News*, 61, 63).—The authors obtained the following results from a small sample of milk from the bottle-nose whale; the numbers are per cent.:—

Total solids (100—105 C.)	51·33
Water	48·67
Solids not fat......................	7·57

Fat	43·76
Ash	0·46

The ash is rich in phosphoric acid, and the fat contains a large proportion of difficulty saponifiable fat (m.p. 51°) presumedly spermaceti.

D. A. L.

Physiological Action and Optical Properties of Inorganic Substances. By J. Blake (*Zeit. physikal. Chem.*, 5, 217—220).—The author, in amplification of a former paper (*ibid.*, 2, 769), here discusses the parallelism between the physiological action of inorganic substances and their optical behaviour, together with the factors of moment in determining these properties—namely, isomorphism, valency, and atomic weight.

Substances of one isomorphous group have in general the same physiological action; in an investigation of 44 elements, the only exceptions to this rule (nitrogen and potassium), were found to be also exceptional with regard to their spectra and general optical activity. Within an isomorphous group. increase of molecular weight (or, more probably, of molecular volume) conditions increased physiological activity. The influence of valency is such as to determine the sphere of the action; thus bivalent elements act on a greater number of nerve centres than univalent elements, trivalent on more than bivalent, and so on. The author draws attention to the connection between the valency of hydrogen, oxygen, and nitrogen and the nature of their spectra. The above relations hold most strictly for electro-positive elements.

J. W.

Action of Related Chemical Compounds on Animals. By W. Gibbs and H. A. Hare (*Amer. Chem. J.*, 12, 145—152) —A continuation of a research, for the first part of which see this vol., p. 280; experiments with the cresols form the subject of the present paper. These all act as sensory and motor paralysants. The ortho- and para-compounds act as stimulants to inhibitory processes; the meta-compound has no such influence. The ortho-compound seems to be the more powerful inhibitory stimulant of the two, and is the most powerful cardiac depressant of the group. After orthocresol in this respect comes paracresol; metacresol having little cardiac influence comparatively; thus, ortho-cresol kills when injected in the strength of 0·08 gram per kilo. of body-weight, paracresol in the dose of 0·1 gram per kilo., and metacresol when the amount equals 0·15 gram per kilo. Metacresol seems to affect the vaso-motor system more than paracresol, but probably not more than orthocresol. Orthocresol and paracresol are grouped as inhibitory stimulants and cardiac depressants; orthocresol and metacresol as vaso-motor depressants. On the nervous system of the frog these compounds act as a paralysants in the same order as they act on the heart. Thus, of orthocresol 0·004 gram per kilo. of body-weight paralyses the nerves and causes death. Paracresol kills at 0·006 gram, and metacresol only at 0·044 gram per kilo.

Chemistry of Vegetable Physiology and Agriculture.

Effect of Copper Salts on Elliptical Yeast. By A. Rommier (*Compt. rend.*, **110**, 536—539).—Grapes from wines which had been treated with solutions of copper salts for the prevention of mildew, either did not ferment at all or fermented in consequence of the development of the species of yeast known as *apiculatus*. The ordinary elliptical wine-yeast did not develop. Direct experiments showed that 0·075 to 0·100 gram of copper in the form of sulphate per 1000 c.c. greatly retarded fermentation by elliptical yeast. It is highly probable, therefore, that the copper salts will exert a similar influence on the sporulation of this yeast on the skin of the grape, but will not prevent the deposition of other yeasts through the agency of insects.

The absence of elliptical yeast will not exert any marked influence in the case of common wines, but will be decidedly injurious when it is required to produce wines of fine bouquet. The use of copper salts should, therefore, be avoided as far as possible. C. H. B.

The Fixation of Free Nitrogen. By Sir J. B. Lawes and J. H. Gilbert (*Proc. Roy. Soc.*, **47**, 85—118).—In a previous paper (*Phil. Trans.*, 1889, 1—107) the authors discussed the history and present position of the question of the sources of the nitrogen of vegetation. The earlier Rothamsted results, as well as those of Boussingault, obtained under conditions which excluded the action of electricity and of microbes, pointed to the conclusion that the higher chlorophyllous plants have not the power of taking up elementary nitrogen. It was concluded that atmospheric nitrogen is not a source of nitrogen in the case of gramineous, cruciferous, chenopodiaceous, or solaneous crops, but with regard to the *Leguminosæ* it was admitted that there was not sufficient evidence to account for the whole of the nitrogen taken up. Of the recent researches bearing on the subject, those of Hellriegel and Wilfarth (Abstr., 1889, 640; and *Ber., botan. Ges.*, **7**, 135) were considered the most conclusive, and in 1888 experiments, on similar lines to Hellriegel's, were commenced at Rothamsted. The plants selected were peas and blue and yellow lupins, but only the peas gave very definite results. There were four pots, each with three pea plants, as follows:—No. 1. Washed sand (9 lbs.), containing a little nitrogen (0·0027 per cent.), and provided with the necessary ash constituents. Nos. 2 and 3. The same prepared sand seeded with soil organisms. No. 4. Garden soil from which the soil extract added to Nos. 2 and 3 was made. About five or six weeks after sowing, the plants of pots 2 and 3 acquired a darker colour than those of pot 1, and from this time the plants (pots 2 and 3) gained both in leaf surface and in number of leaflets, and maintained their brighter green colour. At the conclusion of the experiment it was found that the roots of all the plants had nodules, but that those of the plants of the seeded pots were much larger and more abundant than those of pot 1. The fact that the plants of this pot had nodules at all is attributed to the impurity of the sand, and its not having been sterilised. The roots of the plants grown in garden soil showed comparatively few nodules, which were, moreover, smaller than those of the other pots. None of the plants flowered, owing to the lateness of the season.

The following table shows the amount of dry produce (including roots), and the amount of nitrogen contained in it, as well as the nitrogen of the seeds sown, and the initial and final nitrogen of the sand and soil:—

	Dry produce.	Nitrogen								
		At commencement.			At conclusion.			Gain.	In total products; total initial = 1.	In plants, nitrogen in seed = 1.
		In soil.	In seeds sown.	Total.	In soil.	In produce.	Total.			
	grms.	grms.	grms.	grms.	grms.	grms.	grms.	grms.	grms.	grms.
Pot 1	10·023	0·0999	0·0293	0·1292	0·1096	0·2822	0·3918	0·2626	3·03	9·63
Pot 2	11·777	0·0999	0·0298	0·1297	0·0974	0·5361	0·6335	0·5038	4·88	17·99
Pot 3	11·159	0·0999	0·0291	0·1290	0·0848	0·4357	0·5205	0·3915	4·04	14·97
Pot 4	15·634	7·9989	0·0301	8·0290	7·9989	0·6600	8·6589	0·6299	1·08	21·93

The amount of nitrogen in the 25 c.c. of soil extract, added to pots 2 and 3, is so small (0·790 milligram) that it need not be taken into account. Whilst the amount of dry produce was only slightly increased by the application of soil organisms, the amount of nitrogen was nearly doubled. With regard to pot 4, the results indicating a gain of nitrogen are not to be considered as conclusive, owing to the difficulty of detecting slight changes in the amount of nitrogen in a large bulk of rich soil. This experiment was, in fact, intended more to compare the growth with that of the other pots, than for exact quantitative estimates of gain or loss. There is no evidence to show that either the sand or soil has taken up nitrogen on its own account.

The experiments of the second season included peas, red clover, vetches, blue and yellow lupins, and lucerne. The sand used was a coarse, white sand, which was washed, and sufficiently, if not absolutely, sterilised, by heating for some days at nearly 100°. The necessary ash constituents mixed with an equal weight of calcium carbonate were added to each pot. There were four pots to each series. No. 1 contained the prepared sand alone; Nos. 2 and 3 the same sand, to which a soil extract was added, prepared from a lupin sandy soil for the lupins, and from a garden soil for all the rest. No. 4 garden soil, or for lupins the special lupin soil. The peas and vetches of the unseeded pots were very limited in growth, whilst those of the second and third pots grew luxuriantly, being taller even than those grown in garden soil. On the other hand, the latter were more vigorous and produced flower and seed. The results obtained with yellow lupins were still more striking. Whilst the plants of pot 1 barely appeared above the rim of the pot, those of pots 2 and 3 were large, branched plants, the largest being 2 feet high, which flowered and seeded freely. The plants grown in the lupin soil were considerably smaller, which may be due to the fact that the lupin soil was much less porous than the sand of the other pots The roots of all the plants (peas, vetches, and lupins) grown in sand without soil extract seeding were, like the plants, of very limited development, and were entirely free from modules; in pots 2 and 3, of each series, the root development was very great, and the roots showed an abundance of nodules. In the garden soil and the lupin soil the root development and nodule formation were much less.

The blue lupins failed, with one exception, and the clover and lucerne are left for further growth

The results confirm those of Hellriegel and Wilfarth in showing the fixation of free nitrogen under the influence of microbe seeding, and the resulting nodule formation on the roots of the leguminous plants. Hellriegel agrees with the authors that the *Leguminosæ* utilise soil nitrogen, and he considers that the soil would be drawn on first, and that this source is supplemented by the elementary nitrogen of the air, brought into combination by means of the organisms; he also considers that there would be more or less fixation even with a soil rich in nitrogen. On the other hand, Vines (*Annals of Botany*, **2**, 386) found that the formation of tubercles and presumably also the fixation of free nitrogen, is much reduced by the application of much nitrate; and the Rothamsted experiments indicate that with a rich soil, there are far fewer nodules formed than with a sand containing but little nitrogen and seeded with soil organisms.

Regarding the way in which the organisms, which, in symbiosis with the higher plants, bring about the fixation, much has yet to be learnt. The authors suggest the alternatives:—"(1.) That somehow or other, the plant itself is enabled, under the conditions of symbiotic life, to fix free nitrogen of the atmosphere by its leaves, a supposition in favour of which there seems to be no evidence whatever. (2.) That the parasite utilises and fixes free nitrogen, and that the nitrogenous compounds formed are taken up by the host. On such a supposition, the actually ascertained large gain of nitrogen by the leguminous plant growing in a nitrogen-free, but properly infected. soil becomes intelligible." (Compare Bréal, this vol., p. 79; Marshall Ward, *Proc. Roy. Soc.*, **46**, 431; and Prażmowski, *Landw. Versuchs-Stat*, **37**, 162.)

N. H. M.

The Nitrogen Question. By A. PETERMANN (*Bull. Stat. Agronom Gembloux*, No **47**, 1–17, 1890).—Yellow lupins were grown in vessels containing 1 cub. metre of washed, white sand (1400 kilos). The air-dried sand contained 0·0400 per cent. of organic matter (with 0 0004699 per cent. of nitrogen) and 0 029 per cent. of nutritive mineral matter. The experiments were made in the open air; the rainfall and drainage through the sand and the nitrogen in the rain and drainage were determined. There were six vessels, as follows:—(1) Sand alone; (2) sand with phosphatic slag and potassium and magnesium sulphates; (3) sand and minerals as in (2), and soil extract containing organisms; (4) sand and minerals with sodium nitrate (176·6 grams); (5) sand and minerals with ammonium sulphate (137·5 grams); (6) sand and minerals with dried blood (225·7 grams). The amount of nitrogen applied to vessels 4, 5, and 6 was in each case the same (27·6 grams). 36 seeds of *Lupinus luteus* were sown on May 2, and on July 30 plants of all the six vessels were in flower. In No. 1 nine plants died; the rest were small, with small flowers. Those of Nos. 2 and 3 were nearly identical in appearance, and were much stronger and larger than those of No. 1. The plants of vessels 4, 5, and 6 were much larger still, especially those of No. 6, which were all the time superior to any of the others. The less favourable result with sodium nitrate is attributed to its greater solubility and its consequent removal to the lower part of the sand out of reach of the shorter roots. Nodules were found on the roots in all six vessels.

The numerical results are shown in the following table:—

	Dry produce.	Nitrogen.							
		In produce.	In soil, final.	In drainage.	In seed sown.	In soil, initial.	In manure	In rain.	Derived from air.
	grms.	grms.	grms.	grms.	grms.	grms.	grms.	grms.	grms.
1...	68·4	0·8952	8·1648	0·2290	0·3338	6·5786	—	0·3456	+2·0310
2...	236·5	4·8453	8·1648	0·1764	0·3337	6·5786	—	0·3456	+5·9286
3...	223·5	4·6509	8·8900	0·2288	0·3393	6·5786	—	0·3456	+6·5062
4...	445·0	8·0459	11·4268	19·0254	0·3355	6·5786	27·600	0·3456	+3·6384
5...	447·8	8·0416	12·5146	12·8697	0·3285	6·5786	27·600	0·3456	−1·4268
6...	809·0	10·0044	14·3276	4·5196	0·3308	6·5786	27·600	0·3456	−6·0034

The results show that atmospheric nitrogen may, under certain conditions, contribute to vegetable growth, as in a soil poor in nitrogen and containing soil organisms; and, further, that sodium nitrate is not, as sometimes supposed, injurious to lupins, but is highly beneficial.

Nitrogen determinations made with root nodules show that these are richer in nitrogen than the rest of the plants to which they are attached.

In view of the results obtained by other investigators, indicating that cereals which have no root nodules acquire nitrogen from the air, and that the soil in which they are grown also becomes richer in nitrogen, the author would guard against exaggerating the physiological rôle of the tubercles. They cannot be the only cause of nitrogen fixation, although their presence may explain why the intervention of atmospheric nitrogen is most marked in the case of the *Leguminosæ*.

Further experiments will be made to decide the question whether it is the combined or the elementary nitrogen of the air which is utilised.

N. H. M.

Assimilation of Carbon by Green Plants. By E. H. ACTON (*Proc. Roy. Soc.*, **46**, 118—121).—Plants or shoots grown in a "culture liquid" were deprived of starch by placing them in an atmosphere free from carbonic anhydride, and were submitted to the action of the following substances:—Acraldehyde, acraldehyde-ammonia, the compound of acraldehyde with sodium hydrogen sulphite, allyl alcohol, glucose, acetaldehyde, aldehyde-ammonia, glycerol, levulinic acid, calcium levulinate, cane-sugar, inulin, dextrins, soluble starch, glycogen, extract of natural humus, and the humus-like product of the action of alkalis on cane-sugar. The following results were obtained:—Starch is formed when "soluble starch" is supplied to the leaves, but not when it is applied to the roots. "Extract of natural humus" forms starch when supplied to the roots, but not when supplied to the leaves. Glucose in 0·5 per cent. solution is more readily taken up when supplied to the roots than cane-sugar. The roots of plants can withdraw all the glucose from a 1 per cent. solution and remain healthy. The remaining substances did not produce starch. The author concludes that green plants cannot normally obtain carbon from organic substances, excepting carbohydrates; that they have lost their power of using organic compounds as a source of carbon; and that if a compound of an aldehydic nature is formed as an intermediate product between carbonic anhydride and water on the one hand and glucose on the other, it can only be polymerised at the moment of formation.

H. K. T.

The Diffusion of Alumina in Plants. By L. RICCIARDI (*Gazzetta*, **19**, 150—160).—After giving a summary of the previous work on this subject, the author gives the following analyses, which were made with a view to trace the connection between the character of the soil and the amount of alumina absorbed by the plant, and to ascertain the distribution of the alumina in the parts of individual plants.

(I.) *Analyses of the Plants.*	Aluminia in 100 parts of ash.
Twigs of vine from strongly aluminous soil (Bari)	0·850
" " calcareous " "	0·810
" from moderately calcareous soil (Bari)	1·140
Trunk and branches of "manderin orange" (Bari)	0·218
Peel and seeds of "manderin orange" (Bari)	0·093
" " " (Cava dei Tirreni)	0·121
Leaves of "manderin orange"	0·022
Entire fruit of prickly pear (Bari)	0·063
" " " from Catania (4)	0·092
Phyllodes " " (Bari)	0·148
" " " from Catania (4)	0·167
Dry husks of almond (Bari)	0·695
" nuts " "	0·138
Pulp of the siliqua of *Ceratonia siliqua* (Bari)	0·503
" " " " from Catania (5)	0·607
Carob of *Ceratonia siliqua* (Bari)	0·062
" " " (Catania)	0·064
Tobacco leaves from Cava dei Tirreni	2·151
White lupins	0·042

(2.) *Analyses of the Soils.*

The soil in the neighbourhood of Bari, Ruvo, &c., is formed by the disintegration of the marly clay (1), of a limestone belonging to the cretaceous formation (2), and of a ferruginous earth (3).

The soil in the neighbourhood of Catania consists of the decomposed lava of 1669 (4), and of the lava (5). The soil at Cava dei Tirreni consists of a mixture of the detritus of the Apennine limestones (6); (7), (8), with the volcanic rocks (9) and (10).

From the above analyses, the author concludes that the assimilation of alumina does not depend on the percentage contained in the soil, and that, generally speaking, alumina is most abundant in the trunk and branches of a plant, less so in the husks and seeds, and least of all in the leaves. S. B. A. A.

Organic Acids in the Sorghum Cane. By H. W. Wiley and W. Maxwell (*Amer. Chem. J.*, **12**, 216).—Preliminary investigations of the juice of the Sorghum cane have shown that it contains the following acids in the following order by proportion:—Aconitic, citric, malic, oleic, and formic acids, with decreasing amounts of tartaric, oxalic, and acetic acids, traces only of the last two being present. The authors are awaiting the next season in order to obtain a fresh supply of material. C. F. B.

Function of Tannin in Plants. By M. Büsgen (*Chem. Centr.*, 1890, i, 397—398; *Jena. Zeit.*, **24**, 11—60).—From investigations conducted by the author, he draws the conclusion that tannin continually disappears during the life of plants, and both from those cells such as young cork cells and those of the bark, which die rapidly, as also from those such as the roots of the triticum family, which have a longer term of life. Primary and secondary tannins behave not altogether differently, and these are not necessarily produced in a different manner. Tannin, like starch, appears to be formed just at those parts where there is an abundance of materials present necessary for its production.

On the other hand, whilst starch is used by the plant for the further building up of its structure, there is no proof that tannin is put to this use.

J. W. L.

Tannin in Indian and Ceylon Teas. By D. HOOPER (*Chem. News*, **60**, 311—312).—The tannin in various samples of tea was estimated by precipitation with lead acetate, and the tabulated results indicate that the quantity present was not influenced either by the quality of the tea or by the altitude at which it was grown. Tannin constitutes the "strength" of the tea, and, with 1 part of tea to 100 of boiling water, about 30 per cent. of the tannin in tea is extracted by water in 5 minutes, and about 50 per cent. in 10 minutes.

D. A. L.

Experimental Plots at Grignon in 1889. By P. P. DEHÉRAIN (*Ann. Agron.*, **16**, 1—29).—*Potatoes.*—Excellent results were obtained with Richter's Imperator, which was tried against Van der Veer and Chardon, the best plots of each yielding 33,150, 28,450, and 28,200 kilos. per hectare respectively. The starch contained in these crops amounted to 8,218, 5,498, and 5,234 kilos. respectively. The proportion of small tubers was 8 per cent in Richter's Imperator, 12 in Chardon, and 13 in Van der Veer. The different sized sets produced no sensible differences in the crops. The greatest profit was shown by the plot not manured in 1890, but receiving 50,000 kilos. farmyard manure and 200 kilos. ammonium sulphate per hectare in the previous year.

Sugar-beet.—The results obtained in 1889 with Vilmorin's seed, bought directly, were superior to those obtained with the same variety of seed saved three generations running at Grignon; contrary to the experience of the previous years—the respective mean yields were 40,100 and 37,800 kilos. per hectare. Moreover, the superiority extended to the density of juice and percentage of sugar. The crops obtained with farmyard manure plus nitrate of soda were much larger than when it was omitted, and especially it was proved that at Grignon much better crops of sugar-beet are obtained when the farmyard manure is ploughed in in the autumn instead of spring.

Wheat.—The square-head wheat, which usually resists well, was laid in 1889 at Grignon; above all in the plots dressed with farmyard manure, and on strong soils it is recommended not to use this manure the same year, but at Grignon it may be, as a rule advisable.

Forage Maize.—The highest crop reached 59,700 kilos. per hectare, whereas in previous years 70,000—80,000 have been obtained. Even on plots highly manured for years previously the maize did not this year profit by the accumulation of organic matter in the soil, the great dryness of the summer probably accounting for this.

Oats.—The variety "avoine des salines," taken after sugar-beet, produced an average crop of 31·8 metric quintals per hectare; the variety "avoine géante à grappes" (giant cluster oat), 23·2 metric quintals. On lea ground, the yields were 19·1 and 13·9 metric quintals respectively. J. M. H. M.

Chemistry of the Truffle. By A. CHATIN (*Compt. rend.*, **110**, 435—440; compare this vol., p. 659).—Truffles grown in soil containing 46·09 of calcium oxide contained 75 per cent. of water and 25 per cent. of solid matter, the latter consisting of nitrogen 2·08 parts, non-nitrogenous organic matter 20·42 parts, and ash 2·50 parts. The ash contained only 7·5 per cent. of calcium oxide.

Truffles grown in a highly ferruginous soil contained 74·9 per cent. of water and 25·1 per cent. of solid matter, composed of 4·10 parts of nitrogen, 2·80 parts of ash, and 18·20 parts of non-nitrogenous organic matter. The proportion of iron in the ash was normal; but although the soil contained only traces of phosphorus, the ash contained 23·15 per cent. of phosphoric anhydride.

The ash of the truffle contains about 25 per cent. of phosphoric anhydride, 7 to 8 per cent. of calcium oxide, and 5 per cent. of ferric oxide, and these proportions are not materially altered by variations in the composition of the soil. Manganese is always present in minute quantity, and iodine and chlorine are also constant constituents.

The truffle forms a complete food, rich in nitrogen and in the organic compounds essential to animal life. The proportion of nitrogen is independent of the quantity of nitrogen in the soil. C. H. B.

Absorption of Ammonia from the Air by Vegetable Soils. By T. SCHLOESING (*Compt. rend.*, **110**, 429—434, 499—504).—The soils were exposed in a gallery, through which was drawn air previously filtered through cloth. In order to determine the relation between the quantity of ammonia brought in contact with the soil under these conditions and the quantity which would have come in contact with it if it had been simply exposed to the air similar vessels containing sulphuric acid were exposed in the gallery, and to the open air. It was found that the quantities of ammonia absorbed were as 324 : 200, and hence it was necessary to make a correction for the difference.

Six non-calcareous soils, which had no power of absorbing free nitrogen, were exposed for 16 months, and during the summer were occasionally watered. In five cases there was a slight loss of ammoniacal nitrogen, but in five cases there was a decided gain in nitric nitrogen, amounting to from 26·7 to 38·0 kilos. per hectare per annum. In one of the experiments the gain was much greater even than this. The results, when corrected for the ammonia contained in the suspended matter of the air, and for the difference of conditions, gave an absorption of 15·3, 23·6, 50·1, 22·4, and 20·5 kilos. respectively per hectare per annum.

A soil containing 37 per cent. of calcium carbonate, a non-calcareous soil, and a subsoil gave respectively an increase of 90·1, 75·4, and 66·4 kilos. per hectare per annum, and these numbers, when corrected (200/374), become 47·1, 39·2, and 34·4 respectively.

Eight calcareous soils, containing from 2·1 to 11·15 per cent. of calcium carbonate, all showed a slight increase in the amount of ammonia, and the increase in nitric nitrogen varied from 30·8 to 46·5 kilos. per hectare per annum (corr.).

The same soils exposed in a dry condition, fresh surfaces being exposed by raking up from time to time, absorbed about 0·130 gram of ammonia per kilo., but the increase in nitric nitrogen was very slight.

The absorption of ammonia is greatest when the difference between the tension of the ammonia in the soil and that in the atmosphere is at a maximum, and is, therefore, greatest when the soil is moist and when nitrification converts the ammonia into nitrates as fast as it is absorbed. When the earth is dry, nitrification is suspended, and the ammonia accumulates up to a certain point, beyond which the rate of absorption gradually diminishes. C. H. B.

Vegetable Soils and Atmospheric Ammonia. By BERTHELOT (*Compt. rend.*, **110**, 558—560).—Vegetable soils usually evolve ammonia, but under certain conditions can absorb this gas from the atmosphere. The conditions under which the interactions become reversed are extremely complex, and cannot be regulated or defined. Corrections based on the amount of ammonia absorbed by a given superficial area of dilute sulphuric acid are not admissible, because the action of the acid is not reversible, and does not resemble that of the soil. A coefficient deduced from experiments of this kind is not generally applicable, because the absorption taking place in one locality may be more than counterbalanced by evolution which is going on at the same time in surrounding areas. Almost all investigators in this direction agree that the part played by atmospheric ammonia in the absorption of terrestrial nitrogen by plants is very small, and that vegetable soils are one of the chief sources from which the atmospheric ammonia is derived. C. H. B.

Remarks on the Observations of Berthelot on the Reactions between Vegetable Soil and Atmospheric Ammonia. By T. SCHLOESING (*Compt. rend.*, **110**, 612—613).—Purely polemical.

Composition of the Sea Mud in the New Alluvia of the Zuiderzee. By J. M. VAN BEMMELEN (*Landw. Versuchs-Stat.*, **37**, 239—256).—Analyses were made of the following soils:—(I.) The heavy clay from the former bay Y, which has been dammed in and cultivated. II. A lighter sea-clay, taken from the Zuiderzee, between Medemblik and the Island of Wieringen. III. Various samples of clay from the Zuiderzee. The following numbers show the percentages in I and II, in the soils dried over sulphuric acid:—

	CaO.	MgO.	K_2O.	Na_2O.	Fe_2O_3.	Al_2O_3.	SiO_2.	P_2O_5.
I.	5·73	2·26	2·59	1·13	5·64	14·10	52·5	0·17
II.	8·19	1·42	1·76	1·20	3·33	8·02	65·0	0·11

	CO_2.	Cl.	SO_3.	S.	Humus.	Water.
I.	—	—	—	—	6·93	4·85
II.	5·34	0·45	0·40	0·79	3·25	2·0

The amounts soluble in water, acetic, hydrochloric, sulphuric, and hydrofluoric acids, were determined, and are shown in tables.

The various other samples analysed were from newly-deposited clay and sand layers. The amount of sand they contained varied from 25 to over 90 per cent., whilst the percentage of calcium carbonate varied from 20 to 5. N. H. M.

Composition of the Volcanic Soils of Deli and Malang, and the Clay Soil of Rembang. By J. M. van Bemmelen (*Landw. Versuchs-Stat.*, **37**, 257—278).—For the last 20 years tobacco culture in Deli (Sumatra) has continually developed, and an excellent produce is obtained. Samples of the soil, which is very fertile, were analysed, and the results compared with those obtained from the soil of Malang (Java) and that of Rembang, in Java, which formerly yielded excellent tobacco, but later gave a produce of bad quality. The results of analyses of two Deli soils are given, (I) a reddish-brown clay or loam, and (II) a gray soil, from near Medan. The volcanic clay from Malang (III and IV) is quite different from ordinary clay; the weathered portion is yellowish-brown and plastic. The alluvial clay of Rembang (V) is brownish-yellow, and contains varying amounts of sand. The following are the analytical results given in percentages of the soils dried over sulphuric acid:—

	I.	II.	III.	IV.	V.

Analytical Chemistry.

New Gas Balance. By F. Lux (*Zeit. anal. Chem.*, **29**, 13—18). —The apparatus is identical in principle with the original pattern (*Zeit. anal. Chem.*, **26**, 38, *et seq.*), the gas stream being passed continuously through a globe attached to one arm of a balance, which, by its angle of deviation from the horizontal position indicates the weight, and, therefore, density of the gas. The improvements now introduced consist of the use of an agate plane and steel knife-edge for the central support, a cylindrical arrestment, by which the beam can be held stationary in any position, and a rider by which the deviation from the horizontal can be reduced. M. J. S.

Volumetric Estimation of Bromine in the Presence of Chlorine and Iodine. By N. McCulloch (*Chem. News*, **60**, 259—260).—The proposed method is only applicable in the absence of oxidising and reducing agents and of metals forming bromides insoluble in dilute hydrochloric acid. It is an outcome of the method of titrating a hydrochloric acid solution of iodine or an iodide with standard permanganate until the free iodine is converted into colourless monochloride as indicated by means of chloroform (Abstr., 1888, 626), a method which in the present instance is applied to bromine and bromides to obtain a first approximate estimate of the amount present. The reactions involved in the new method are—1. The production of manganic chloride without the evolution of chlorine, by the action of hydrochloric acid on permanganate in the presence of manganous chloride, and the manganic chloride not being attacked by hydrocyanic acid. 2. The conversion of bromine or iodine or their hydracids into monochlorides by the manganic chloride. 3. The decomposition by hydrocyanic acid of the compounds of chlorine, bromine, and iodine with one another, the result being that when permanganate is added in excess to a solution of hydrocyanic and hydriodic acid containing the required proportions of manganous chloride, hydrochloric acid, and hydrocyanic acid, cyanogen chloride, bromide, and iodide are ultimately produced at the expense of the manganic chloride first formed; consequently the amount of this salt reduced is a measure of the quantity of bromine or iodine present, and is ascertained by estimating by the iodine method the non-reduced manganic chloride remaining in the solution. Under the prevailing conditions, the accuracy of the method is affected neither by the action of hydriodic acid on cyanogen bromide or iodide, nor by the spontaneous decomposition of the manganic chloride. The solutions required are permanganate (31·9 grains to 10,000 grains of water), potassium iodide (82·78 grains to 10,000 grains of water), chloroform, hydrocyanic acid (potassium cyanide solution, 600 grains of 95 per cent. salt to 13½ ounces of water, acidified), and manganous chloride solution (½ lb. of crystallised salt to 4 ounces of water) containing 4 mols. of hydrochloric acid to every 3 mols. of the salt. All these reagents are purified to suit the requirements of the method, and whenever necessary are standardised under conditions similar to those to be encountered in their application. To make the estimation, the weighed bromide dissolved in ½ ounce of water is treated with excess of the standard permanganate (the quantity required having been approximately determined by the method already alluded to) and cooled to 55° F. The manganic hydrate is dissolved by adding about one-third of the volume of the solution of strong hydrochloric acid; excess of hydrocyanic acid is then added and the whole cooled. After half an hour the solution is titrated with standard iodide until nearly decolorised, and finally the excess of iodine is accurately determined by adding chloroform and titrating with permanganate. The bromine is calculated by taking the difference between the amounts of bromine represented by total permanganate and iodine used. If iodine is also present, it would be included in this bromine, and must therefore be determined separately by the permanganate-hydrochloric method and allowed for.

D. A. L.

Estimation of Free Halogens and of Iodides in Presence of Chlorides and Bromides. By P. LEBEAU (*Compt. rend.*, **110**, 520—522).—30 to 40 c.c. of carbon bisulphide and an equal volume of water is introduced into a flask holding about 200 c.c., and is mixed with a definite volume of the liquid to be analysed and a few drops of indigo sulphate solution. Standard bromine-water is then added drop by drop with vigorous agitation. The liberated iodine dissolves in the carbon bisulphide, and the upper layer of liquid remains blue until the whole of the iodine has been liberated. The slightest excess of bromine decolorises the indigo. The bromine solution must be kept in a bottle with a glass stopper, and used from a burette with a glass stop-cock, and its strength must be determined frequently.

Free halogens are best estimated by adding to the solution an excess of zinc powder and titrating the filtered liquid with standard silver nitrate.

C. H. B.

Volumetric Estimation of Sulphuric Acid. By A. GAWALOWSKI (*Zeit. anal. Chem.*, **29**, 19).—The author reaffirms the accuracy of his method (Abstr., 1888, 751), which had been disputed.

M. J. S.

Detection of Thiosulphuric Acid in Urine. By W. PRESCH (*Arch. path. Anat.*, **119**, 148—167).—See this vol., p. 812.

Estimation of Phosphoric Acid in the Presence of Silica. By K. PREIS (*Listy Chem.*, **13**, 153—154).—The author proves by numerous experiments that phosphoric acid may be estimated in the presence of pretty large quantities of silica (solution of soluble glass acidified with hydrochloric acid was employed), when the precipitate of ammonium phosphomolybdate is washed with pure, cold water. But as the liquid comes turbid through the filter towards the end, double filters should be used.

B. B.

Estimation of Total Phosphorus in Urine. By CHAPPELLE (*J. Pharm.* [5], **21**, 344—345).—10 c.c. of the urine is heated with 5 c.c. of sulphuric acid during several hours, or until the liquid becomes decolorised. The solution is diluted to 50 c.c., neutralised with sodium hydroxide, and precipitated with magnesium mixture in the usual way.

J. T.

Behaviour of Silica and its Compounds in Fused Microcosmic Salt. By J. HIRSCHWALD (*J. pr. Chem.* [2], **41**, 360—367).—

The insolubility of silica in fused microcosmic salt has long been recognised as a test for that substance.

If microcosmic salt is fused on a platinum loop and heated to the highest temperature of the blowpipe flame for some time, it gradually becomes turbid from the presence of crystals which, as seen magnified 400 times, are hexagonal pyramids; they are probably a sodium pyroborate, and evidently identical with the crystals obtained by Wunder (*J. pr. Chem.* [2], 1, 460). The possibility of mistaking these crystals for undissolved silica is obvious.

A bead of fused sodium hexametaphosphate dissolved at a bright red heat 2·55 per cent. (of its original weight) of powdered rock crystal before it became turbid; but this number is probably lower than it should be, for phosphoric acid is most likely lost during the heating. No pyrophosphate crystals could be detected in the bead, but transparent, spindle-shaped crystals were seen after it had cooled.

Many mineral silicates, even in the form of splinters, dissolve completely in the fused salt. A classification of such silicates is given according as they dissolve in the form of powder to a clear glass (1) after some time, (2) easily, (3) very easily. The experiments were made with the aid of the microscope.

Many minerals free from silica remain undissolved in the fused salt. A. G. B.

Detecting Metallic Silver in the Presence of Lead. By A. JOHNSTONE (*Chem. News*, 60, 309).—The metallic bead obtained with fusion mixture on charcoal before the blowpipe, is dissolved in nitric acid, the solution nearly neutralised with sodium carbonate, and strips of copper and zinc immersed in it. The silver is deposited on the copper and can be tested, whilst the lead separates on the zinc. T. P. Blunt points out in a letter (*Chem. News*, 61, 11) that a more rapid method of detecting silver is by adding a saturated solution of lead chloride to the solution containing the metallic bead dissolved in nitric acid. D. A. L.

Impurities in Commercial Barium Carbonate. By R. WEGSCHLIDER (*Zeit. anal. Chem.*, 29, 20).—In a specimen from a well-known German maker, traces of zinc and iron were found. In another preparation, a not inconsiderable quantity of manganese was present. M. J. S.

Separation of Barium and Strontium. By R. FRESENIUS (*Zeit. anal. Chem.*, 29, 20—28).—The author's experiments fully confirm the statement of Schweitzer that the action of cold ammonium carbonate, or that of boiling potassium carbonate mixed with sulphate, on a mixture of barium and strontium sulphates is totally different from their action on the individual sulphates when separate. However varied the mode of treatment, part of the barium sulphate was converted into carbonate, whilst part of the strontium sulphate remained unattacked, the proportions varying according to the preponderance of one or the other sulphate. Rose's methods of separation are therefore quite valueless. M. J. S.

Estimation of Zinc in Blende containing Manganese. By W. Stahl (*Chem. Centr.*, 1890, i, 297; from *Berg. Hutt. Zeit.*, **49**, 5—6).—The solution of blende in nitric acid is concentrated, and potassium chlorate is added as long as the green vapours of chlorous anhydride are evolved; the manganese being thus peroxidised. The mixture is boiled, diluted carefully with water, rendered ammoniacal, and filtered. The manganese and the greater portion of the lead are thus separated, and the remainder of the latter may be precipitated by ammonium phosphate. This precipitate must be dissolved in nitric acid, and reprecipitated in order to obtain all the zinc in solution, after which its quantity is determined by means of a standard solution of sodium hydrosulphide. J. W. L.

Sensitive Test for Certain Impurities in Mercury. By G. Gore (*Chem. News*, **61**, 40—41).—Pure mercury was treated with minute but known quantities of amalgams prepared from the same mercury, and the effect of these mixtures on electrolytes was observed by means of an ordinary astatic torsion galvanometer of 100 ohms resistance, 0·00013258 volt being the minimum degree of E.M.F. required to visibly move the needles. The results were as follows, the numbers being parts of mercury to one of the foreign metal:—

Metal added.	Electrolyte consisting of	
	1 grain HCl or H_2SO_4 in 120 c.c. water.	10 grains KCl in 120 c.c. water.
Magnesium	110,274,000,000	13,430,858,806
Zinc	104,950,000,000	18,034,482,758
Cadmium	184,828,432	10,404,225
Tin	38,900,000	8,531,632
Copper	15,484,375	1,640,160
Bismuth	9,762,300	1,621,000
Lead	5,651,149	1,050,341
Silver	905	79

This forms a delicate means of detecting impurities of this class in mercury; some mercury containing all the above metals was found to produce no deflection of the needle after a second distillation.

D. A. L.

Volumetric Estimation of Iron in Ferrum Reductum. By A. Partheil (*Chem. Centr.*, 1890, i, 495—496; from *Apoth. Zeit.*, **5**, 55).—The author has applied the following method to the estimation of the iron in ferrum reductum, on the supposition that it consists of a mixture of metallic iron and magnetic oxide of iron, and the results are satisfactory.

1 gram ferrum reductum is dissolved in a 200 c.c. flask with 40—50 c.c. of sulphuric acid (1 : 5). Potassium permanganate solution is now added drop by drop until the solution is just coloured, any slight excess being reduced by the addition of a minute quantity

of sugar. The solution is now diluted to the mark, and 50 c.c. ($=0\cdot25$ gram ferrum reductum) added to a solution of 2 grams of potassium iodide, and finally a few c.c. of hydrochloric acid. After remaining an hour at the ordinary temperature, the free iodine is estimated by titration with decinormal sodium thiosulphate, starch being used as indicator. Ferrum pulv. is treated in the same way. The total percentage of iron is obtained from the number of c.c. of sodium thiosulphate used, and that of metallic iron is obtained by the use of the formula:—

$$Z = \frac{2\cdot03\,m}{p} - 262\cdot5,$$

where $p =$ weight of substance in grams, $m =$ c.c. sodium thio sulphate. J. W. L.

Analysis of Chrome-Iron Ore. By R. FRESENIUS and E. HINTZ (*Zeit. anal. Chem.*, 29, 28—35).—The following method was adopted with success for a very refractory ore containing 61 per cent. of chromium, 28 per cent. of iron, and 9 per cent. of combined carbon and graphite. About 5 grams of the mineral, placed in a porcelain boat, is gradually heated in a stream of dry chlorine, in a hard-glass tube, connected with a Péligot's tube, a Woulff's bottle, and two more Péligot's tubes in succession, all of which contain water. The heat is so regulated that most of the ferric chloride condenses in the tube. When cold, the receivers are exchanged for a fresh Péligot tube containing water, the chlorine is displaced by carbonic anhydride, and then dry hydrogen passed through, while the boat and the sublimate are gently heated, to reduce part of the chromic chloride to chromous chloride, and thus render it soluble. After cooling, the contents of the boat, consisting of carbonaceous matter, graphite, slag, particles of unattacked chrome ore, manganous chloride, and traces of iron and chromium chlorides. are washed, dried, and ignited in a stream of oxygen, then in hydrogen to reduce the oxide of iron, and then again in chlorine with the original receivers. Any residue now remaining is washed, dried, and weighed, and if its amount is considerable is further analysed. The second sublimate is heated in hydrogen like the first, and the contents of the two tubes are then treated with a measured quantity of hydrochloric acid of sp. gr. 1·1, and the solution added to the contents of the receivers, and the washings of the residue in the boat. If this liquid does not remain clear, the sediment is collected, and fused with a mixture of sodium carbonate and potassium chlorate, and the solution of the fused mass is evaporated with hydrochloric acid to dryness, and again taken up with a known volume of hydrochloric acid of 1·1 sp. gr. Any insoluble matter is washed, dried, and preserved; the solution is added to the principal one. A sufficient amount of sodium carbonate is now added to leave about 4 per cent of hydrochloric acid (of 1·1 sp. gr.) free, and the liquid is then treated with hydrogen sulphide, first at 70°, and then cold. The precipitate is dissolved in hydrochloric acid containing bromine, and the solution, after removal of the bromine by ammonia, is again acidified with hydrochloric acid, and precipitated by hydrogen sulphide. The metals of the 5th and 6th groups contained in this precipitate are separated by the usual methods. The filtrate is added to the principal one, which is then evaporated to dryness for the separation of the silica, and the precipitate is ignited together with that obtained from the fusion. If white, it is weighed; the silica is removed by heating with hydrofluoric acid; any residue is fused with potassium hydrogen sulphate. and tested for titanic acid by boiling, and for bases by ammonia If it is not white, it must be fused with sodium carbonate and potassium nitrate, and the solution again evaporated with hydrochloric acid, the filtrate being then united with the principal solution, and the precipitate treated as above.

The solution is now treated with chlorine, the excess of which is expelled by heating. After evaporating to about a litre, and cooling, it is nearly neutralised with sodium carbonate, and mixed in a flask with a small excess of precipitated barium carbonate. The precipitate is thoroughly washed, dissolved in hydrochloric acid, and made up accurately to 1 litre. Of this, 200 c.c. is evaporated, and the barium it contains is precipitated by cautious addition of sulphuric acid to the hot solution, avoiding excess. The filtrates from the barium sulphate (which requires to be repeatedly digested with hydrochloric acid to free it from iron and chromium) are evaporated, mixed with sodium carbonate and potassium chlorate, and fused. The melt is extracted with hot water, and the residue fused a second time with carbonate and chlorate. The ferric oxide is finally dissolved in hydrochloric acid, and precipitated with ammonia as usual. It should be tested for alumina and silica, and these, if necessary, deducted. The solution containing the chromium is made alkaline with ammonia. Any precipitate produced is collected on a filter and examined for alumina, aluminium phosphate, silica, and titanic acid. The chromate is finally reduced by hydrochloric acid and alcohol, and precipitated as chromic oxide. This precipitate may contain phosphoric acid.

The filtrate from the barium carbonate precipitate will contain the manganese, nickel, cobalt, and zinc. It is freed from barium as above, and after nearly neutralising with ammonia, is mixed with ammonium acetate. and treated with hydrogen sulphide, which throws down nickel, cobalt, and zinc. These are separated by the usual methods, whilst the manganese in the filtrate is precipitated first with bromine and ammonia, and then, for removal of alkali, with ammonium sulphide.

For the estimation of the carbon, phosphorus, and sulphur, 5 grams is treated with chlorine as above, and the contents of the boat are digested with a mixture of chromous chloride and hydrochloric acid, and filtered through an asbestos filter. The carbon is thoroughly washed, and then oxidised by chromic and sulphuric acids. The solution in the receivers, which contains all the sulphur and phosphorus as sulphuric and phosphoric acids, is evaporated with addition of sodium chloride for removal of silica; the sulphuric acid is precipitated by barium chloride, and the phosphoric acid from the filtrate (after evaporation with nitric acid for removal of chlorides) by molybdate, with the usual precautions. Any arsenic in the mineral will accompany the phosphoric acid, and after weighing the magnesium phosphate it must be precipitated as sulphide and deducted.

For estimating the graphite, 10 grams of the very finely-powdered ore is digested with hydrochloric acid until the residue is no longer affected by a magnet brought near the flask. This requires some weeks. The graphitic residue is washed on an asbestos filter with water, potash, alcohol, and ether, and its amount ascertained by oxidation with chromic and sulphuric acids. M. J. S.

Detection of Tin in Minerals. By A. Johnstone (*Chem. News*, **60**, 271).—The mineral is heated before the blowpipe on charcoal with white flux, sometimes with the addition of borax or potassium cyanide or both. The ignited residue with some of the surrounding carbon is crushed in a mortar, washed with water, and the metallic scales remaining behind tested for tin, by dissolving in hydrochloric acid, and treating with gold chloride or with hydrogen sulphide.

D. A. L.

Quantitative Estimation of Antimony. By F. Beilstein and O. v. Blaese (*Chem. Centr.*, 1890, i, 350; from *Bull. Acad. St. Pétersbourg* [2], 1, 209—211).—The authors recommended that antimony should be weighed as sodium antimonate, $NaSbO_3 + 3\frac{1}{2}H_2O$. Of the air-dried salt, 1000 parts of water at 12·3° dissolves 0·31 part; 1000 parts of alcohol of 15·8 per cent. at 12·3° dissolves 0·13 part; 1000 parts of alcohol of 25·6 per cent. at 12·3° dissolves 0·07 part; of the freshly precipitated and washed salt, 1000 parts of alcohol of 25·5 per cent at 18·1° dissolves 0·0956 part. Sodium hydroxide and carbonate reduce the solubility of the salt somewhat; ammonia and potassium salt dissolve the salt rather more than water; in glacial acetic acid the salt is quite insoluble.

The authors, therefore, recommend the following method:—The precipitated antimony sulphide is washed from the filter with water, and warmed with addition of concentrated sodium hydroxide solution and 70 c.c. of hydrogen peroxide. After the oxygen has been evolved, one-third of the volume of 90 per cent. alcohol is added, and the whole allowed to remain for 36 hours in the cold. The precipitated sodium antimonate is first washed by decantation, then on the filter, with a solution consisting of 1000 c.c. of 25 per cent. alcohol, 7 grams of sodium acetate, and 7 c.c. of glacial acetic acid, until no trace of sulphuric acid remains; then, finally, with 50 per cent. alcohol. The analyses are very satisfactory. J. W. L.

Estimating Minute Quantities of Gold. By G. Tate (*Chem. News*, **61**, 43—46; 54—55; 67—70).—The author advocates and fully describes the microscopic measurement of beads of gold obtained in assays, and its application to the estimation of that metal. Beads as small as 0·00075 inch diameter, and representing 0·000001 grain, can be measured; the method is, therefore, susceptible of great accuracy, and requires smaller quantities for analysis than gravimetric methods.

Various experimental results show:—1. The even distribution of gold in ingots of lead-gold alloy; 2. That the loss of gold in parting gold-silver alloy increases with the proportion of the latter metal; 3. That in cupellation there is practically no loss of gold; and 4. That very minute quantities of gold can be separated from highly complex mixtures, and detected by the use of the microscopic method.

D. A. L.

Electrolytic Estimation of Palladium. By E. F. Smith and H. F. Keller (*Amer. Chem. J.*, **12**, 212—216).—Attempts to electrolyse a solution of palladium cyanide with excess of potassium cyanide, or of palladious chloride with a large excess of potassium thiocyanate, did not give quantitative results; the deposited metal was black, and exhibited spongy spots. Good results were obtained by electrolysing a solution made by dissolving 0·2228 gram of palladio-diammonium chloride, $PdN_2H_6Cl_2$, in ammonia, and adding 20 to 30 c.c. of the same reagent (sp. gr. 0·935) and 75 c.c. of water. The current was of such a strength as to generate 0·9 c.c. of mixed gases per minute in a water voltameter, and was allowed to run during the night. Good results were also obtained with a slightly larger excess of ammonia, and a current giving 0·8 c.c. per minute, running for 16 hours, and also with double the amount of palladium, and a current giving 0·7 c c. per minute running for 18 hours. It was necessary to have excess of ammonia present in order to prevent the deposition of palladium oxide on the positive pole. The deposit of palladium, which was bright and metallic in appearance, was dried at 110° to 115°. As it was very slow in dissolving, even in fuming nitric acid, it was found expedient to first coat the platinum vessels employed with a thin layer of silver.

C. F. B.

Colorimetric Methods for Determining Nitrates in Potable Waters. By S. Rideal (*Chem. News*, **60**, 261).—The "phenol sulphuric acid" and "carbazole" tests are compared. In the "phenol sulphuric acid" experiments, a solution containing 0·7215 gram of potassium nitrate per litre, and "phenol sulphuric acid," prepared by dissolving 15 grams of phenol in 92·5 c.c. of sulphuric acid, diluted with 7·5 c.c. of water, were employed; 1 c.c. of the latter was applied to the dry residue from the water, to which was then added 1 c.c. of water and 3 drops of sulphuric acid; the whole being now gently warmed, diluted, transferred to a Nessler tube made up to 100 c.c., and the colour compared with that obtained with the standard nitrate. In the carbazole tests, 100 c.c. of water was taken, the chlorine precipitated with silver sulphate (4·3945 grams per litre), 2 c.c. of aluminium sulphate (5 grams per litre) added, the whole made up to suitable bulk, and filtered. To 2 c.c. of the filtrate, 4 c.c. of sulphuric acid was added, and when cool, 1 c.c. of a mixture, prepared by mixing 1 c.c. of glacial acetic acid solution of carbazole (containing 0·6 gram per 100 c.c.) with 15 c.c. of sulphuric acid, the colour being compared against the standard nitrate. The results from five different waters were:—

	Nitrogen in parts per 100,000				
	1.	2.	3.	4.	5.
By "phenol sulphuric acid"	0·025	0·050	0·200	1·400	1·60
By carbazole............	0·025	0·045	0·209	1·380	1·65

D. A. L.

Colorimetric Methods for Determining Nitrates in Potable Waters. By A. E. Johnson (*Chem. News*, 61, 15).—Referring to the note by S. Rideal (preceding abstract) on this subject, the author points out that he prefers using a standard nitrate solution of one-tenth the strength—100 c.c. of the 0·7215 gram solution, diluted to a litre; moreover, he prepares his "phenol sulphuric acid" by digesting the mixture for eight hours in a boiling water bath, and, when cool, adding water and hydrochloric acid; convenient quantities are 80 c.c. of liquefied crystalline phenol, 200 c.c. of H_2SO_4, and 420 c.c. of H_2O, and 140 c.c. of HCl. His procedure is, briefly:—The water and standard nitrate are evaporated to dryness simultaneously, and the residue in each case is treated with 1 c.c. of the "phenol sulphuric acid," and heated gently for 15 minutes; with bad waters, a red colour soon appears; then they are diluted, treated with ammonia, and the colour compared in Nessler tubes, &c. Larger quantities of water and less nitrate are evaporated for good waters, whilst bad waters may even be diluted. D. A. L.

Estimation of Water, Humus, Sulphur, &c., in Soils. By J. M. van Bemmelen (*Landw. Versuchs.-Stat.*, 37, 279—290).—With regard to the estimation of water, the colloïdal substances present in soils retain more or less water, according to (1) their composition and state of equilibrium, (2) the tension of the aqueous vapour, and (3) the temperature. The amount of water lost by an air-dried soil at 100°, has no special meaning, and it is suggested that, for comparison, the results of analyses should be calculated to show percentages in the soils dried over sulphuric acid. The water which remains, the strongly combined water, is determined separately. The humus is determined by multiplying the amount of carbon by 1·724. The amount of carbon is found, in the case of soils containing calcium carbonate, by adding the amount which remains as carbonate after burning, to that absorbed as carbonic anhydride in the potash bulbs, and deducting that of the carbonates originally present, which is separately determined.

The carbonates are determined at the ordinary temperature; if the soil is boiled with acid, too high results will be obtained, owing to the partial decomposition of the humus.

The loss by ignition can only be considered as the sum of the humus and water, in the case of soils which contain no carbonates, chlorides, and sulphides. Moistening the ignited soil with ammonium carbonate solution is to be avoided for several reasons. In the case of sea-mud, the author determined the carbonic anhydride, sulphuric acid, and chlorine in the soil before and after ignition, and then applied the necessary correction.

The strongly combined water cannot be determined exactly, and is derived either from the difference between loss on ignition and the humus, or from the difference between the amount of water determined by analysis and the amount of water corresponding with the humus. In volcanic soils, the humus was assumed to contain 5 per cent., and in soils derived from the sea 6 per cent. of water.

In the estimation of sulphuric acid, difficulties may arise from the insolubility of a small part of the sulphates, and from the presence of sulphur in the organic matter of the soil. If the aqueous extract contains ferric oxide or more than a trace of humus, these must be got rid of, or the results will not be exact. In the analysis of soils which gave extracts containing only a little humus, the silicic acid was removed, then the ferric oxide and alumina were precipitated by boiling sodium carbonate, the solution acidified and precipitated with barium chloride and filtered after two days. The ferric oxide and alumina were redissolved, the solution treated with barium chloride, and kept for some days. Another method employed was to heat the substance with an excess of sodium carbonate in a stream of oxygen in a combustion-tube, the temperature being kept sufficiently low to prevent the glass from being attacked. Sulphuric acid was also determined by heating the substance with sodium carbonate and potassium nitrate in a platinum crucible at a dull red heat. The solutions were always evaporated on the water-bath, and not directly over a gas flame.

Silicic acid and alumina in the colloïdal silicates were determined in successive extracts, made with dilute hydrochloric acid, dilute potash, stronger hydrochloric acid, dilute potash. The residues of the solutions are heated with sulphuric acid to destroy the organic matter. The silica is then completely, or almost completely, separated from the alumina, when the residue is treated with hydrochloric acid. The silica is always tested with hydrofluoric acid to see if it is pure. In estimations of alumina and silica, the latter, after it has been weighed, is treated with hydrofluoric and sulphuric acids, and the small amount of alumina in the residue determined.

The alkaline bases are separated from the alkaline earths by Deville's method, with oxalic acid, after precipitating any sulphuric acid which may be present. Corrections are applied for a trace of lime and potash in the oxalic acid, and for the small amount of magnesia which remains with the alkalis.

Manganese is most conveniently determined by Carnot's method (Abstr., 1889, 443). The hydrochloric acid extract of the soil is evaporated down, heated with potassium hydrogen sulphate, and the neutralised solution of the residue precipitated with hydrogen peroxide solution (20 c.c.), and ammonia (30 c.c.). The precipitate is washed by decantation, put into the carbonic acid apparatus, and treated with oxalic and dilute sulphuric acids. From the amount of carbonic anhydride obtained, the amount of manganese is calculated, assuming the precipitate to have the formula Mn_6O_{11} (Carnot, *loc. cit.*).

N. H. M.

Estimation of Ash in Food and Drugs. By W. Kwasnik (*Arch. Pharm.* [3], **28**, 178—182).—This operation is much facilitated by mixing the powdered substance with an equal weight of Kassner's

recently described calcium plumbate. In the case of liquids, such as milk, the residue, after evaporation, is charred, mixed with the plumbate, and roasted. Any plumbate reduced is re-oxidised, and the temperature is so low that chlorides are not volatilised. Results quoted to show the exactness of the process are perfectly satisfactory.
J. T.

Maumené's Test for Essential Oils. By R. WILLIAMS (*Chem. News*, **61**, 64—65).—The successful working of this test is influenced by the nature of the oil, the strength of acid used, by the mode of adding the acid, and manner of stirring. The author has applied it to many essential oils in the following manner:—100 fluid grains of oil was mixed with 20 fluid grains of sulphuric acid, in a beaker surrounded with cotton-wool, and stirred vigorously with a thermometer. The numerous figures obtained in this manner are tabulated, and indicate a probable useful application of the test, especially for confirming the presence of resin in oil of cassia. D. A. L.

Estimation of Ferrocyanides in the Bye-products of Gas Works. By R. GASCH (*Chem. Centr.*, 1890, i, 294—295; from *J. Gasbeleucht Wasserversorg*, **32**, 966).—Of the several methods which have been recently recommended for the determination of ferrocyanides in the bye-products of gas works, the author considers Żulkowsky's (Abstr., 1884, 501) the most applicable. He recommends, however, a solution of uranium acetate, 1 per cent., instead of ferric chloride, as indicator, a drop of the solution which is being titrated being brought on to a porcelain slab to which is added a drop of the uranium acetate solution, when the presence of any excess of ferrocyanide is indicated by the formation of a brown coloration. Moreover, instead of preparing a standard solution of potassium zinc sulphate, the author prefers the use of a standard solution of potassium ferrocyanide containing 20 grams per litre, with which the strength of the zinc solution may be readily determined. In applying the method to old gas-waste, 20 grams are rubbed in a warm mortar, with a little (15—20 per cent.) sodium hydroxide solution, and warm water gradually added until the whole is of a thin consistence; it is then filled into a 200 c.c. flask, shaken, and filtered directly into the burette from which the titration is made. In the case of gas liquor, it is desirable to add a crystal of ferrous sulphate and a small piece of sodium hydroxide. The formation of ferrous cyanide proceeds readily, and may be hastened by warming, after which the determination is carried out in the usual manner. If it is found that so little ferrocyanide is present that it cannot be directly determined, it is precipitated as Prussian blue, filtered, and dissolved in potassium hydroxide solution, which is then titrated from the burette as in the preceding case. J. W. L.

Volumetric Estimation of Potassium Ferricyanide. By G. KASSNER (*Arch. Pharm.* [3], **28**, 182—186).—A weighed quantity of ferricyanide is dissolved in water, and treated with so much potassium hydroxide that an excess remains after the reduction of the salt, and sufficient but not too much hydrogen peroxide is added, so that in a few seconds the liquid takes a scarcely perceptible yellow tint. To remove the excess of peroxide, the alkaline liquid is heated to boiling, until a drop of the solution gives no coloration when added to potassium iodide and starch. The solution is then cooled considerably, diluted, acidified with dilute sulphuric acid, and titrated with potassium permanganate. The results are very exact. J. T.

Assay of Commercial Glycerol. By M. Vizern (*J. Pharm.* [5], 21, 345—347).—Crude glycerol is usually sold by soap-makers as containing 80 per cent. of glycerol. This is affirmed on the part of buyers to be indicated by a minimum sp. gr. of 1·300 at 15°, and a boiling point of 155°. The author shows that an imitation crude glycerol of 80 per cent. strength had a sp. gr. of 1·289 and boiling point of 136° at 756 mm. Commercial samples were titrated for glycerol with dichromate (Hehner's method) after treatment with silver oxide and basic lead acetate. The results show that it is impossible to determine exactly the amount of glycerol in a sample by the specific gravity and boiling point, also that 80 per cent. glycerol has generally a density below 1·3, and a boiling point below 150°. J. T.

The Value of the Phenylhydrazine Test for Sugar. By J. A. Hirschl (*Zeit. physiol. Chem.*, 14, 377—389).—Many tests for sugar in urine are fallacious, because the reactions in question are given by other substances as well.

The most trustworthy tests are those with yeast, and with the polarimeter. Recently, v. Jacksch has introduced the phenylhydrazine test (Abstr., 1886, 744), and the present investigation is directed to determining whether this test may be added as a third trustworthy reaction for detecting the presence of sugar in urine. Such an investigation is all the more necessary since Thierfelder (Abstr., 1887, 717) and Geyer (*Wiener med. Presse*, 30, 1686) have stated that glycuronic acid, a substance very liable to be mistaken for sugar, forms a compound with phenylhydrazine acetate analogous to that on the formation of which the detection of sugar depends. Geyer, indeed, states that the resemblance of the crystalline compounds obtainable is so close as to render the test of little value.

In the present research, experiments were first performed with pure sodium glycuronate. This was dissolved in water and mixed with phenylhydrazine hydrochloride and sodium acetate in the usual way, and placed in the water-bath at 100° for a quarter of an hour. It was then removed, and the precipitate which formed on cooling examined microscopically. The needles which were present mixed with amorphous matter were thicker than those of phenylglucosazone, but showed the same radial grouping, and were difficult to distinguish from them. If, however, the mixture was allowed to remain for a longer time than a quarter of an hour (30—60 minutes) in the water-bath, the precipitate obtained was amorphous, brownish-yellow, and altogether different and easily distinguishable from phenylglucosazone. Its melting point, after half-an-hour's stay in the water-bath, was 107—108°; after an hour, 150°. Fifty different kinds of urine were then submitted to the test: an hour's stay in the water-bath was always employed; 45 of these gave the amorphous, brown precipitate with a melting point of 150°. In one case there was no precipitate. In four cases there was the typical formation of yellow, crystalline needles (melting point 205°). In these four cases alone the fermentation test gave positive results; three were from patients suffering from diabetes mellitus, the fourth was a case of glycosuria occurring in a patient with cerebral hæmorrhage.

If the amorphous precipitate obtained in the first 45 cases consisted of the phenylhydrazine-compound of glycuronic acid, it would appear that glycuronic acid is a constant constituent of human urine.

In addition to dextrose, three other sugars have been described in human urine: (1) levulose (Zimmer, *Deutsch. med. Woch.*, **2**, 329; Seegen, *Centr. med. Wiss.*, **22**, 753); this has been found only, mixed with dextrose, in diabetes. It cannot be distinguished from dextrose by the phenylhydrazine test, but only by the polarimeter. (2) Lactose (Hofmeister, *Zeit. physiol. Chem.*, **1**, 101). This is found only in the urine of suckling women. The compound, phenyllactosazone, formed by the action of phenylhydrazine, occurs in needles, which are about ten times the width of those of phenylglucosazone, and do not show the same orderly arrangement. Their melting point is 200°. (3) Maltose has been found in diabetic urine (Le Nobel); this gives a precipitate of phenylmaltosazone, which occurs in yellow tables melting at 82°.

The conclusions drawn are that the phenylhydrazine test is a perfectly trustworthy one.

(1) If the urine gives perfectly typical needles of phenylglucosazone, it certainly contains glucose. 0·03 per cent. of sugar in urine, 0·003 per cent. of sugar in water, can by this means be detected.

(2) It is essential that the test-tube should be allowed to remain one hour in the water-bath.

(3) If the result is a yellowish-brown, amorphous precipitate, sugar is not present, but the substance which behaves in this way is probably glycuronic acid. W. D. H.

Estimation of Sugar in Urine by Fermentation. By P. Guttmann (*Chem. Centr.*, 1890, i, 355—356; from *Deut. med. Wochenschr.*, **16**, 7—9).—The author has not found Einhorn's method, in which the carbonic anhydride obtained by fermentation is estimated, very suitable for the determination of sugar in diabetic urine. On the other hand, Roberts' method (*Med. Journ. Edinburgh*, 1861, 326) has given satisfactory results. 100—120 c.c. of the urine is filled into a vessel, and treated with 5—10 grams of fresh yeast, and then allowed to ferment. The density is determined before and after the fermentation at 15°, from which, by means of Worm-Müller's formula (*Pflüger's Archiv*, **33**, 211—220), the amount of sugar is obtained. J. W. L.

Estimation of Inverted Sugar. By J. Formánek (*Listy Chem.*, **14**, 132).—The solution precipitated with Fehling's solution is poured on to a filter containing water, in order to prevent it from

absorbing copper solution, which cannot subsequently be washed out, and the washed cuprous oxide is dissolved in nitric acid on the filter, washed out, and the copper estimated by electrolysis of the solution.

B. B.

Estimation of Acetone in Methyl Alcohol and in the Liquids used for Methylating Alcohol. By L. VIGNON (*Compt. rend.*, **110**, 534—536).—The acetone is converted into iodoform ($C_3H_6O = CHI_3$), which is extracted with ether free from alcohol, and weighed after evaporation of the ether. Krämer (Abstr., 1880, 826) specifies certain quantities of iodine and sodium hydroxide, but the quantity of iodine required for complete conversion of the acetone into iodoform varies with the order in which the liquids are mixed, and with other conditions of experiment, and if the iodine is not in large excess the results are too low. The author recommends the following mode of working. 5 c.c. of the liquid to be examined is diluted to 250 c.c. 5 c.c. of this mixture is agitated with 10 c.c. of binormal sodium hydroxide in a graduated and stoppered cylinder holding 100 c.c., and 5 c.c of binormal iodine in potassium iodide is then added. After vigorous agitation, 10 c.c. of ether free from alcohol is added. The volume of the ethereal solution is observed, and 5 c.c. is withdrawn, evaporated in a vacuum, and the iodoform weighed. If V is the volume of the ethereal solution, p the weight of the iodoform, and x the weight of acetone in 100 c.c. of the liquid,

$$x = 1000\,pV\;58/5 \times 394 = pV \times 29{\cdot}44.$$

The method is only applicable in absence of aldehyde, ethyl alcohol, or any substance besides acetone which will yield iodoform.

C. H. B.

Estimation of Acetone as Iodoform. By G. ARACHEQUESNE (*Compt. rend.*, **110**, 642—644).—Complete conversion of acetone into iodoform requires a quantity of iodine considerably in excess of the calculated quantity. In addition to sodium acetate and sodium iodide, iodate and formate, and probably salts of some other organic acids, are formed. Krämer recommends too low a proportion of iodine or too large a quantity of the liquid to be examined (compare preceding abstract). C. H. B.

Estimation of Fat in Milk. By LEZÉ (*Compt. rend.*, **110**, 647—649).—The process is based on the fact that if the milk is treated with an acid, and afterwards with ammonia, the fat separates readily.

A mixture of 100 vols. of milk with 200 to 250 vols. of pure concentrated hydrochloric acid is placed in a flask with a long graduated neck, heated until the liquid acquires a brown colour, and then mixed with dilute ammonia until the fat gradually separates, and the liquid becomes clear. Warm water is added so that the fat is brought into the graduated neck, and the volume of the fat is read off. The fat melts at 32—33°, and its sp. gr. at 15° is 0·93. At the melting point its sp. gr. is 0·90, and hence the volume of the fat in cubic centimetres × 0·9 gives the weight of fat in the quantity of milk taken. Good results are obtained with 44 c.c. of milk and 100 c.c. of acid. The temperature at which separation occurs readily is about 80°.

C. H. B.

Analysis of Butter. By S. Bondzyński and H. Rufi (*Zeit. anal. Chem.*, 29, 1—6).—The most characteristic constituents of butter are the volatile fatty acids, or rather their glycerides. Since the same acids are also freely soluble in water, the separation of them by distillation can be replaced by one of the following more convenient methods:—(1.) 4—5 grams of the butter is saponified with 50—60 c.c. of N/2 alcoholic potash, and the unneutralised potash is titrated by N/2 hydrochloric acid. The alcohol is then evaporated off, and the soap is decomposed by an excess of hydrochloric acid. The precipitated, insoluble fatty acids are washed with hot water on a filter, dissolved in alcohol, and titrated with N/2 or N/4 potash. The difference between the quantity of potash neutralised in the saponification and that required by the insoluble acids gives the amount corresponding with the volatile acids. (2.) 4—5 grams of the butter is saponified; the alcohol is removed by evaporation, and the aqueous solution is treated with the exact amount of hydrochloric acid necessary for neutralising the potash used. The insoluble fatty acids are washed, and the soluble acids in the filtrate are titrated with N/10 potash. The results of these methods agree with one another, and with the distillation process. The insoluble acids can be dissolved in ether, and weighed after evaporation. If then titrated with potash, the corresponding amount of glycerol can be calculated, and therefrom that of the glycerides of the insoluble acids, which by difference gives the amount of the glycerides of the volatile acids.

Fresh butter always contains small quantities of free insoluble acids and oleïc acid; free volatile acids are not present. As the butter becomes rancid, the increase in acidity is due mainly to the insoluble acids. Free volatile acids are only developed at a somewhat advanced stage of rancidity. The free acids can be estimated by dissolving about 20 grams of the butter in alcohol and ether, and titrating with N/20 alcoholic potash. Or an ethereal solution may be treated with dry calcium hydroxide, when the calcium salts of palmitic, stearic, and other related acids form a precipitate, which can be collected, decomposed by sulphuric acid. and extracted with ether. The calcium oleate remains in solution. If the solution is evaporated and burnt, and the lime weighed, the oleïc acid can be calculated from it. Free volatile acids can be estimated by melting the butter in hot water, washing on a filter, and titrating the filtrate. Phenolphthaleïn should in all cases be used as indicator.

Some experiments have also been made towards the estimation of hydroxy-acids in butter by Benedikt's acetylation method (Abstr., 1887, 620). The acetyl number 18·2 was found for butter.

M. J. S.

Valuation of Crude Cocaïne from Peru. By E. R. Squibb (*Zeit. anal. Chem.*, 28, 743—744).—A moisture estimation is made in the usual way: 2 grams of the sample is then dissolved in 12 c.c. of ether (0·725 sp. gr.), and filtered from insoluble matter, which is washed with ether, dried, and weighed. The ethereal solution, which will amount to about 50 c.c., is shaken with 10 c.c. of normal oxalic acid in a separation bulb. The acid is then run into a second separation bulb, and the ethereal solution is shaken with 10 c.c. of water containing 2 drops of oxalic acid, and then twice with 3 c.c. of water, these aqueous liquids being then added to the acid. The washed ethereal solution is now run into a tared beaker, the bulb is rinsed with 15 c.c. of ether and 2 c.c. of water, all of which is added to the acid solution. After subsiding, the acid layer is run back into the first bulb, and the ether, after twice washing with 3 c c. of water, is added to the former ethereal solution, and the whole evaporated to obtain the weight of the impurities soluble in ether. The bulb is once more rinsed with 15 c.c. of ether and 2 c c. of water, which mixture is added to the acid solution. This is then treated with normal soda, adding 1 drop in excess of neutrality. After shaking and settling, the sodium oxalate is run into the empty bulb, the ether is washed twice with 3 c.c. of water, and run into a tared beaker, taking care that no water accompanies it. The bulb is rinsed with 10 c.c. of ether and 2 c.c. of water. This is added to the oxalate solution with 1 drop more of soda. After vigorous shaking, the aqueous liquor is run away. The ethereal liquid is added to the previous one, and the whole evaporated. The cocaine is dried at 90° and weighed. Recent estimations have given 94 per cent. in the best sorts, and 78 in the worst. M. J. S.

Cocaïne Chromate. By K. Mezger (*Chem. Centr.*, 1890, i, 352; from *Pharm. Zeit.*, **34**, 697—698).—From a hydrochloric acid solution, chromic acid precipitates the *cocaine chromate*, $C_{17}H_{21}NO_4,H_2CrO_4$, in beautiful, silky, lustrous plates. If 0·05 gram of crystallised cocaïne hydrochloride is dissolved in 5 c.c. of water, and five drops of a 5 per cent. solution of chromic acid added, a distinct precipitate is formed as each drop falls into the solution; this, however, immediately dissolves again. If now 1 c.c. of strong hydrochloric acid is added, a heavy, yellow precipitate of the chromate is formed. Of the other alkaloids, ecgonine, sparteïne, atropine, caffeine, pilocarpine, codeïne, and morphine do not form yellow precipitates with chromic acid or potassium chromate, whereas quinine, quinidine, cinchonidine, cinchonine, hydroquinine, apomorphine, brucine, strychnine, and veratrine form precipitates with 5 per cent chromic acid if the solutions are neutral, cocaïne being the only one which is precipitated only after the addition of hydrochloric acid. J. W. L.

Estimation of Paratoluidine. By G. A. Schoen (*Zeit. anal. Chem.*, **29**, 86; from *Bull. de Mulhouse*, 1888, 365).—A mixture of the hydrochlorides of para- and ortho-toluidine (which must be free from aniline and xylidine) gives with potassium dichromate a brown precipitate and a red filtrate. The intensity of the red coloration depends on the amount of paratoluidine present. The amount must first be learnt approximately from the specific gravity (that of paratoluidine is 0·99, of orthotoluidine, 1·004, at 15°), and if above 8 per cent., must be reduced by an appropriate addition of orthotoluidine. 1 c.c. of the mixture is then shaken with 2 c.c. of hydrochloric acid and 30 c.c. of water until dissolved, and then 1 c.c. of a cold saturated solution of potassium dichromate is added and allowed to remain for an hour with occasional shaking. The colour is then compared with that produced in a mixture of the toluidines in known proportions. M. J. S.

Detection of Blood Stains. By LEONE and DENARO (*Gazzetta*, **19**, 97—99).—Old, decomposed stains, from which water will no longer dissolve out the colouring matter, are treated with a solution of potash or soda. If hæmatin is present, it will pass into solution, and the filtered liquid will appear green in a thin layer, and red in a thick layer. The solution will also contain iron, which may be detected in the ash. The evaporation and ignition for this purpose must be conducted in silver, and not in porcelain vessels, since the latter give up an appreciable amount of iron. S. B. A. A.

Detection of the Colouring Matter of the Yolk of Egg. By S. BEIN (*Ber.*, **23**, 421—422).—Thudichum has long since shown that yellow colouring matters, termed by him "luteïnes," can be obtained from the yolk of egg and that these yield with nitric acid a blue coloration, which turns yellow and shows two or three characteristic bands in the spectrum. This reaction has been employed for the detection of egg-substance mixed with other organic matter, but the author shows that the non-formation of this coloration does not prove the absence of egg-substance, as these colouring matters gradually undergo alteration in air and light, more quickly at 60° to 80°, and then cease to give Thudichum's reaction. The formation of the coloration, on the other hand, does not prove the presence of these substances, as other organic compounds, especially certain nitrogenous decomposition-products give the same reaction. H. G. C.

An Exact Method for the Estimation of Egg-substance. By S. BEIN (*Ber.*, **23**, 423—424).—In the previous abstract it has been shown that the qualitative test hitherto employed for the detection of egg-substance is not trustworthy, and no method of estimating the amount of these substances has been previously published. The present paper gives a method by which the quantitative estimation of these substances may be readily made, depending on the fact that two of the chief constituents of yolk of egg, namely, glycerolphosphoric acid and lecithin, both contain phosphoric acid. These compounds may be extracted with ether, the ethereal solution evaporated, and the residue carefully ignited at a low temperature with a fragment of potassium nitrate, and the residual phosphoric acid weighed. Lecithin has been shown to consist of an ether-like compound of neurine and distearylglycerolphosphoric acid, having the formula $C_{44}H_{90}NPO_9$, and according to Gobley (*Annalen*, **60**, 275), yolk of egg contains 1·2 per cent. of glycerolphosphoric acid and 7·2 per cent. of lecithin. Every 1·12902 grams of phosphoric acid found, therefore, represents 100 grams of yolk of egg. H. G. C.

General and Physical Chemistry.

New Form of Gas Battery. By L. MOND and C. LANGER (*Proc. Roy. Soc*, **46**, 296—304).—The form described may be termed a *dry* gas battery. A diaphragm of a porous, non-conducting material, mostly plaster of Paris, is impregnated with dilute sulphuric acid (or other electrolyte), and covered on both sides with thin platinum-foil containing about 1,500 perforations per square centimeter, which is overlaid in its turn by a film of platinum-black. The foil is placed in contact at small intervals with strips of a good conductor, so as to reduce the internal resistance to a minimum. Diaphragms so prepared are placed side by side or one above the other, with non-conducting frames intervening in such a way as to form chambers through which the gases to be employed are passed. One side of each diaphragm is exposed to one gas (air); the other to the other gas (hydrogen), the spaces between the diaphragms being so connected that the gases pass through the whole series.

The electromotive force of such a battery was found to vary considerably with the quality of the platinum-black. The best results were obtained with a material precipitated from a boiling solution of platinum tetrachloride, neutralised with sodium carbonate, and reduced by a boiling solution of sodium formate. In this case, the electromotive force was 0·97 volt. The resistance of a plate of plaster of Paris 8 mm. thick and of 350 sq. cm. surface was observed to be 0·02 ohm. Experiment showed that the maximum amount of work was obtained when the external resistance was nearly double the internal resistance. Practically, it was found most convenient to work the battery with an electromotive force of about 0·73 volt, which allows a current of 2—2·5 ampères to be taken out of an element with 700 sq. cm. active surface, covered with 0·35 gram of platinum-foil and 1 gram of platinum-black. No less than half the energy of combustion of the hydrogen is converted into electrical energy. It seems to make little difference whether oxygen and hydrogen are employed, or air and a gas containing about 30—40 per cent. of hydrogen (such as can be got by the action of steam, with or without air, on coal, coke, &c.). The temperature should be kept constant at 40° by passing excess of air through the battery.

The authors discuss the cause of the divergence of the electromotive force from the value it should have according to Thomson's theorem, which would indicate an electromotive force of 1·47 volts. The battery exhibits polarisation after having been at work for some time. This is caused by a change in the concentration of the acid at the two electrodes, and may be remedied by interchanging the gases from time to time. (See next abstract.) J. W.

Air Batteries. By C. R. A. WRIGHT and C. THOMPSON (*Proc. Roy. Soc.*, **46**, 372—376).—The authors direct attention to a former paper by them (*Proc. Roy. Soc.*, **44**, 182), and point out that the gas batteries there described are practically identical in principle with that described by Mond and Langer (see preceding abstract). They further indicate that many of the results obtained by the latter are in complete agreement with experiments of their own. J. W.

Chemistry of Storage Batteries. By E. Frankland (*Proc. Roy. Soc.*, **46**, 304—308).—In continuation of a former paper (Abstr., 1883, 839), the author describes some experiments undertaken with a view to ascertain what lead compounds actually take part in the chemical reactions on charging and discharging secondary batteries.

Finely powdered lead oxide was treated with successive portions of dilute sulphuric acid until the liquid exhibited a permanent acid reaction. There resulted a buff-coloured powder having the composition $Pb_5S_3O_{14}$. Red lead (Pb_3O_4) treated in the same manner yielded a brownish-red compound corresponding with the formula $Pb_3S_2O_{10}$. These new salts must constitute the original active material of storage cells formed in the above way, so that the following equations will represent the actions at the different plates on charging and discharging.

If the buff salt is the active material, then we have—

I. On charging.

(*a.*) Positive plates.. $Pb_5S_3O_{14} + 3H_2O + 5O = 5PbO_2 + 3H_2SO_4$.

(*b.*) Negative „ .. $Pb_5S_3O_{14} + 5H_2 = 5Pb + 3H_2SO_4 + 2H_2O$.

II. On discharging.

(*a.*) Positive plates.. $5PbO_2 + 3H_2SO_4 + 5H_2 = Pb_5S_3O_{14} + 8H_2O$.

(*b.*) Negative „ .. $5Pb + 3H_2SO_4 + 5O = Pb_5S_3O_{14} + 3H_2O$.

If the red salt is the active material, the equations become—

I. On charging.

(*a.*) Positive plates.. $2Pb_3S_2O_{10} + 2O_2 + 4H_2O = 6PbO_2 + 4H_2SO_4$.

(*b.*) Negative „ .. $Pb_3S_2O_{10} + 4H_2 = 3Pb + 2H_2SO_4 + 2H_2O$.

II. On discharging.

(*a.*) Positive plates.. $6PbO_2 + 4H_2SO_4 + 4H_2 = 2Pb_3S_2O_{10} + 8H_2O$.

(*b.*) Negative „ .. $3Pb + 2H_2SO_4 + 2O_2 = Pb_3S_2O_{10} + 2H_2O$.

The latter alternative would seem to explain the practical observation that only half as much active material is required on negative as on positive plates. J. W.

Electromotive Force of Metallic Salts. By C. L. Speyers (*Amer. Chem. J.*, **12**, 254—261).—Solutions of hydrochloric, nitric, acetic, and sulphuric acids, and of the zinc salts of these acids, were experimented with, as well as solutions of these salts containing free acid; the solutions contained 1 gram equivalent of each substance in from 1 to 24 litres of water. In these solutions were immersed an amalgam of mercury containing 1 per cent. of zinc, serving as the negative plate, and a globule of mercury, serving as the positive; connection was made with an electrometer, and the electromotive force was measured as soon as it had attained a constant value. The electromotive force increases slightly on dilution. It has approximately the same value in solutions of nitric, acetic, and sulphuric acids of equivalent strength, but a lower value in the case of hydrochloric acid; and in the case of a mixture of hydrochloric with one of the other acids, the electromotive force is little greater than with hydrochloric acid alone. The electromotive force of solutions of the zinc salts is considerably less than that of equivalent solutions of the corresponding acids, and the chloride has a lower electromotive force than the nitrate, acetate, and sulphate. In the case of concentrated mixtures of zinc salts, and of mixtures of salts with free acid, the electromotive force has a value but slightly greater than in the case of the constituent of lower value. The electromotive force of $\frac{1}{2}$ZnR + HR′ is equal to that of $\frac{1}{2}$ZnR′ + HR; the agreement is not satisfactory, however, in the case of zinc nitrate and sulphuric acid.

C. F. B.

Rate of Solution of Carbonates in Acids. By W. Spring (*Bull. Soc. Chim.* [3], **3**, 174—177).—At 15°, the rates of solution of the following carbonates in 10 per cent. hydrochloric or nitric acid are:—Iceland spar, 1; witherite, 1·284; cerusite, 0·757; arragonite, 0·476; azurite, 0·334; malachite, 0·231; smithsonite, 0·087; dolomite, 0·025. The individual carbonates dissolve with equal rapidity in each acid of the strength indicated; increase of temperature causes an increased rate of dissolution which varies for each mineral, and no definite law appears to hold; the rate of solution seeming to be independent of their chemical constitution, but dependent on varying physical factors.

T. G. N.

Rate of Solution of Iceland Spar in Hydrochloric Acid. By W. Spring (*Bull. Soc. Chim.* [3], **3**, 177—184; compare Abstr., 1888, 900).—The rate of solution of separate faces of Iceland spar is not only dependent on the chemical nature of the spar, but also on its elasticity, and the velocity of solution is expressed by the equation

$$v = \sqrt{a^2 \sin^2 \phi + c^2 \cos^2 \phi};$$

a = the minimum elasticity = 0·60294; c = the maximum elasticity = 0·6728; and ϕ = the angle made by the face attacked with the optic axis, which for the cleavage plane is 26° 15′ 14″.

The variation in velocity is affected by the temperature, and is represented by the expression

$$v = u\,(0·001T^2 + 0·775).$$

The experimental data agree closely with the calculated values.

T. G. N.

Change of Volume on Dissolving Salts in Water. By G. C. SCHMIDT (*Monatsh.*, 11, 35—41).—On dissolving a salt in water, or on diluting a salt solution, a contraction takes place in the total volume. From this it follows that the volume occupied by a molecule of the salt must be less when in solution than when in the solid state, and less in a dilute than in a concentrated solution.

The molecular volume of a salt when in solution may be calculated by means of the formula $V = (aq - \alpha)/d - aq/\delta$, where α is the molecular weight of the anhydrous salt, aq the weight of water present to each molecule of the salt, d the density of the salt solution, and δ that of water. If p is the percentage of anhydrous salt in the solution, then $aq = (100 - p)\alpha/p$.

Employing this formula, it will be found that the molecular volume of a dissolved salt decreases with rising dilution, until at length a limit is reached at which it remains practically constant. This is rendered evident by the following two examples:—

KCl at 18°.		Cane-sugar at 17·5°.	
Per cent. of dissolved salt.	Mol. vol.	Per cent. of dissolved sugar.	Mol. vol.
24	34·95	50	214·49
10	30·06	20	210·60
5	30·02	5	209·95
3	29·98	3	209·88
2	29·97	2	209·85
1	29·97	1	209·83

To account for this behaviour, the author assumes that in the case of salts like potassium chloride, which are electrolytes, it is due to the dissociation of the salt into its ions, which increases and approaches a limit with rising dilution; and that in the case of non-electrolytes like cane-sugar, it is probably due to the fact that complex molecules exist in the concentrated solutions which are broken up on increasing the dilution.

Arrhenius has shown that in a dilute solution the molecular volume of an electrolyte should be an additive function of those of its two ions. If an electrolyte having the ions x and y is dissolved in water, the volume of the resulting solution becomes $1 + ax + by$, where a and b are constants depending on the nature of the ions, but quite independent of one another. In like manner, for any other electrolyte with the ions s and t, the volume would become $1 + cs + dt$, the constants in this case being c and d. If the equivalent weights of the ions in the above instances are given by x, y, s, and t, then the molecular volume of the electrolyte in the first case is $a + b$, and in the second $c + d$, and if one of the ions in the two electrolytes happens to be the same, that is, if $a = c$ or $b = d$, then either $b - d$ or $a - c = \text{const.}$

In order to test the above relation, the author has calculated the molecular volumes of a number of electrolytes when in solution, using for this purpose the density determinations of Kohlrausch, Kremer, and Gerlach. The numbers are calculated for 5 per cent. solutions at a temperature of 18°, and are given in the following table :—

Salt.	Mol. vol.	Salt.	Mol. vol.
KCl..............	30·02	NH_4Cl..............	38·51
KI..............	47·80	NH_4I..............	58·21
KBr..............	37·00	NH_4NO_3..............	50·19
KNO_3..............	41·69	LiCl..............	19·82
$KC_2H_3O_2$..............	54 38	LiI..............	40·69
K_2SO_4..............	48·69	$BaCl_2$..............	30·76
NaCl..............	19·49	$Ba(NO_3)_2$..............	56·65
NaI..............	37·70	$CuCl_2$..............	15·89
$NaNO_3$..............	31·20	$Cu(NO_3)_2$..............	41·74
Na_2SO_4..............	19·00	$SrCl_2$..............	24·01
$NaC_2H_3O_2$..............	43 66	$Mg(NO_3)_2$..............	40·30

Reference to the above table will show that the differences KCl — NaCl, KI — NaI, $KNO_3 - NaNO_3$, $KC_2H_3O_2 - NaC_2H_3O_2$ are all approximately equal to 10, and also that $K_2SO_4 - Na_2SO_4 = 19·69$. Then again KCl — KI, NaCl — NaI, LiCl — LiI all approximate to —20; and it will be evident from other cases which might be selected that the molecular volumes of electrolytes are made up of two constants, one of which depends on the positive and the other on the negative ion. One or two exceptions were noted to this rule, but these are explained by the fact that the salts with which they occurred are poor conductors and not fully dissociated in a 5 per cent. solution.

H. C.

The Nature of Solutions. By S. U. PICKERING (*Phil. Mag.* [5], **29**, 427—434).—This paper is a *résumé* of one which appeared in the Trans., 1890, 64, special attention being directed to those points which the author considers refute Arrhenius' objections (*Phil. Mag.*, **28**, 36) to his conclusions. S. U. P.

Deductions from Van't Hoff's Theory. By S. PAGLIANI (*Gazzetta*, **19**, 235—251).—In the equation $PV = iRT$ applied to solids in dilute solution, Arrhenius considers i to be the ratio between the absolute pressure exercised by a substance in solution and that which it would exercise if no dissociation took place; for extremely dilute solutions, i therefore equals unity, and for other dilute solutions, it is taken as equal to the ratio (α) of the effective molecular electric conductivity to the limiting value of that conductivity with increasing dilution; from these assumptions, Arrhenius deduces the formula

$i = 1 + (k - 1)\alpha$, where k is the number of ions into which each active (that is, dissociated) molecule is split up (Abstr., 1887, 631).

The author objects to this formula on the grounds that some electrolytes have a maximum electrical conductivity, so that the equation is inapplicable, and that k is a variable quantity, its value depending on the conditions of dilution and temperature of the solution of the electrolyte. The equation also indicates that when $i = 1$, $k = 1$, which is untrue for many conductors, also as for binary compounds $k = 2$, and $\alpha = 1$ when dissociation is complete, $i = 2$ at that stage, a result disproved by Raoult's experiments on HCl, HBr, HI, NaCl, KBr, KI. The agreement of many of the values of i calculated by Arrhenius from the molecular depressions with the values calculated from α is only apparent since the calculations were not made from solutions of the same degree of concentration.

The objections to the determination of i from the formula $i = \frac{t}{18\cdot5}$, from Blagden and Rüdorff's law, from the diminution of vapour tension, and from the isotonic coefficient are also discussed.

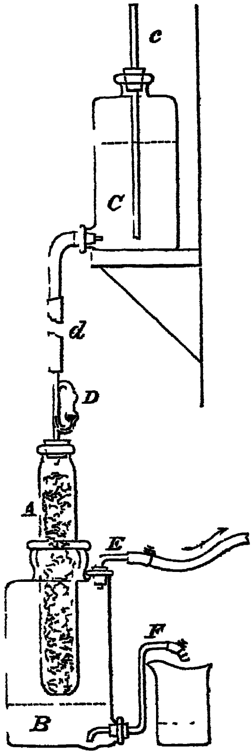
The heat of solution of a gas may be determined either from Van't Hoff's equation, $\frac{\delta \log C}{\delta T} = \frac{Q}{2iT^2}$, which becomes $Q = 2T^2\frac{\delta \log C}{\delta T}$ when $i = 1$ (where C is the concentration of a solution saturated at temperature T, and Q is the quantity of heat absorbed by the solution of one molecule of the substance), or from Kirchoff's equation $q = -g\frac{RT^2}{J}\frac{\delta \log \beta R}{\delta T}$ or $Q = \frac{MRT^2}{J}\frac{\delta \log \beta R}{\delta T}$ (*Pogg. Ann.*, **103**, 194), where R is the constant for the gaseous state, and β is the weight of gas absorbed by the unit of weight of liquid at the temperature T and a pressure equal to unity, so that βR is Bunsen's coefficient of absorption. These equations give concordant results for perfect gases (where $i = 1$), but not where the state of the gas is changed as by absorption, diffusion, or by particular conditions of temperature and pressure. The great discrepancies between the theoretical values of Q so deduced and the values obtained by experiment are, according to the author, due to the neglect in Kirchoff's equation of the molecular work done during dissolution, to the variable value of i in Van't Hoff's equation, and to a less extent to the variation of the heat of dissolution with the concentration of the solution. The author then discusses the determination of the value of i for solids in solution from Van't Hoff's equation in the form $i = Q \div \frac{2\delta \log C}{\delta T}T^2$, and the conditions of applicability of this formula.

S. B. A. A.

The Theory of Osmotic Pressure. By S. U. Pickering (*Phil. Mag.* [5], **29**, 490—501).—Without questioning the practical utility of this theory, the author doubts whether it can be regarded as sufficiently well established to give any support to a purely physical theory of solution. Taking the lowering of the freezing point of a solvent by the addition of dissolved matter as the most fully investigated phenomenon connected with osmotic pressure, he shows that the depression (produced by 1 foreign molecule on 100 solvent molecules), instead of being constant whatever the dissolved substance is, exhibits a variation amounting to 500 per cent. in extreme cases, even when very weak solutions are taken. He argues that the higher values must be taken as being the "normal" values in the case of water, just as they are in the case of other solvents, especially as the assumption that the lower value (1·03°) is the normal one involves the rejection of the atomic theory, since it is $1\frac{1}{2}$ times the normal value for other solvents, and could only be explained by assuming that the molecule of water is $1\frac{1}{2}H_2O$. The smaller value being the normal one, necessitates, moreover, the view that salts and acids are entirely dissociated into their ions in weak solutions, and such a view must lead to the conclusion that the more stable a body is, the more easily is it dissociated, and that in the dissociation we have an actual creation of energy; a conclusion which is quite inadmissible. Instances are quoted to show that the nature of solvent, instead of being without effect on the so-called constant, causes it to vary by amounts up to 27,600 per cent. The constancy, moreover, does not hold good when the proportions of the solvent and dissolved body are varied, even when the variations are confined to solutions so weak that the dissolved body is as much dilated as it would be if it were gaseous, and the deviations from regularity in such cases do not occur in any regular manner or direction. Finally, that, whereas, according to the osmotic pressure theory, strong solutions should give abnormally small values for the depression, they give, in every case at present investigated, abnormally large ones. S. U. P.

Precipitation. By G. WATSON (*Chem. News*, **61**, 207—208).—With regard to the accumulation of precipitates on scratche made on the sides of the glass containing vessel, experiments with basic antimonious chloride and with calcium hydrogen phosphate have led to the following observations :—The phenomenon does not take place until the precipitate, at first bulky, changes into the denser crystalline condition; neither does it take place on new scratches made after change is complete, nor on old scratches which have been washed with acid. But old scratches with crystals adhering, are capable of starting and accelerating the formation of the crystalline precipitate, in the same way as the presence of previously formed precipitate will aid precipitation, as shown by Baubigny in the case of nickelous sulphide, and now by the author in the case of the precipitation of arsenic as sulphide from warm solutions of phosphoric acid. Hence, the author concludes that the phenomenon in question is not alone the result of the potent surface energy of abraded glass, but is also due to the simultaneous occurrence of a condensation change. D. A. L.

A Self-regulating Gas-generator. By H. W. HILLYER (*Amer. Chem. J.*, **12**, 228—230).—This consists of an acid reservoir, C, and a generator, AB. The former is an aspirating bottle of a gallon or more capacity, provided with a stopper and glass tube, *c*, to regulate the liquid pressure. A piece of stout indiarubber tubing connects it to the bulb-tube D, which passes through a rubber stopper in the cylinder A, and terminates in a narrow aperture $\frac{1}{16}$th of an inch in diameter. The generator consists of a glass cylinder, A, and a glass vessel, B, which are ground or cemented together gas-tight. The cylinder A is about 20 inches long by 2½ in diameter, and serves to hold the ferrous sulphide, zinc, or marble. The vessel B is about 16 inches high by 9 in diameter, and serves as a reservoir both for waste acid and for gas. The acid flows down into A, and by the pressure of the gas generated is forced over the contents of the cylinder and into the vessel B, the gas escaping through the tube E. When E is closed, the pressure in the generator rises and soon becomes great enough to stop the flow of acid through *d*D. A too sudden rise of pressure, which might force the acid from D*d* back into C, is prevented by the large capacity of the vessel B, and a further safeguard is provided by filling the lower bend of D with mercury. The waste acid drops into B almost neutral, and is forced out through F, on opening the stop-cock, by the pressure of the gas in B. The acid in C is renewed by removing the stopper and tube *c*, and the cylinder A is refilled by removing its rubber stopper, after closing the pinch-cock on *d*. The generator is connected to a series of gas-cocks placed in



the laboratory through two wash-bottles which have their long tubes joined together; this device is necessary to prevent the water in the wash-bottle being driven back into the generator B, in consequence of the lowering of pressure caused in this vessel when the waste acid is removed through F. The apparatus supplies gas at a considerable pressure, and it is therefore necessary that all the joints should be gas-tight. C. F. B.

Inorganic Chemistry.

Rate of Decomposition of Chlorine-water by Light. By G. GORE (*Proc. Roy. Soc.*, **46**, 362—363).—By studying the action of diffused daylight and sunlight on chlorine-water by means of the voltaic balance, the author finds that the decomposition at first takes place with moderate uniformity and gradually diminishing decrease of voltaic energy. At the minimum, the liquid contains only hydrochloric, hypochlorous, and chloric acids. On further exposure, the voltaic energy increases slowly until the solution contains only hydrochloric acid and hydrogen peroxide. Thus there are here two essentially different periods of chemical change—first, the period of the formation of oxygen acids of chlorine, and second, the period of the decomposition of these acids into hydrochloric acid and hydrogen peroxide. J. W.

Igniting Point of Sulphur. By J. R. HILL (*Chem. News*, **61**, 125—126); and by B. BLOUNT (*ibid.*, 153—154).—Hill concludes from experimental observations that sulphur ignites at 248°. In his experiments, the sulphur contained in a test-tube, fitted with a double bored cork, was heated in a bath of sulphuric acid, while a current of air, heated to about 60,° was aspirated through the sulphur-tube. Blount, under somewhat similar circumstances, found the igniting point of sulphur to be 261°, but owing to the supply of air being very limited, this number is probably too high. D. A. L.

Simple and Rapid Preparation of Pure Gases. By H. BORNTRÄGER (*Zeit. anal. Chem.*, **29**, 140).—Instead of using an acid for the evolution of carbonic anhydride, sulphurous anhydride, and similar gases, it is convenient to use sodium hydrogen sulphate. A mixture of equivalent quantities of the respective salts in powder gives, when wetted with water, a regular stream of the required gas, which will be free from the impurities usually derived from the use of an acid.
M. J. S.

Silver Silicate. By J. D. HAWKINS (*Amer. J. Sci.* [3], **39**, 311—312).—This salt forms as a yellow precipitate when pure sodium silicate is added to a neutral solution of a silver salt. When heated, it becomes first brownish-red, then the original yellow, and at a red heat decomposes into silver, oxygen, and silica. It is soluble in ammonia, and is decomposed by all acids. D. A. L.

Dimorphism of Barium Oxide: a New Catalytic Phenomenon. By G. Brügelmann (*Zeit. anal. Chem.*, 29, 123—126).—Barium oxide, prepared by strongly heating the hydroxide in clay or graphite crucibles, is obtained as a felted mass of elastic needles, which, since they show chromatic polarisation, cannot belong to the regular system, but are probably hexagonal. Their specific gravity is 5·32 (water at 15° = 1). The same hydroxide, when dehydrated in a platinum crucible, yields an oxide which, although distinctly crystalline, shows no polarisation, and therefore seems to belong to the regular system. It has the specific gravity 5·74, and appears to be identical with that produced by igniting the nitrate (Abstr., 1880, 701). M. J. S.

Characteristics of the Alkaline Earths and Zinc Oxide. By G. Brügelmann (*Zeit. anal. Chem.*, 29, 126—129; see Abstr., 1880, 701).—Recent experiments have shown that the magnesium oxide obtained by igniting the nitrate is not amorphous, but crystalline. Strontium oxide is also crystalline when prepared by the ignition of the carbonate or hydroxide. Strontium and barium oxides prepared in platinum crucibles are pure white, not grey, as hitherto believed. Barium hydroxide is decomposed at a much lower temperature than the carbonate, but between these limits of temperature barium oxide does not absorb carbonic anhydride. The specific gravities of the oxides vary slightly according to the compounds from which they are obtained, but, with the exception of barium oxide, no evidence of dimorphism has been obtained. M. J. S.

Atomic Weight of Magnesium. By W. M. Burton and L. D. Vorce (*Amer. Chem. J.*, 12, 219—226).—The method used was similar to that formerly adopted in determining the atomic weight of zinc (Abstr., 1888, 1247). Magnesium ribbon was placed in a short length of iron tubing, and this was placed in the closed end of a longer tube of very hard glass. The tube was exhausted, and the magnesium was then distilled into the fore part, and the whole allowed to cool while the vacuum was still maintained. A slight coating of magnesium silicide formed at first on the tube, but this protected the glass, and the rest of the metal which distilled over could be easily detached, and was free from silicide. The middle part of the distilled metal was taken, and redistilled three times in a similar manner; a crystalline bar of pure white magnesium was thus obtained free from silicon, carbon, calcium, and iron, although these could be detected in the ribbon used. The purified metal was dissolved in nitric acid (prepared as described in the previous paper), diluted with an equal volume of specially purified water; the excess of water was then evaporated, and the nitrate converted into oxide by heating first in a sand-bath, and finally in a muffle furnace. The operation was performed in a porcelain crucible, previously tared against another one which was treated in precisely the same way as the first. Ten experiments were made, and these gave for the atomic weight of magnesium numbers varying between 24·271 and 24·304, the mean being 24·287 (O being taken as 16).

In some cases very perfect crystals were obtained when the magnesium was distilled. These were examined by G. H. Williams, and found to be holohedral hexagonal forms isomorphous with those of zinc and beryllium. They exhibited faces of the primary prism and of the primary pyramid, together with basal planes; the axial ratio was determined to be $a : c = 1 : 1·6202$. C. F. B.

Crystalline Metallic Precipitates. By H. N. Warren (*Chem. News*, **61**, 183).—By using a zinc rod wrapped in coils of asbestos paper for the reduction of solutions of metallic salts, the action is somewhat retarded, and a crystalline precipitate of the reduced metal forms without any previous spongy precipitate, and adheres to the asbestos paper. In this way, crystalline precipitates of lead, copper, &c., have been obtained, whilst by the use of a magnesium rod crystalline zinc was precipitated, and iron, manganese, and zirconium gradually reduced. Solutions of antimony chloride, with sufficient tartrate to prevent the precipitation of the basic salt, yield, in addition to a crystalline incrustation, a black precipitate of explosive antimony. D. A. L.

Copper Precipitate formed in Ordinary Water. By Grimbert and Barré (*J. Pharm.* [5], **21**, 414—415).—A solution of copper sulphate poured into ordinary water produces a considerable turbidity, which becomes a voluminous, bluish-green, crystalline deposit after a time. Under the microscope, it shows rhomboidal laminæ which polarise light; these are sometimes isolated, sometimes grouped in stars of six branches. It is a tetrabasic copper sulphate, $3CuO,CuSO_4 + 4H_2O$, insoluble in water, but soluble in acids. Heated at 100° it is unchanged, but towards 200° the whole of its water is expelled, and its colour becomes olive green. It has the same composition as the mineral brochantite. The deposit is inferred to be due to the presence of calcium hydrogen carbonate in the water, as very dilute alkaline carbonates are known to precipitate tetrabasic copper sulphate, and no precipitate is produced if the hydrogen carbonate is removed. J. T.

Earths of the Cerium and Yttrium Groups. By A. Bettendorff (*Annalen*, **256**, 159—170).—Orthite, from Strömsboe, near Arendal, and from Hitteroë, was freed from cerium oxide and thorium oxide by Debray's method (*Compt. rend.*, **96**, 928), and the earths of the cerium and yttrium groups then separated by means of potassium sulphate, by a modification of the method described by Mosander. The separation of the constituents of the two groups was then accomplished by systematic partial decomposition of the nitrates; this can be easily done with the nitrates of the yttrium group, but in the case of the cerium group it is advisable to place the platinum crucible containing the nitrates in a slightly larger porcelain crucible, in order to ensure a more regular decomposition. In this way the earths which are precipitated by potassium sulphate can be easily freed from lanthanum by two or three operations; the lanthanum oxide obtained is very pure (RO = 108·76), but it always contains small quantities of didymium.

The basic nitrates thus freed from lanthanum give a brown oxide (RO = 113·2 to 114), which contains all the didymium and samarium earths, as well as larger or smaller quantities of gadolinium and terbium earths.

The further purification of the oxide (RO = 108·76) was carried out by v. Welsbach's method (*Monatsh.*, 6, 477—491), namely, by fractional crystallisation of the ammonium nitrate double salts, but in neutral instead of in acid solution. After about 18 operations, the ammonium lanthanum nitrate is obtained in a pure condition, and the double salt of the neodidymium is separated from the more sparingly soluble double salt of the praseodidymium, as is shown by a spectroscopic examination of the mother liquors; the absorption spectra of the second, seventh, twelfth, and eighteenth mother liquors are given in a diagram.

The oxide of the pure lanthanum ammonium nitrate, prepared as described above, has the equivalent RO = 108·15, R_2O_3 = 324·45 (O = 15·96, S = 31·98), from which the atomic weight of lanthanum is found to be R = 92·19, or R‴ = 138·28; Cleve (*Jahresb.*, 1883, 36) found R‴ = 138·22. The spark spectrum of the chloride, prepared from this oxide, is given in a diagram, and the measurements of the wave-lengths of the lines are given in a table; the author's measurements agree well on the whole with those of Thalèn, but some of Thalèn's lines could only be observed with difficulty. λ 4330, which has been observed by Thalèn, but which, according to Cleve, is not a lanthanum line, was present in the spectrum of the author's preparation. F. S. K.

Uranyl Chromate and its Double Salts. By J. Formánek (*Annalen*, 257, 102—116).—*Uranyl potassium chromate*,

$$2(UO_2)CrO_4,K_2CrO_4 + 6H_2O,$$

is obtained by mixing a solution of uranyl nitrate (1 mol.) with a solution of potassium chromate (1 mol.), and evaporating over sulphuric acid, or by treating potassium uranate with a warm, concentrated solution of chromic acid and evaporating the filtered solution over sulphuric acid. It forms yellow, monosymmetric crystals, $a : b : c = 0·7566 : 1 : 1·9714$, $\beta = 72° 38'$, and is partially decomposed by water. The corresponding *ammonium* double salt,

$$2(UO_2)CrO_4,(NH_4)_2CrO_4 + 6H_2O,$$

forms yellow, monosymmetric crystals, $a : b : c = 0·8016 : 1 : 1·0196$, $\beta = 72° 31'$, similar to those of the potassium salt, and is partially decomposed by boiling water; the compound $2(UO_2)CrO_4,(NH_4)_2CrO_4 + 3H_2O$ was also obtained. The *sodium* double salt,

$$2(UO_2)CrO_4,NaCrO_4 + 10H_2O,$$

forms small, yellow crystals, and is readily soluble in water.

Uranyl chromate, $(UO_2)CrO_4 + 11H_2O$, prepared by dissolving the hydroxide in an aqueous solution of chromic acid, and concentrating the filtered solution on the water-bath, crystallises from boiling water in yellow needles, effloresces on exposure to the air, and loses the whole of its water at 200°; only silver, lead, mercurous, and bismuth salts produce precipitates in its aqueous solution.

In precipitating chromic acid as mercurous chromate, in presence of uranium salts, the mercurous nitrate employed must be free from oxides of nitrogen, and the solution must be slightly acid; otherwise some of the uranium salt is also precipitated.

When hydrogen sulphide is passed into a solution of uranyl nitrate and mercurous nitrate, mercuric sulphide is precipitated, and at the same time the uranyl is reduced to the uranous salt; tungstates and titanates are also quickly reduced by hydrogen sulphide in presence of mercuric chloride. F. S. K.

Precipitation of Tin from Acid Solutions by Metallic Iron. By B. SCHULTZE (*Ber.*, **23**, 974—976).—Tin is completely precipitated from solution in inorganic acids by the action of a mixture of metallic tin, metallic iron, and iron rust. The free acid is neutralised by the ferric hydrate, the stannic salts which are simultaneously formed are reduced by the tin to stannous compounds, and from these all the tin is thrown down by the iron. The operation requires several days for completion, and the absence of every trace of free acid and stannic salt is essential to success. J. B. T.

Mineralogical Chemistry.

Deposits of Barium Sulphate from Mine-water. By F. CLOWES (*Proc. Roy. Soc.*, **46**, 368—369).—Deposits containing some 90 per cent. of barium sulphate have been found in the water-boxes of various coal mines in the neighbourhood of Newcastle-upon-Tyne. The author publishes the results of his analyses of three of these, and discusses their probable mode of formation. J. W.

Tyrolite from Utah. By W. F. HILLEBRAND and E. S. DANA (*Amer. J. Sci.*, **39**, 271—273).—Analysis of material collected at the Mammoth mine gave the following results:—

CuO.	CaO.	As_2O_5.	H_2O.	SO_3.	Fe_2O_3.	Insoluble.	Total.
45·08	6·78	28·52	17·21	2·23	0·08	0·16	100·06

The percentage of SO_3 is practically the same as that formerly found by Hillebrand (Abstr., 1888, 1043). It is, therefore, necessary to consider this as a proper constituent of the mineral. Some of the specimens of tyrolite collected are crystallised with sufficient distinct-

ness to allow of a somewhat more complete determination of the form than has hitherto been possible. The crystals are undoubtedly orthorhombic.
B. H. B.

Occurrence of Polycrase in Carolina. By W. E. HIDDEN and J. B. MACKINTOSH (*Amer. J. Sci.*, **39**, 302—306).—A few crystals of the mineral described were found in 1888 in Henderson Co., North Carolina, the associated minerals being zircon, monazite, xenotime, cyrtolite, and magnetite. The pure mineral is nearly coal-black, and has a sp. gr. of 4·78 and a hardness of 5·5. It is infusible, and on analysis yielded:—

Nb_2O_5. Ta_2O_5. TiO_2.	Y_2O_3.	Fe_2O_3.	UO_3.	H_2O.	Total
48·97	27·55	3·19	13·77	5·18	98·66

The reactions are quite similar to those given by the Hitteroe polycrase.

In September, 1889, large crystals of polycrase were found near the Upper Saluda River, in South Carolina, about 20 miles from the first described locality. The sp. gr. of these crystals varies between 4·925 and 5·038. On analysis the following results were obtained:—

Nb_2O_5. Ta_2O_5. TiO_2.	Y_2O_3.	PbO.	FeO.	Fe_2O_3.	UO_3.
47·88	21·23	0·46	2·47	0·18	19·47

CaO.	H_2O.	SiO_2.	Insoluble.	Total.
0·68	4·46	1·01	0·12	97·96

This mineral is very closely allied to, if not identical with, the polycrase from Hitteröe, Norway, analysed by Rammelsberg. The approximate formula of the Carolina mineral is $Nb_2O_5,4TiO_2,5RO,2\frac{1}{2}H_2O$. It should be noted that this is the first occurrence of a columbotitanate accredited to an American locality.
B. H. B.

Manganiferous Spring waters. By W. P. MASON (*Chem. News*, **61**, 123).—Sixty-two springs in the United States are reputed to contain manganese, usually as carbonate, but only seven have as much as nine parts per million or above, and in five of these the manganese is present as sulphate or chloride, whilst its condition in the other two is doubtful. Excelsior Springs, near Kansas City, Mo., are, however, comparatively rich in manganese carbonate, yielding per million:—$MnCO_3$, 9·41; Al_2O_3, 2·10; SiO_2, 12·0; K_2SO_4, 4·86; NaCl, 17·60; $FeCO_3$, 23·43; $CaCO_3$, 302·75; $MgCO_3$, 54·7; KCl, 2·8; $NaHCO_3$, 8·35.
D. A. L.

Organic Chemistry.

The Marsh Gas Fermentation. By BERTHELOT (*Bull. Soc. Chim.* [3], 3, 331).—According to Schloesing, marsh gas and carbonic anhydride are formed in equal volumes when dung ferments. Since these gases must result chiefly from the decomposition of cellulose, their formation may be represented by the following equation:—

$$nC_6H_{10}O_5 + nH_2O = 3nCO_2 + 3nCH_4.$$

This equation necessitates the liberation of as much heat as is represented by 41 × *n* Cals., which is slightly superior to that liberated in the alcoholic fermentation. T. G. N.

Double Cyanides of Zinc and Mercury. By W. R. DUNSTAN (*Pharm. J. Trans.* [3], 20, 653).—Rammelsberg observed that when zinc sulphate is added to a solution of mercury potassium cyanide, $HgK_2(CN)_4$, a white precipitate is produced. Gmelin suggested that this consists of a cyanide of zinc and mercury, $HgZn(CN)_4$, but no analysis of the precipitate was made by either chemist. During his recent investigation of the antiseptic properties of the metallic cyanides, Sir Joseph Lister prepared this substance, and found it to be of exceptional value as a surgical antiseptic. It was observed, however, that in its preparation the larger part of the mercuric salt is dissolved, especially during the washing of the precipitate with cold water; a smaller part (from 5 to 15 per cent.) remains in the precipitate, and cannot be dissolved from it by cold water.

The author finds that the quantity of mercuric cyanide retained by the precipitate, and not dissolved from it by cold water, is mainly dependent on the amount of water present during precipitation, and that by reducing the quantity to the lowest limit consistent with the solution of the reacting salts, the amount of retained mercuric cyanide may be raised to rather more than 36 per cent., which corresponds approximately with the formula $2Zn(CN)_2,Hg(CN)_2$. Similar results were obtained by precipitating a solution of zinc potassium cyanide, $ZnK_2(CN)_4$, with mercuric chloride, and also by dissolving equivalent quantities of zinc potassium cyanide and mercury potassium cyanide in water, and decomposing the mixed salts with sufficient sulphuric acid to remove the whole of the potassium as sulphate. On the other hand, the same substance was not produced by evaporating to dryness a solution of mercuric cyanide with freshly precipitated zinc cyanide; neither was it obtained by the action of hydrocyanic acid on a mixture of the freshly precipitated oxides suspended in water or alcohol; the product of both these reactions was a mixture of the two cyanides, from which cold water completely dissolved the mercuric cyanide.

Although pure salts were employed in the preparation of the material, a little zinc hydroxy-salt was invariably produced, but experiment showed that the retention of the mercuric cyanide is not conditioned by the presence of a hydroxy-salt of zinc or mercury. By prolonged boiling with water, the mercuric cyanide is completely removed from the substance. From the evidence so far obtained, the author is inclined to believe that the mercuric cyanide is retained by the zinc cyanide in some mechanical way, and that the substance is not a definite chemical compound. But this question is being further investigated. All attempts to prepare a double cyanide of the formula suggested by Gmelin were failures. W. R. D.

Ammeline. By A. SMOLKA and A. FRIEDRICH (*Monatsh.*, 11, 42—60; compare Abstr., 1889, 114, and this vol., p. 618).—Ammeline may be synthesised by heating together in a paraffin-bath dicyanodiamide (1 mol.) and ethyl carbamate (2 mols.). The mixture melts at 182—185°, and after heating for a quarter of an hour at 190°, the clear liquid becomes clouded. On raising the temperature to 195° for half an hour, ammeline separates, and may be crystallised from hot aqueous soda, when it forms spherules consisting of microscopic needles. Ammeline is also formed by heating together at 190°, a mixture of anhydrous biguanide sulphate (1 mol.) and ethyl carbonate (4 mols.).

Ammeline is only slightly soluble in water, at 23°, one part in 4677; at 100°, one part in 1260. When freshly prepared it dissolves readily in sulphuric, chromic, oxalic, and in concentrated formic and acetic acids, forming the corresponding salts. The sulphate,

$$(C_3H_5N_5O)_2,H_2SO_4 + H_2O,$$

crystallises in aggregates of very small, microscopic needles, very sparingly soluble in and decomposed by boiling water; the chromate, $(C_3H_5N_5O)_2,H_2CrO_4 + 2H_2O$, crystallises in long, yellow, microscopic needles, is only slightly soluble in, and is decomposed by water; the oxalate, $(C_3H_5N_5O)_2,H_2C_2O_4$, is an anhydrous, white, microcrystalline powder.

The synthesis of ammeline from dicyanodiamide and ethyl carbamate points to its having the constitution represented by the formula  $\mathrm{HN}{<}\begin{array}{l}\mathrm{C(NH)\cdot NH}\\ \mathrm{CO{-}{-}{-}{-}NH}\end{array}{>}\mathrm{CNH}$, and thus harmonises with the conclusions drawn by the authors from their synthesis of phenylammeline (*loc. cit.*). G. T. M.

Mixtures of Alcohol and Water. By T. FARRINGTON (*Chem. News*, 61, 208).—Investigations with mixtures of alcohol and water indicate that the greatest rise of temperature, 10°, is obtained by the admixture of water with 28 to 50 per cent. of alcohol, and the following is the relationship between the densities and refractive indices for the liquids given :—

	Sp. gr.	Refractive index.		
		Observed.	Calculated	
			From formula.	From vols. of the components.
Alcohol	0·7978	1·3645	—	—
Water	0·9990	1·3320	—	—
5 alcohol + 10 water..	0·9610	1·352	1·3535	1·343
5 alcohol + 5 water...	0·9348	1·361	1·3622	1·348

Whilst a curious relationship exists in the rate of the passage of the liquids through a small aperture, as the following numbers show:—

	Very small aperture. Seconds.	Small aperture. Seconds.
Water................	240	20·9
Alcohol...............	270	22·7
1 alcohol + 2 water....	346	26·9

D. A. L.

The Supposed Hydrates of Alcohol. By S. U. Pickering (*Zeit. physikal. Chem.*, 6, 1).—Mendeléeff stated that the first differential of the densities of solutions of alcohol in water which he quoted in the Trans., 1887, 778, formed a rectilineal figure, given on p. 780, showing three distinct breaks, indicative of the existence of three definite hydrates. The author plots out Mendeléeff's values, both those quoted on p. 778, as well as four other sets of values for the density differentials at other temperatures, and shows that they all form curvilinear and continuous figures bearing no resemblance to Mendeléeff's drawing. The author has previously shown (Trans., 1890, 81) that a similar statement made by Mendeléeff as to the densities of sulphuric acid solutions was equally mistaken, and he calls in question Mendeléeff's statement that he had found the rectilineal character of the first differential to hold good in the case of 100 different salts, for Mendeléeff gave alcohol as a "typical" specimen, remarking that "no other solution besides that of alcohol, and none of its other properties, are known with such a degree of accuracy." The author states that he has good grounds for considering that the solid products obtained by Mendeléeff on cooling two solutions of alcohol consisted of ice, and not of two definite hydrates.

The author has examined by differentiation all the values obtained by other physicists for the densities, without finding any evidence of the existence of any hydrates. S. U. P.

Nitrethyl Alcohol. By R. Demuth and V. Meyer (*Annalen*, 256, 28—49; compare Abstr., 1889, 366).—Nitrethyl alcohol has a sp. gr.

of 1·1691 at 19·4°, and its molecular formula is $C_2H_5NO_3$, as is shown by molecular weight determinations in glacial acetic acid solution. The *sodium* salt, $C_2H_4NO_3Na$, is a colourless, granular, hygroscopic powder readily soluble in water; it combines with acetic chloride with great energy, and explodes when treated with concentrated nitric acid.

The compound $N_2Ph{\cdot}CH(NO_2){\cdot}CH_2{\cdot}OH$ separates as a yellowish-red precipitate when an aqueous solution of the pure sodium salt is treated with a solution of diazobenzene chloride; it crystallises from light petroleum in yellowish-red needles, melts at 104°, and is very readily soluble in the ordinary solvents. When impure nitrethyl alcohol, prepared as previously described, is treated with diazobenzene chloride, benzeneazonitromethane, $N_2Ph{\cdot}CH_2{\cdot}NO_2$ (m. p. 153°), separates from the solution in crystals. The formation of this compound is most probably due to the presence of nitracetic acid in the crude nitrethyl alcohol.

Acetylnitrethyl alcohol, $C_4H_7NO_4$, was obtained in an impure condition by warming the pure alcohol with acetic anhydride; it is a yellowish oil, and cannot be distilled even under reduced pressure. The *chloride*, $C_2H_4ClNO_2$, was also obtained, but only in an impure condition, by treating the alcohol with phosphoric chloride in the cold; it is a yellow oil, and cannot be distilled.

Sodionitrethyl alcohol is not acted on by ethyl iodide even when it is boiled therewith, so that its constitution is probably expressed by the formula $NO_2{\cdot}CHNa{\cdot}CH_2{\cdot}OH$.

Nitrethyl alcohol reacts readily both with chloral and phenyl cyanate, but the products cannot be obtained in a pure condition; it is completely decomposed by warm hydrochloric acid and by potassium permanganate. When treated with nitrous acid (1 mol.), it yields methylnitrolic acid as the principal product, but when a large excess of nitrous acid is used, the principal product is an acid free from nitrogen, probably glycollic acid.

When nitrethyl alcohol is reduced with sodium amalgam in slightly acid solution, it is converted into a brown, strongly basic liquid which is miscible with water in all proportions, absorbs carbonic anhydride from the air, and cannot be distilled; the hydrochloride of this substance is a brownish, very hygroscopic syrup. The results obtained on analysis agreed with those required by a mixture of mono- and di-ethyleneoxydiamine, but it could not be separated into these compounds by the method described by Wurtz (*Annalen*, **121**, 226), and no crystalline salts could be obtained. F. S. K.

Ethereal Salts of Phosphorous Acid. By O. Jaehne (*Annalen*, **256**, 269—285).—Ethyl phosphite, $P(OEt)_3$, is obtained, together with the compound $C_{14}H_{35}P_3O_8$, described by Geuther (Abstr., 1884, 1282), and a little ethyl phosphate, when phosphorus trichloride is gradually added to finely divided sodium ethoxide, covered with ether; the yield is 70 per cent. of the theoretical. It is a pleasant smelling liquid of sp. gr. 1·075 at 15°, and boils at 192—195°. When heated with iodine at 190°, it is partially decomposed with formation of ethyl iodide and diethylphosphoric iodide, and when heated with sodium ethoxide at 150—190°, sodium diethyl phosphite, ethylene, and alcohol are produced. Acetic chloride at 190° seems to decompose it into ethyl chloride, ethyl acetate, and ethyl dihydrogen phosphite; acetic anhydride at 240° seems to have a similar action. When boiled with acetamide, it seems to be converted into the amide of diethylphosphorous acid.

The compound $C_{14}H_{36}P_2O_5$ (see above) is not decomposed by sodium ethoxide at 230°; when treated with phosphorus trichloride, it yields ethyl phosphate, phosphite and chloride, and phosphorous acid.

Methyl phosphite, $P(OMe)_3$, prepared as described in the case of the ethyl salt, is a highly refracting liquid of sp. gr. 1·1785 at 15°, and boils at 185° with considerable decomposition. The *propyl* salt, $P(OPr)_3$, is a yellowish liquid of sp. gr. 1·004 at 15°, and boils at 240° with slight decomposition. The *isobutyl* salt, $P(OC_4H_9)_3$, is a yellowish liquid of sp. gr 0·952 at 15°, and boils at 248—255°. The *isoamyl* salt, $P(OC_5H_{11})_3$, boils at 265—270°, and its sp. gr. is 0·9005 at 15°. F. S. K.

American Fusel Oil. By J. H. Long and C. E. Linebarger (*Chem. News*, **61**, 185—187).—Most American distillers use corn (maize) mixed with small amounts of other grains for the mash. The authors have examined a sample of fusel oil obtained at Chicago, and separated from alcohol fermented during the spring season by the 72-hour period. It was saturated with water, allowed to settle, dried first with anhydrous copper sulphate, then with potassium carbonate, and fractionally distilled. The higher fractions were separated by fractional crystallisation of the barium amyl sulphates, &c., and identified by their boiling points, optical activity, and conversion into the iodides; whilst the boiling points and conversion into the bromides served for the identification of lower boiling constituents. In this way the sample of several gallons of fusel oil was found to consist chiefly of active and inactive amyl alcohol, with some isobutyl alcohol and isopropyl and ethyl alcohols, and traces of normal propyl and normal butyl alcohols. A very small proportion, consisting of alcohols and ethereal substances, boiled above 133°. D. A. L.

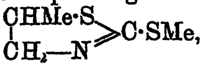
Derivatives of β-Bromopropylamine. By P. Hirsch (*Ber.*, **23**, 964—967).—Propylene-ψ-thiocarbamide,  $\left.\begin{array}{l}CHMe\cdot S\\ CH_2\cdot NH\end{array}\right>C{:}NH$, is obtained by the action of potassium thiocyanate on β-bromopropylamine; it is identical with the compound obtained by Gabriel (this vol., p. 127) by the action of hydrogen bromide on allylthiocarbamide, and isomeric with trimethylene-ψ-thiocarbamide,

$$CH_2<\begin{array}{l}CH_2—S\\ CH_2\cdot NH\end{array}>C{:}NH.$$

The picrate, $C_4H_8N_2S,C_6H_3N_3O_7$, is deposited from water in curved, needle-shaped crystals melting at 199—200°. The platinochloride forms yellowish-red, needle-shaped crystals melting at 210—212°. Propylene-ψ-carbamide,  $\left.\begin{array}{l}CHMe\cdot O\\ CH_2\cdot NH\end{array}\right>C{:}NH$, is formed by heating together β-bromopropylamine and potassium cyanate. The picrate crystallises from hot water in lustrous needles melting at 186°. With carbon bisulphide, β-bromopropylamine yields *μ-β-mercaptomethylthiazoline*,

$\begin{array}{l}\mathrm{CHMe{\cdot}S}\\ \mathrm{CH_2{-}N}\end{array}\!\!\gg\mathrm{C{\cdot}SH}$, isomeric with μ-mercaptopenthiazoline,

$\mathrm{CH_2}\!<\!\begin{array}{l}\mathrm{CH_2{-}S}\\ \mathrm{CH_2{\cdot}NH}\end{array}\!\!>\mathrm{C{:}SH}$ (this vol., p. 472). The compound crystallises from hot water in long, white needles, and melts at 82°; it is soluble in alkalis, but not in acids. By treating an alkaline solution of mercaptomethylthiazoline with an alkyl iodide, the corresponding thioether is obtained. *Methylmercaptomethylthiazoline*,



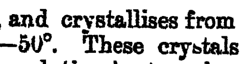
$\begin{array}{l}\mathrm{CHMe{\cdot}S}\\ \mathrm{CH_2{-}N}\end{array}\!\!\gg\mathrm{C{\cdot}SMe}$, is a colourless, oily liquid boiling at 216—218°. The corresponding *ethyl*-compound boils at 228—229°, and the *propyl*-derivative at 246—248°. These compounds are all strong bases, and have an extremely unpleasant odour.

If β-bromopropylamine hydrobromide is warmed with an equivalent quantity of baryta-water, 2 mols. HBr are eliminated, and on distillation a basic substance is obtained of the formula C_3H_7N. It seems to be amidopropylene; it is isomeric with allylamine, from which it is distinguished by giving a crystalline compound with potassium bismuthoiodide. The new base is also isomeric with the two compounds formed by the action of potash on γ-bromopropylamine hydrobromide (compare Abstr., 1888, 1292).

β-Bromopropylbenzamide, $\mathrm{CHMeBr{\cdot}CH_2{\cdot}NHBz}$, is obtained by treating β-bromopropylamine with benzoic chloride in the cold. The amide crystallises from benzene in needles melting at 78°, and if it is dissolved in water, the solution evaporated, and the residue treated with potash, a substance is obtained of the formula $C_{10}H_{13}NO_2$; this crystallises from benzene in white, lustrous leaves, melts at 92—93°, and is most probably *β-hydroxypropylbenzamide*, $\mathrm{OH{\cdot}CHMe{\cdot}CH_2{\cdot}NHBz}$. The same substance is formed by the action of benzoic chloride on the solution, containing β-oxypropylamine, which remains after distilling off the amidopropylene (see above).

On adding methylthiocarbimide to β-bromopropylamine dissolved in benzene, two substances are formed; the one separates as an oil, the other remains dissolved in the benzene. The oily compound is *methylpropylene-ψ-thiocarbamide*,

$\begin{array}{l}\mathrm{CHMe{\cdot}S}\\ \mathrm{CH_2{\cdot}NH}\end{array}\!\!>\mathrm{C{:}NMe}$, or



$$\begin{array}{l}\mathrm{CHMe{\cdot}S}\\ \mathrm{CH_2{-}N}\end{array}\!\!\gg\mathrm{C{\cdot}NHMe};$$

it solidifies on standing, and crystallises from light petroleum in long needles melting at 49—50°. These crystals are particularly easily soluble in water, and the solution is strongly alkaline. The picrate is obtained in the form of needles melting at 145°. The platinochloride crystallises from water in large, dark-red needles melting at 143°. The second compound is obtained on evaporating the benzene; it is deposited from methyl alcohol in long, white crystals melting at 64°, has the formula $C_7H_{13}N_3S_2$, and is a compound of equal molecules of methylpropylene-ψ-thiocarbamide and methylthiocarbimide. Allylthiocarbimide yields two corresponding compounds: allylpropylene-ψ-thiocarbamide crystallises from light petroleum in quadratic prisms melting at 56°. The picrate is deposited from water in long crystals which melt at 130°. The second product of the action of allylthiocarbimide crystallises from dilute alcohol in white, lustrous prisms melting at 52°. Allylpropylene-ψ-thiocarbamide is also obtained by heating symmetrical diallylthiocarbamide with hydrochloric acid under pressure. An oily, isomeric base,

$$\begin{array}{l}\mathrm{CHMe}\text{———}\mathrm{S}\\ \;|\\ \mathrm{CH_2{\cdot}N{\cdot}(C_3H_5)}\end{array}\!\!>\mathrm{C{:}NH}$$

is prepared by the action of allyl iodide on propylene-ψ-thiocarbamide. The picrate crystallises from water in small, triangular prisms melting at 126°. This research shows that the reactions of β-bromopropylamine are completely analogous to those of bromoethylamine. J. B. T.

Tribromopropaldehyde and Tribromopropionic Acid. By L. Niemilowicz (*Monatsh.*, 11, 87—99).—*Tribromopropaldehyde*, $CH_2Br{\cdot}CBr_2{\cdot}COH$, is obtained, together with tribromopropionic acid and a liquid polymeride of dibromethylene, on dissolving glycerol in five times its weight of sulphuric acid, treating the solution with hydrobromic acid (sp. gr. 1·49), and heating at 125°. It is an oil which unites energetically with water to form a white, crystalline hydrate, $C_3H_3Br_3O + 2H_2O$, and on heating splits up into hydrobromic acid and the polymeride of dibromethylene above mentioned. The hydrate crystallises in needles or in plates; melts at 61·5°; is only very slowly attacked on boiling with water, yielding a black, humus-like acid product; on oxidation with an equivalent quantity of nitric acid it gives tribromopropionic acid; and yields unsymmetrical dibromethylene, hydrobromic and formic acids on treatment with potash, a decomposition which explains the physiological action of the aldehyde.

Tribromopropionic acid, $CH_2Br{\cdot}CBr_2{\cdot}COOH$, is formed in variable quantity, depending on the strength of the hydrobromic acid used and the temperature of the reaction, in the production of tribromopropaldehyde by the method above described. It crystallises from carbon bisulphide in transparent plates, soluble in alcohol, ether, chloroform, and the alkalis, but is scarcely dissolved by water or by dilute acids. It melts at 93°, and forms a sodium salt crystallising with 2 mols. H_2O; a calcium salt crystallising in slender, white needles; and an iron salt, $(C_3H_2Br_3O_2)_3Fe$, crystallising in characteristic red, hexagonal plates. G. T. M.

Aldol. By G. Magnanini (*Gazzetta*, 19, 366—367).—Phenylhydrazine acetate precipitates from aqueous solutions of aldol a heavy oil, which, on exposing its ethereal extract for some time in a vacuum, is changed into a transparent, reddish, viscous mass. On heating this substance, it is decomposed, and at a temperature above 160—180°, products pass over which give the pyrazoline reaction with sulphuric acid and potassium dichromate; among these products, aniline and a substance having the odour and reactions of the indoles have been observed. The latter compound is probably the real hydrazone; it is decomposed by the action of hydrochloric acid in the cold, forming a green colouring matter.

By the prolonged action of hydroxylamine hydrochloride, &c., on aldol, the only product is a mobile, neutral liquid which has the same boiling point as acetaldoxime.

Paraldol is found by Raoult's method to have in acetic solutions the molecular formula $(C_4H_8O_2)_2$. S. B. B. A.

Decahydrated Lead Acetate. By A. E. Fasnacht and C. R. Lindsey (*Chem. News*, **61**, 196—197).—Rhombic plates of the composition $Pb(OAc)_2 + 10H_2O$ have been obtained. Axial ratios, 0·7002 : 1 : 0·9125, observed faces ∞P, $\bar{P}\infty$, $\infty\breve{P}\infty$, $\breve{P}\infty$. They are colourless and transparent, but gradually become opaque and milk-white; they melt at 22·2°, and have a sp. gr. of 1·689. D. A. L.

Conversion of Ethyl Acrylate into β-Alanine. By V. Wender (*Gazzetta*, **19**, 437—440).—Körner and Menozzi have given a method for the formation of unsaturated (olefinoïd) acids by the elimination of nitrogen from the paraffinoïd amido-acids, and have shown that the reaction may be reversed (Abstr., 1887, 1031, 1100), thus obtaining aspartic acid from fumaric and maleïc acids. To test the latter reaction in the oleïc series, pure ethyl acrylate (15 grams) prepared by Caspary and Tollens' method, by the action of zinc and sulphuric acid on αβ-dibromopropionic acid, was heated with alcoholic ammonia (55 c.c. of 15 per cent.) for 10 hours in a sealed tube at 110—115°. The product was freed from alcohol, dissolved in water, and extracted with ether, the aqueous solution boiled with baryta (24 grams), until no more ammonia was evolved. On removing the barium, the residue yielded on concentration colourless, tabular crystals which, like those of β-alanine, melt with decomposition at 178°, and are very freely soluble in water. To confirm its identity with β-alanine, the product was converted into the copper salt, which crystallises in large, blue tables or prisms, of the composition $(NH_2{\cdot}C_2H_4{\cdot}COO)_2Cu,6H_2O$. This differs from the salt obtained by Heintz (Abstr., 1871, 127) from crude β-alanine, the latter crystallising with only 5 mols. H_2O; the copper salt of pure β-alanine prepared from β-iodopropionic acid contains $6H_2O$, however.

α-Alanine may accordingly be transformed into the β-compound by first converting it into ethyl acrylate. S. B. A. A.

Derivatives of Angelic and Tiglic Acids. By P. Melikoff and P. Petrenko-Kritschenko (*Annalen*, **257**, 116—132; compare Abstr., 1887, 29, and 1888, 1177).—The authors have made some further experiments in order to show that the α-chloro-α-methylhydroxybutyric acid (m. p. 115·5°) obtained from tiglic acid (Abstr., 1887, 29) is not identical with the α-chlorhydroxyvaleric acid (m. p. 103°, not 105°) obtained by treating angelic acid with hypochlorous acid; this is clearly proved by a comparison of the behaviour of the potassium and silver salts of the two acids, as well as by a comparison of the two acids themselves.

The β-chlorohydroxy-acid (m. p. 92°) obtained by the combination of hydrochloric acid and the glycidic acid from angelic acid is isomeric with the β-chlorhydroxy-acid (m. p. 75°) which is obtained by the action of hypochlorous acid on angelic acid, and on tiglic acid. When the acid (m. p. 92°) is warmed with sodium carbonate, it is converted into ethyl methyl ketone, identical with the compound obtained from the β-chlorhydroxy-acid prepared from tiglic acid; the acid melting at 92° is therefore αβ-chlor-α-hydroxy-, and that melting at 103° an α-chloro-β-hydroxy-valeric acid.

The authors discuss the behaviour of various unsaturated acids with hypochlorous acid, and conclude that Michael's rules (Abstr., 1819, 1140) are inapplicable in a large number of cases.

F. S. K.

Schmidt's Process for the Conversion of Oleic Acid into Solid Fatty Acids. By R. Benedikt (*Monatsh.*, 11, 71—83).—To investigate the process, a mixture of oleic acid with one-tenth of its weight of zinc chloride was heated at about 185° (if the temperature is allowed to rise above 195°, no solid acids are obtained), until a small quantity of it solidified when cooled. The solid product of the action consisted of additive products with zinc chloride, and these, on boiling with dilute hydrochloric acid, were converted into isomeric hydroxystearic acids, one of which was further converted by loss of water into the lactone of γ-hydroxystearic acid. The action of zinc chloride consequently resembles that of sulphuric acid (compare Geitel, Abstr., 1888, 578), and confirms the opinion of Saytzeff (Abstr., 1888, 815), that oleic acid must be represented by the formula

$$CH_3\cdot[CH_2]_{13}\cdot CH\colon CH\cdot CH_2\cdot COOH.$$

On distilling these hydroxystearic acids, oleic and the solid isoleic acids are formed. Schmidt's solid "fatty acids" consist chiefly of a mixture of isoleic acid and stearolactone.

G. T. M.

Ethyl α-β-Diacetopropionate. By I. Ossipoff (*Bull. Soc. Chim.* [3], 3, 326—328).—Ethyl sodacetoacetate and chloracetone in molecular proportion were heated in alcohol at 100°, and on distillation yielded two fractions, one boiling at 104—106° under a pressure of 37—38 mm., and another boiling at 121—123° under a pressure of 33—35 mm. Neither of these is pure ethyl diacetopropionate, but each contains much ethyl acetoacetate.

The heats of combustion of the second fraction were taken, and gave a mean value of 1110 cals. T. G. N.

Acetyllevulinic Acid and Constitution of γ-Ketone Acids. By J. Bredt (*Annalen*, **256**, 314—340).—Acetyllevulinic acid (Abstr., 1887, 126) is formed when α-angelicalactone is treated with acetic anhydride at the ordinary temperature, or more quickly, at 100°, a reaction which is further evidence in favour of the lactone formula for levulinic acid.

The *hydrazone* of levulinic phenylhydrazide,

$$NHPh\cdot N\colon CMe\cdot CH_2\cdot CH_2\cdot CO\cdot NH\cdot NHPh,$$

is formed when acetyllevulinic acid is treated with phenylhydrazine in glacial acetic acid solution, or when α-angelicalactone is treated with phenylhydrazine in ethereal solution; it crystallises from hot alcohol in prisms, and melts at 178°. The formation of this compound cannot be regarded as evidence against the lactone formula for acetyllevulinic acid, because the diacetates of aldehydes behave in an exactly similar manner. When benzaldehyde diacetate, $CHPh(OAc)_2$, for example, is treated with phenylhydrazine in glacial acetic acid solution, the hydrazone of the benzaldehyde separates from the solution in crystals, and the mother liquors contain acetylphenylhydrazine (m. p. 128·5°).

Œnanthaldehyde diacetate, under the same conditions, is converted into œnanthaldehydephenylhydrazine and acetylphenylhydrazine.

The dilactone,  $\begin{matrix} CH_2{\cdot}CH_2 \\ | \\ CO - O \end{matrix}>C<\begin{matrix} CH_2{\cdot}CH_2 \\ \quad\ | \\ O - CO \end{matrix}$, isolated by Volhard (this vol., p. 30) from the distillation products of succinic acid, and which stands in the same relation to acetyllevulinic acid as the latter does to aldehyde diacetate, also combines with phenylhydrazine in acetic acid solution. The compound obtained crystallises in colourless needles, does not melt at 290°, and is insoluble in alkalis; it has the composition $C_{19}H_{20}N_4O_2$, and is formed from the intermediate product $COOH{\cdot}CH_2{\cdot}CH_2{\cdot}C(N_2HPh){\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}NH{\cdot}NHPh$, by the elimination of 1 mol. H_2O.

Levulinic cyanide and levulinic chloride both interact with phenylhydrazine, the former, however, only very slowly, yielding the hydrazone of levulinic phenylhydrazide (m. p. 178°) described above. Since both the chloride and the cyanide are doubtless γ-substituted-γ-lactones, acetyllevulinic acid has an analogous constitution,

$$CH_2<\begin{matrix} CH_2- \\ CO{\cdot}O \end{matrix}>CHMe{\cdot}OAc.$$

Levulinic chloride can be conveniently prepared by treating levulinic acid with excess of acetic chloride, and cooling the mixture as soon as the reaction commences; the product is then kept under reduced pressure until free from acetic chloride. Michael's statement that acetyllevulinic is formed in this reaction is incorrect.

Ethyl levulinate is not acted on by acetic anhydride even at 160—170°.

When silver levulinate is treated with acetic chloride, or when silver acetate is treated with levulinic chloride, acetyllevulinic acid is formed.

F. S. K.

Action of Ammonia on Dehydrodiacetyllevulinic Acid. By G. Magnanini (*Gazzetta*, 19, 275—284).—The formation of dehydrodiacetyllevulinic acid, $C_9H_{10}O_4$, by heating levulinic acid with acetic anhydride was previously described (Abstr., 1888, 812).

The best yield is obtained by heating levulinic acid with acetic anhydride for not less than 10 hours at a temperature of 220—225°, removing the excess of acetic acid and anhydride by distillation in a vacuum, treating the resinous residue with water, and completely extracting by boiling with sodium carbonate. The alkaline solution is repeatedly extracted with ether, the extract freed from ether, and the residue crystallised from boiling water; the yield never exceeds 4 per cent. By evaporating the ethereal solution, it may be obtained in monoclinic prisms, $a:b:c = 1.58975:1:.087707$, $\beta = 69° 41' 13''$. Forms observed (001), (100), (010), (110), ($\bar{2}01$), ($\bar{1}11$), (*hko*), (*hol*).

The ethereal extract from the alkaline solution contains an oil having an agreeable odour and boiling at 73—85° under a pressure of 9—10 mm. of mercury.

The action of acetic anhydride on levulinic acid at 100° results in the quantitative conversion of the latter into its monacetyl-derivative. On heating levulinic acid with five times its weight of acetic anhydride for six hours at 150—155°, a mixture of acetyllevulinic acid and of angelolactone is obtained, but no dehydrodiacetyllevulinic acid is formed if the temperature is either much below 200° or over 230°.

When the acid (1 gram) is heated in a sealed tube with ammonia (12—13 grams, sp. gr. = 0·905) for 5—6 hours at 100°, it is almost quantitatively converted into the compound $C_8H_{11}NO$, which partially separates on standing in long, lustrous needles. The bulk of this product is extracted from the solution with ether, it melts when pure at 94·5°, and has an odour recalling that of an acetylpyrroline. On heating it with zinc-dust, an oil passes over having an odour recalling that of the homologues of pyrroline, and colouring a strip of pinewood moistened with hydrochloric acid an intense red; it is itself resinified by that reagent.

The compound $C_8H_{11}NO$ does not yield an oxime on heating it with hydroxylamine hydrochloride, sodium carbonate, and alcohol, the product consisting of the sodium salt of a new acid which is precipitated by ether from a concentrated alcoholic solution, and decomposes at 162°. S. B. A. A.

Ethereal Salts of Alkyoxyquartenylic Acids. By E. Enke (*Annalen*, **256**, 201—218; compare Koll, Abstr., 1889, 488).—Ethyl β-chloroquartenylate, $CH_3{:}CCl{\cdot}CH_2{\cdot}COOEt$, is obtained by dissolving β-chloroquartenylic acid, prepared by Geuther's method, in alcohol, and saturating the solution with hydrogen chloride; it boils at 155—157°. The *methyl* salt boils at 139—141°, the *propyl* salt at 175—177°, and the *isobutyl* salt at 187°.

Methyl β-methoxyquartenylate, $CH_3{:}C(OMe){\cdot}CH_2{\cdot}COOMe$, obtained by treating methyl chloroquartenylate with sodium methoxide in alcoholic solution, is a colourless liquid boiling at 175·8° (corr.); the corresponding *ethoxy*-derivative boils at 195·7° (corr.), the *propoxy*-derivative at 230·4° (corr.), and the *isobutoxy*-derivative at 253·7° (corr.).

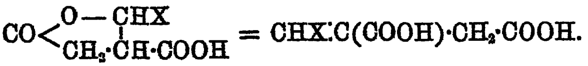
Ethyl β-methoxyquartenylate, $CH_3{:}C(OMe){\cdot}CH_2{\cdot}COOEt$, boils at 178·4° (corr.), the *propoxy*-derivative at 228·6° (corr.), the *isobutoxy*-derivative at 247·3° (corr.), and the *amyloxy*-derivative at about 254—260° with partial decomposition.

Propyl β-methoxyquartenylate boils at 180—182°; the *ethoxy*-derivative melts at 18° and boils at 205·3° (corr.), the *propoxy*-derivative boils at 229·7° (corr.), and the *isobutoxy*-derivative at 251·4° (corr.).

Butyl β-methoxyquartenylate boils at 184·5° (corr.); the *ethoxy*-derivative melts at 11° and boils at 206·4° (corr.), the *propoxy*-derivative boils at 228·5° (corr.), and the *isobutoxy*-derivative at 249·8° (corr.).

F. S. K.

Action of Sodium and Sodium Ethoxide on Ethereal Salts of Lactone Acids and on Lactones. By R. Fittig (*Annalen*, **256**, 50—63; compare Abstr., 1885, 375).—It has been previously shown (Roser, Abstr., 1884, 459, and Frost, Abstr., 1885, 393) that when ethyl terebate (ethyl dimethylparaconate) is treated with sodium or sodium ethoxide, it is converted into sodium ethyl tereconate; the ethyl salts of propyl-, isobutyl-, and phenyl-paraconic acid behave in like manner, being converted into the sodium ethyl salts of the isomeric itaconic acids in accordance with the equation



$$\mathrm{CO}<\begin{matrix}\mathrm{O-CHX}\\ \mathrm{CH_2\cdot CH\cdot COOH}\end{matrix} = \mathrm{CHX{:}C(COOH)\cdot CH_2\cdot COOH}.$$

The same intramolecular change takes place to a slight extent, as has been already shown (compare this vol., pp. 584, 775), when the substituted paraconic acids are distilled; the unsaturated bibasic acids obtained by either of these methods being identical.

Methylitaconic acid, propylitaconic acid, and phenylitaconic acid are readily converted into saturated acids; isobutylitaconic acid, on the other hand, is as difficult to reduce as teraconic acid. In chemical behaviour the itaconic acids resemble teraconic acid very closely, but, unlike the latter, they are only very partially reconverted into the paraconic acids by treatment with hydrochloric, hydrobromic, or sulphuric acid; this change can, however, be brought about by treating the acids with bromine and then with sodium amalgam. By boiling the acids obtained by the action of bromine on propyl- and isobutyl-itaconic acids with water, the unsaturated lactone acids corresponding to aconic and terebilenic acid are formed; the constitution of these compounds is probably expressed by the formula

$$\mathrm{CO}<\begin{matrix}\mathrm{O-CHX}\\ \mathrm{CH{:}C\cdot COOH}\end{matrix}.$$

The brominated phenylparaconic acids behave quite differently, as, when boiled with water, they are decomposed with evolution of carbonic anhydride, yielding benzoylpropionic acid.

The ethyl salt of terpenylic acid shows a totally different behaviour from that exhibited by the ethereal salts of the substituted paraconic acids, and when treated with sodium or sodium ethoxide, it yields the sodium salts of two isomeric diterpylic acids, $C_{16}H_{22}O_7$, 2 mols. of the lactone acid combining together with elimination of 1 mol. of water. The diterpylic acids are readily decomposed by acids with evolution of carbonic anhydride, yielding crystalline, neutral dilactones, $C_{17}H_{22}O_5$, which form salts, $C_{15}H_{21}O_7M'_2$, when boiled with alkalis; on decomposing these salts with hydrochloric acid, the lactone acids, $C_{15}H_{24}O_6$, are obtained, but they are readily reconverted into dilactones. The abnormal behaviour of terpenylic acid seems to show that it is not a paraconic acid, and it is possible that it has the constitution  $\mathrm{CO}{<}\begin{array}{l}\mathrm{O-CPr^{\beta}\cdot COOH}\\ \mathrm{CH_2\cdot CH_2}\end{array}$.

The simple lactones, valerolactone and caprolactone, behave in a certain sense like ethyl terpenylate, as, when treated with sodium ethoxide, they yield sodium salts which are decomposed by hydrochloric acid into dilactones, formed from 2 mols. of the lactone with elimination of 1 mol. of water. These dilactones are decomposed on boiling with bases, giving salts from which crystalline monocarboxylic acids (divalonic and dihexonic acids), polymeric with the original lactones. are obtained; these acids are unstable, and, on warming with dilute mineral acids, are decomposed into neutral, very stable compounds (dimethyloxetone and diethyloxetone). The constitution of these compounds has not yet been ascertained. In the case of valerolactone, the first product (divalerolactone) probably has the constitution  $\begin{array}{l}\mathrm{CH_2\cdot CH_2}\\ \mathrm{CHMe\cdot O}\end{array}{>}\mathrm{C{:}C}{<}\begin{array}{l}\mathrm{CO\cdot O}\\ \mathrm{CH_2\cdot CHMe}\end{array}$, and the monocarboxylic acid (divalonic acid) obtained therefrom the constitution

$$\begin{array}{l}\mathrm{CH_2\cdot CH_2}\\ \mathrm{CHMe\cdot O}\end{array}{>}\mathrm{C{:}C(COOH)\cdot CH_2\cdot CHMe\cdot OH};$$

on warming this acid with dilute mineral acids, carbonic anhydride is evolved, and it may be assumed that the compound

$$\begin{array}{l}\mathrm{CH_2\cdot CH_2}\\ \mathrm{CHMe\cdot O}\end{array}{>}\mathrm{C(OH)\cdot CH_2\cdot CH_2\cdot CHMe\cdot OH}$$

is formed as an itermediate product, and then decomposed into dimethyloxetone,  $\begin{array}{l}\mathrm{CH_2\cdot CH_2}\\ \mathrm{CHMe\cdot O}\end{array}{>}\mathrm{C}{<}\begin{array}{l}\mathrm{CH_2\cdot CH_2}\\ \mathrm{O-CHMe}\end{array}$, with elimination of water.

The oxetone obtained from caprolactone would, in accordance with these views, be a diethyloxetone of the constitution

$$\begin{array}{l}\mathrm{CH_2\cdot CH_2}\\ \mathrm{CHEt\cdot O}\end{array}{>}\mathrm{C}{<}\begin{array}{l}\mathrm{CH_2\cdot CH}\\ \mathrm{O-CHEt}\end{array},$$

and divalonic and dihexonic acid would be dimethyl- and diethyloxetonecarboxylic acid respectively.

F. S. K.

Valerolactone. By R. Fittig and H. Rasch (*Annalen*, **256**, 126—134; compare Abstr., 1885, 375, and preceding abstract).—*Divalolactone*, $C_{10}H_{14}O_3$, is obtained when valerolactone (10 grams) is warmed for about 12 hours with a solution of sodium (2·5 grams) in absolute alcohol (25 grams); after distilling off the alcohol, the product is dissolved in cold water, the well-cooled solution acidified with dilute hydrochloric acid, and the precipitated oil extracted with ether. It gradually solidifies to a yellowish, wax-like mass, but it cannot be obtained in crystals as it is so very readily soluble in all ordinary solvents; it seems to distil under the ordinary pressure with slight decomposition, but is only slightly volatile with steam.

Divalonic acid (*dimethyloxetonecarboxylic acid*), $C_{10}H_{18}O_4$, is formed when divalolactone is warmed for a long time with soda: on acidifying the cold solution with hydrochloric acid, the acid is precipitated as an oil, but it soon solidifies. It crystallises from ether in well-defined, colourless, hexagonal plates, melts at 130° with decomposition, and is readily soluble in alcohol, but only very sparingly in ether, chloroform, and cold water. It dissolves in cold alkaline carbonates with evolution of carbonic anhydride, and is precipitated unchanged on the addition of acids; it does not seem to be acted on by sodium amalgam in alkaline solution. The impure acid decomposes spontaneously with evolution of carbonic anhydride, yielding dimethyloxetone, but the pure compound is stable. The *silver* salt, $C_{10}H_{15}O_4Ag$, crystallises from hot water in dark plates. The *barium* salt, $(C_{10}H_{15}O_4)_2Ba$, is amorphous and readily soluble in alcohol and water. The *calcium* salt, $(C_{10}H_{15}O_4)_2Ca$, is also amorphous, but much more sparingly soluble in alcohol and water than the barium salt.

Dimethyloxetone, $C_9H_{16}O_2$, is formed when divalonic acid is boiled with water or dilute mineral acids. It is a colourless, neutral oil with an agreeable, turpentine-like smell, and boils at 169·5° (thermometer entirely in the vapour); its sp. gr. is 0·978 at 0°, and its molecular formula $C_9H_{16}O_2$, as is shown by vapour-density determinations by V. Meyer's method. It is miscible with alcohol, ether, chloroform, &c., in all proportions, and is soluble in 18 parts of water at the ordinary temperature, but it separates again from the aqueous solution on warming or on adding potassium carbonate. It reduces ammoniacal silver nitrate solution in presence of sodium hydrate, is readily volatile with steam, and is not decomposed by boiling dilute acids or alkalis. It dissolves in a concentrated aqueous solution of sodium hydrogen sulphite, and cannot be extracted from the solution by shaking with ether. When warmed with hydroxylamine in aqueous solution, it yields a readily soluble syrup, and it combines with phenylhydrazine to form a yellowish oil. It is not acted on by acetic anhydride at 190°, or by sodium amalgam, but when heated with hydriodic acid it is completely decomposed.

The compound $C_3H_{16}Br_2O$ separates in crystals when dimethyloxetone is treated with ice-cold concentrated hydrobromic acid. It crystallises from chloroform in long needles, melts at 42°, and is very readily soluble in ether, chloroform, carbon bisulphide, light petroleum, &c., but insoluble in cold water; it is decomposed by boiling water and by alkaline carbonates, being reconverted into dimethyloxetone. F. S. K.

Caprolactone. By R. Fittig and H. Dubois (*Annalen*, **256**, 134—147; compare Fittig, Abstr.. 1885, 375, and this vol., p. 866). —*Dihexolactone*, $C_{12}H_{18}O_3$, is obtained by treating caprolactone (10 grams) with a solution of sodium (2 grams) in absolute alcohol; after heating at 100° for 3 to 4 hours, the alcohol is evaporated, the residue dissolved in water, the ice-cold solution acidified with hydrochloric acid, and the precipitated oil immediately extracted with ether; the ethereal solution is evaporated at the ordinary temperature, the residual oil shaken first with soda and then with water, to free it from caprolactone, then dissolved in alcohol, and the filtered solution evaporated, whereon dihexolactone remains as a colourless, mobile, neutral oil. It boils above 300° with slight decomposition, and is readily soluble in alcohol and ether, but only sparingly in water; it is slightly volatile with steam, and is not decomposed by boiling water, but when heated with dilute mineral acids is quickly converted into diethyloxetone.

Dihexonic acid (*diethyloxetonecarboxylic acid*), $C_{12}H_{20}O_4$, is obtained by dissolving dihexolactone in warm soda, shaking the solution with ether to free it from diethyloxetone, acidifying the well-cooled alkaline solution, and extracting the precipitated oil with alcoholic ether. It crystallises in thick, colourless prisms, melts at 106°, and is readily soluble in alcohol and chloroform, but only sparingly in water and ether; it is not acted on by sodium amalgam, and it dissolves unchanged in cold dilute sodium carbonate, but when treated with warm water or cold dilute acids it is converted into diethyloxetone. The *calcium* salt, $(C_{12}H_{19}O_4)_2Ca$, and the *barium* salt, $(C_{12}H_{19}O_4)_2Ba$, are amorphous, soluble in alcohol and water, and decomposed by carbonic anhydride. The *silver* salt, $C_{12}H_{19}O_4Ag$, is insoluble in cold water, but readily soluble in alcohol, from which it separates in amorphous, cauliflower-like aggregates; it is decomposed by boiling water or when heated alone at 100°. The *sodium* salt, $C_{12}H_{19}O_4Na$, crystallises from alcohol in colourless needles, and is decomposed by boiling water.

Diethyloxetone, $C_{11}H_{20}O_2$, prepared by boiling dihexolactone with a dilute mineral acid, is a colourless, mobile, pleasant-smelling liquid, very sparingly soluble (1 in 380 parts at 15°) in water, but readily in alcohol, ether, chloroform, and most ordinary solvents; the aqueous solution becomes turbid on warming, but clear again on heating to about 80°. It is not decomposed by boiling baryta-water or by concentrated sulphuric acid, and with ammoniacal silver nitrate solution, sodium hydrogen sulphite, sodium amalgam, phenylhydrazine, and acetic acid, it behaves like dimethyloxetone (preceding abstract); it does not combine with hydroxylamine, but with benzoic chloride at 100° it yields a thick, brown oil. When heated with dilute (1 : 2) nitric acid it is gradually oxidised, with evolution of carbonic anhydride, yielding caprolactone and an acid which is most probably propionic acid.

The compound $C_{11}H_{10}Br_2O$ is formed when diethyloxetone, dihexolactone, or dihexonic acid is treated with concentrated hydrobromic acid at 0°. It separates from chloroform in colourless crystals, melts at 35°, and is readily soluble in alcohol, ether, and chloroform, but insoluble in water; when treated with sodium amalgam, or boiled with water or sodium carbonate, it is converted into dimethyloxetone.

F. S. K.

Action of Methylamine on Ethyl Maleate and Fumarate. By G. Körner and A. Menozzi (*Gazzetta*, 19, 422—432; compare Abstr., 1887, 1031—1100).—When ethyl maleate is heated with an alcoholic solution of methylamine at 105—110°, the product consists of a mixture of a crystalline solid and a liquid in varying proportions; if the ethyl maleate (12 grams) is heated for 8—10 hours with an alcoholic solution of methylamine (50 c.c. of 33 per cent.), the product consists of a mass of needles soaked in the solution of the liquid compound; when a smaller quantity of methylamine solution is used (35 c.c. of 25 per cent.), and the heating is continued for 4—5 hours, the liquid product is more abundant.

Methylsuccinamic (methylaspartic) dimethylamide,

$$NHMe\cdot CO\cdot CH(NHMe)\cdot CH_2\cdot CO\cdot NHMe,$$

is the solid product of the preceding reaction, it is separated from the liquid by diluting the mixture with ether and filtering; when pure, it crystallises from absolute alcohol in long, white needles which are very readily soluble in water, easily soluble in alcohol, but almost insoluble in dry ether. The aqueous and alcoholic solutions are strongly alkaline; on heating, they evolve ammonia, becoming first neutral and finally acid; on boiling with baryta-water, methylamine is evolved and barium methylaspartate is formed.

Methylamidomethylsuccinamic acid (dimethylasparagine),

$$NHMe\cdot CO\cdot CH(NHMe)\cdot CH_2\cdot COOH,$$

is obtained by heating the aqueous solution of the preceding compound for several days; on concentrating the solution, a bye-product is first deposited in scales; on further concentration, the solution is converted into a solid mass, which, after repeated crystallisation from alcohol, forms colourless, shining, anhydrous plates which turn yellow at 215° and melt at 291°. The aqueous solution is feebly acid and optically inactive. It combines with both acids and bases: the *nitrate* forms white prisms which contain 1 mol. H_2O, and decompose on heating to 82—83°; the *copper* salt, $(C_6H_{11}N_2O_3)_2Cu + 2H_2O$, forms blue prisms or warty aggregates very soluble in water. On boiling with baryta-water, dimethylasparagine loses a molecule of methylamine with formation of barium methylaspartate.

The deposit of scales obtained in the preparation of dimethylasparagine crystallises from boiling water in flattened, opaque, white, lustrous needles having the composition $C_6H_{10}N_2O_2$; on boiling this substance with baryta-water, the products are the same as those obtained from dimethylasparagine; hence it is either the methylimide of methylaspartic acid or an isomeride.

Diethyl methylaspartate is the liquid product of the action of methylamine on diethyl maleate. The ethereal solution of the crude product also contains small quantities of a crystalline bye-product and traces of methyl maleate. The diethyl salt is obtained pure by moving the ether and alcohol from this solution, precipitating the bye-product with pure ether, converting the methyl aspartate which remains in solution into the chloride or sulphate, and saponifying with soda. It is a colourless and almost odourless oil, heavier than water, and only very sparingly soluble in it, forming an alkaline solution; it combines with acids forming crystalline salts which are very soluble in water, but when boiled with alkaline hydrates or carbonates it undergoes hydrolysis, yielding salts of methylaspartic acid. When heated at 110° with alcoholic methylamine, the dimethylamide is formed; this dissolves slowly in the cold in aqueous methylamine with formation of dimethylasparagine; it is converted by aqueous ammonia into monomethylasparagine.

The bye-product crystallises from alcohol in shining needles which melt at 144°, and have the composition $C_6H_{11}NO_3$. It is insoluble in dilute alkalis, and is converted by strong ammonia into a white powder which crystallises from water in shining needles; it probably has the constitution

$$\begin{array}{l} CO-CH_2 \\ \vert \qquad \vert \\ NMe\cdot CH\cdot COOEt \end{array}.$$

Methylamidosuccinamic acid (*monomethylasparagine*), $C_5H_{10}N_2O_3 + H_2O$, is prepared by heating diethyl methylaspartate with aqueous ammonia until the solution becomes acid; on concentration, a bye-product first crystallises out in scales; subsequently monomethyasparagine is deposited in spherical aggregates of needles. It combines with both acids and bases. The *copper* salt crystallises in anhydrous bluish-violet scales which decompose at 191°.

On boiling the acid with potash, a methylaspartate is formed with evolution of ammonia; the same reaction takes place on heating with hot mineral acids. Its constitution is therefore expressed by the formula $NH_2\cdot CO\cdot CH(NHMe)\cdot CH_2\cdot COOH$.

The bye-product is probably the imide of methylaspartic acid; it has the composition $C_5H_8N_2O_2$. It crystallises from boiling water in lustrous needles which blacken and decompose at 235°. On boiling with potash or baryta-water, a methylaspartate is formed with evolution of ammonia.

Methylaspartic acid, $C_5H_9O_4 + H_2O$, may be obtained by any of the reactions given. It is best prepared by boiling pure dimethylasparagine with baryta-water until no more methylamine is evolved, decomposing the barium salt, and concentrating. It crystallises from boiling water in pointed pyramids which lose their water of crystallisation at 100°, undergo alteration at 120°, and melt at 133—134°. The anhydrous acid melts at 178°. It is sparingly soluble in water (2·62 per cent. in water at 20·4°), and the solution is strongly acid and inactive to light. On standing, it deposits monoclinic, transparent crystals, $a : b : c = 0{\cdot}6467 : 1 : 0{\cdot}4489$, $\beta = 80° 25'$. It forms salts with both acids and bases; the *monopotassium salt* crystallises in shining needles, the *monosodium salt* in nodules, the *monobarium salt* in spherical aggregates of needles containing 4 mols. H_2O; all these salts are very soluble in water, and are precipitated from their solutions by concentrated alcohol in the form of oils. The *ammonium salt* is decomposed by exposure to the air. A *silver salt* is obtained on adding silver nitrate to a solution of an alkaline salt; it is crystalline, and darkens on exposure to light. A crystalline *cadmium salt* may be obtained in the same way. The *nitrate* forms monoclinic tables; the *hydrochloride* crystallises in prisms. The *monethyl salt* is obtained by saturating an alcoholic solution of the acid with hydrogen chloride, and decomposing the hydrochloride with silver oxide and water. It crystallises from 98 per cent. alcohol in very slender, shining needles which melt at 181·5°.

Ethyl fumarate, on treatment with methylamine, yields the same products in the same proportions as ethyl maleate. S. B. A. A.

Eulyte.—By G. CIAMICIAN and C. ZAITI (*Gazzetta*, **19**, 263—267).—Baup (*Annalen*, **81**, 96) and Bassett (this Journal, 1872, 98) described two substances formed by the action of nitric acid on citraconic acid, namely, *eulyte*, $C_6H_8N_4O_7$, and *dislyte*, $C_8H_6N_4O_6$. The directions given by these authors only lead, however, to the formation of *eulyte*. It is best prepared by dissolving pure citraconic acid in nitric acid (sp. gr. = 1·45) and heating until chemical action commences. When the reaction is complete, the product is allowed to remain for some time, and the thick, white, crystalline deposit which forms is filtered through glass fibre; the filtrate yields a further deposit of the white compound on standing. After washing with cold water and drying in a vacuum, this substance melts at 185°, in this respect approximating to dislyte (m. p. = 189°). It consists, however, of a mixture of two substances, as by repeated crystallisation from alcohol its melting point is reduced to 102—102·5°, and by repeatedly dissolving it in ethyl acetate and precipitating with light petroleum an acid compound is obtained melting at 201—202·5°, and identical with mesaconic acid. The same separation may be effected by treating the white deposit with sodium carbonate; the eulyte remains undissolved, and is purified by solution in benzene and reprecipitation with light petroleum. It forms colourless needles which melt at 101—102·5°, and dissolve readily in warm alcohol, benzene, and ethyl acetate. It is almost insoluble in water and in light petroleum, and quite insoluble in cold alkalis, and in acids; it may be heated with concentrated sulphuric acid without undergoing any change. It dissolves in hot potash forming a yellow solution. On treatment with water, the acid filtrate from the eulyte yields an oily substance which still contains eulyte, and spontaneously solidifies after a time. It would appear that maleïc acid is not acted on by nitric acid in a manner analogous to citraconic acid. S. B. A. A.

Ethyl Propylparaconate. By R. FITTIG and A. SCHMIDT (*Annalen*, **256**, 105—109).—*Ethyl propylparaconate*, $C_{10}H_{16}O_4$, is a colourless liquid boiling at 211—216 (96 mm.).

Propylitaconic acid, identical with the compound obtained by distilling propylparaconic acid (this vol., p. 588), is formed when ethyl propylparaconate is treated with sodium ethoxide in absolute alcoholic solution, and the sodium ethyl salt thus produced is hydrolysed with soda: it is not acted on by cold concentrated hydrobromic acid.

Butylsuccinic acid, $C_8H_{14}O_4$, is obtained, together with a volatile compound with a peculiar odour, when propylitaconic acid is treated with sodium amalgam in slightly acid solution. It separates from water in ill-defined crystals and melts at 81°.

When propylitaconic acid is treated with bromine in ice-cold aqueous solution, it yields a crystalline acid melting at 124—124·5°, and an oil with a most irritating odour; the two products are separated by distilling with steam. The acid (m. p. 124—124·5°), which separates from hot water in slender needles, is very readily soluble in chloroform and water, and easily in ether, alcohol, and hot benzene, but is insoluble in carbon bisulphide and light petroleum.

The *barium* salt has the composition $(C_8H_9O_4)Ba$, so that the acid is probably propaconic acid,

$$CO<\begin{matrix}CH{:}C{\cdot}COOH\\ |\\ O{-}CHPr\end{matrix}$$

. F. S. K.

Ethyl Terpenylate. By R. Fittig and S. Levy (*Annalen*, 256, 109—126).—*Ethyl terpenylate*, $C_{10}H_{16}O_4$, is obtained by dissolving terpenylic acid, prepared by the method previously described (Fittig and Kraft, Abstr., 1882, 42), in alcohol, and saturating the solution with hydrogen chloride. It forms large, monosymmetric crystals, $a : b : c = 1{\cdot}0512 : 1 : 0{\cdot}3805$, $\beta = 50°58'$, melts at 37·5°, and boils at 305° (thermometer almost entirely in the vapour); it is readily soluble in alcohol and ether, but only sparingly in boiling water.

α- and β-Diterpodilactone are formed when ethyl terpenylate (20 grams) is added to sodium (4 grams) covered with a little pure ether, the mixture heated gradually until the ether has evaporated, and then kept at about 100° for 6 hours. The thick, gum-like product is exposed to the air until the unchanged sodium is completely oxidised, then dissolved in water and any unchanged ethyl terpenylate extracted with ether; the alkaline solution is acidified with hydrochloric acid, the precipitated oil redissolved by diluting and boiling, and the filtered solution allowed to cool, whereon the two dilactones separate in yellowish crystals. The crystalline mixture is boiled with baryta-water, the excess of barium precipitated with carbonic anhydride, and the filtered solution allowed to cool; the barium salt of α-diterpoxylic acid then separates from the solution in well-defined, prismatic crystals, and the mother liquors, on evaporation, yield crystals of the barium salt of the corresponding β-acid.

Barium α-diterpoxylate, $C_{15}H_{24}O_7Ba + 6H_2O$, forms monosymmetric crystals, $a : b : c = 0{\cdot}9346 : 1 : 0{\cdot}5949$, $\beta = 65° 54'$, and is readily soluble in hot, but only sparingly in cold water. The *calcium* salt ($+ 6H_2O$), prepared by boiling an aqueous solution of α-diterpodilactone (see below) with calcium carbonate, crystallises from concentrated solutions in colourless, slender needles, and is more readily soluble than the barium salt. The *silver* salt, $C_{15}H_{24}O_7Ag_2$, is insoluble in water. The free *diterpoxylic* acid cannot be isolated.

α-Diterpolactonic acid, $C_{15}H_{24}O_6$, is obtained when an ice-cold solution of barium α-diterpoxylate is carefully treated with dilute hydrochloric acid, and the lactone acid immediately extracted with ether. It separates from cold chloroform in compact, colourless crystals, and is readily soluble in ether and alcohol; it melts at 158—160°, and is decomposed at a somewhat higher temperature with liberation of water and formation of α-diterpodilactone.

α-Diterpodilactone, $C_{15}H_{22}O_5$, is best prepared by boiling an aqueous solution of barium diterpoxylate for a short time with excess of hydrochloric acid; on cooling, the dilactone separates from the solution in colourless needles. It melts at 153—154°, and is almost insoluble in chloroform, benzene, and carbon bisulphide, and only sparingly in cold water, but more readily in alcohol. It is insoluble in cold sodium carbonate, but when boiled with baryta-water, it is gradually converted into barium diterpoxylate.

β-Diterpolactone acid, $C_{15}H_{24}O_6$, separates in crystals when the

mother-liquors from the barium α-diterpoxylate (see above) are treated with cold dilute hydrochloric acid. It separates from water in rhombic prisms, $a:b:c = 0·7319:1:0·2592$, melts at 186—187°, and decomposes at a slightly higher temperature; it dissolves in sodium carbonate, but is precipitated unchanged on the addition of acids.

Barium β-diterpoxylate ($+ 3\frac{1}{2}H_2O$), prepared by boiling the lactone acid with baryta-water, crystallises in small, colourless needles, and is very readily soluble in water. The *calcium* salt, $C_{15}H_{24}O_7Ca$, is a colourless, semi-crystalline compound, very readily soluble in water. The *silver* salt, $C_{15}H_{24}O_7Ag_2$, is amorphous and only sparingly soluble in water.

β-Diterpodilactone, $C_{15}H_{22}O_5$, prepared by heating the lactone acid above its melting point, or by boiling a solution of barium β diterpoxylate with dilute hydrochloric acid, crystallises in large, colourless needles, melts at 134—135°, and resembles the corresponding α-compound in its behaviour with solvents; when boiled with baryta-water, it is converted into the barium salt of β-diterpoxylic acid.

α-Diterpylic acid, $C_{16}H_{22}O_7$, is obtained when the alkaline solution of the crude product of the action of sodium on ethyl terpenylate is carefully acidified in the cold with dilute hydrochloric acid, and the precipitated oil immediately extracted with ether; on evaporating the ethereal extract at the ordinary temperature, α-diterpylic acid gradually separates in crystals, whilst the corresponding β-acid remains as an oil. It crystallises from hot water in colourless needles, melts at 216 with decomposition, and is moderately easily soluble in boiling water and hot alcohol, but only sparingly in ether, and almost insoluble in cold water. The *barium* salt crystallises in small needles and is readily soluble in water; the *calcium* salt crystallises in plates and is only sparingly soluble. When the acid is heated for a long time at 216°, or boiled with dilute hydrochloric acid, it is completely converted into α-diterpodilactone. F. S. K.

Ethyl Isobutylparaconate. By R. FITTIG and J. KRAENCKER (*Annalen*, **256**, 97—105).—*Ethyl isobutylparaconate*, $C_{11}H_{18}O_4$, is obtained by saturating an alcoholic solution of the acid, prepared as previously described (this vol., p. 590), with hydrogen chloride: it is a colourless, crystalline compound, melts at 16—17°, and boils at 293°.

Isobutylitaconic acid, $COOH·CH_2·C(COOH):CH·CH_2Pr^{\beta}$, is prepared by treating ethyl isobutylparaconate with sodium ethoxide in alcoholic solution and hydrolysing the product with soda as described in the preparation of phenylitaconic acid (this vol., p. 895); small quantities of succinic acid and regenerated isobutylparaconic acid are also formed in the reaction, and the itaconic acid is best obtained in a pure condition by dissolving the acid mixture in water, neutralising with calcium carbonate and boiling the filtered solution, whereon calcium isobutylitaconate separates as a powder. The acid separates from water in ill-defined crystals, and melts at 160—165° with liberation of water; when heated quickly, the temperature may be raised to 170° before the acid is completely liquefied. It is rather sparingly soluble in chloroform, benzene, and hot water, but readily in alcohol and ether. The *calcium* salt, $C_9H_{12}O_4Ca$, and the *barium* salt,

$C_9H_{12}O_4Ba$, are more readily soluble in cold than in hot water. The *silver* salt, $C_9H_{12}O_4Ag_2$, is very sparingly soluble in hot water, and gradually darkens on exposure to the light. The *ethyl* salt, $C_9H_{12}O_4Et_2$, is a colourless liquid, and boils at 265°. Isobutylitaconic acid is not reduced by sodium amalgam, and when heated with concentrated hydrochloric or sulphuric acid, only a trace of isobutylparaconic acid is formed, most of the acid remaining unchanged.

Isobutaconic acid, $CO<\begin{matrix}O—CH·CH_2Pr^{\beta}\\ \quad\ \ | \\ CH:C·COOH\end{matrix}$, is obtained, together with a neutral oil, the nature of which could not be ascertained, when isobutylitaconic acid is suspended in water and treated with bromine; the neutral oil, which contains bromine, is separated by distilling with steam, the residual solution extracted with ether, and the mixture of isobutaconic acid and isobutylitaconic acid obtained in this way separated into its constituents by means of their calcium salts. Isobutaconic acid crystallises from water in long, colourless needles, and melts at 165—170° with partial decomposition. The *calcium* salt, $(C_9H_{11}O_4)_2Ca$, and the *barium* salt, are crystalline compounds, readily soluble in water and alcohol. The *silver* salt, $C_9H_{11}O_4Ag$, is only sparingly soluble in water. When the acid is reduced with sodium amalgam, it is converted into isobutylparaconic acid.

F. S. K.

Reduction-products of Dichloromuconic Acid. By A. BAEYER and H. RUPE (*Annalen*, **256**, 1—28; compare Baeyer, Abstr., 1888, 1069, and 1889, 1176).—The remarkable reduction of $\Delta^{1,4}$-dihydroterephthalic acid to Δ^{2}-tetrahydroterephthalic acid led the authors to investigate the behaviour of dichloromuconic acid. From the results of this investigation, Baeyer concluded that the double linkings in the unsaturated hydroterephthalic acids behave exactly like those of open chain unsaturated fatty acids, provided it be assumed that the presence of halogen-atoms does not influence the course of the reactions. The behaviour of mucic acid itself has now been studied; the results show the complete analogy between this acid and $\Delta^{1,4}$-dihydroterephthalic acid, and prove the correctness of Baeyer's conclusion.

The dichloromuconic acid, $COOH·CH:CCl·CCl:CH·COOH$, employed in these experiments was prepared by Bode's method (*Annalen*, **132**, 95); the *methyl*-salt, obtained by treating the acid chloride with methyl alcohol in the cold, crystallises from hot dilute alcohol in colourless, nacreous plates, melts at 156°, and is readily soluble in ether, hot alcohol, and glacial acetic acid.

$\Delta^{\beta\gamma}$-Hydromuconic acid, $COOH·CH_2·CH:CH·CH_2·COOH$, can be obtained by dissolving dichloromuconic acid (5 grams) and sodium hydroxide (12 grams) in water (50 grams), and gradually treating the ice-cold solution with 4 per cent. sodium amalgam (60 to 80 grams), the whole being constantly shaken; if the solution is not shaken well, 120 to 140 grams of the amalgam are required. The solution is then decanted from the mercury, nearly neutralised with dilute sulphuric acid in the cold, the filtered solution carefully neutralised and evaporated until crystallisation commences; the sodium sulphate is separated by filtration, the hydromuconic acid precipitated with dilute hydrochloric acid, and, after keeping for 12 hours, separated by filtration, washed with a little water, and recrystallised from hot water. It forms long, colourless, pointed prisms, melts at 195°, and is identical with Bode's "muconic acid" (*loc. cit.*). The constitutional formula $COOH{\cdot}CH{:}CH{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$, previously assigned to this acid by Baeyer, who obtained it by reducing diacetylenedicarboxylic acid (Abstr., 1885, 760), is incorrect. It is only sparingly soluble (1 in 170 parts at 15°) in water, and when boiled with soda, it is converted into the isomeric $\Delta^{\alpha\beta}$-acid, so that it must be regarded as the labile form of hydromuconic acid. The calcium, barium, and strontium salts are more sparingly soluble in cold than in hot water. The *methyl* salt is formed when methyl dichloromuconate is treated with zinc-dust and glacial acetic acid; as soon as the addition of zinc-dust produces no further development of heat, the solution is filtered, the filtrate treated with sodium carbonate until a permanent precipitation is produced, and then extracted with ether. It is a yellowish, rather mobile oil, which solidifies in a freezing mixture; on hydrolysis with cold dilute soda, it yields hydromuconic acid (m. p. 195°). When $\Delta^{\beta\gamma}$-hydromuconic acid is oxidised with 3 per cent. potassium permanganate in the cold, it yields malonic acid, a proof that it has the constitution assigned to it above.

$\Delta^{\alpha\beta}$-*Hydromuconic acid*, $COOH{\cdot}CH{:}CH{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$, is formed when the labile modification (m. p. 195°) is boiled with excess of soda; as soon as a crystalline precipitate is produced, the solution is diluted, acidified with dilute sulphuric acid, and kept for a long time, whereon crystals of the new acid separate from the solution. It crystallises from hot water in plates, melts at 168—169°, and is moderately easily soluble (1 in 111 parts) in cold water, but only sparingly in ether. Its salts do not differ appreciably from those of the labile acid. On oxidation with 3 per cent. potassium permanganate, it yields oxalic acid and succinic acid.

Both muconic acid and the hydromuconic acids can, theoretically, exist in geometrically isomeric modifications; electrolytic measurements carried out by Ostwald seem to show that the stable hydromuconic acid is a mixture.

Adipic acid can be obtained by reducing dichloromuconic acid with sodium amalgam in boiling alkaline solution, but the process is rather troublesome.

Methyl β-bromhydromuconate is obtained when β-bromo-$\Delta^{\beta\gamma}$-hydromuconic acid, $COOH{\cdot}CH_2{\cdot}CBr{:}CH{\cdot}CH_2{\cdot}COOH$ (m. p. 183°), prepared by treating $\Delta^{\beta\gamma}$-hydromuconic acid with bromine in hot aqueous solution, is converted into the acid chloride, and then treated with methyl alcohol in the cold: it crystallises from hot alcohol in long, colourless needles melting at 80°.

A *bromhydromuconic acid* is obtained when a hot concentrated solution of $\Delta^{\alpha\beta}$-hydromuconic acid is treated with bromine until a permanent coloration is produced. In crystallises in very slender needles, melts at 158—160°, and has probably the constitution

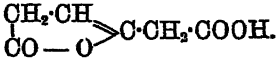
$$COOH{\cdot}CBr{:}CH{\cdot}CH_2{\cdot}CH_2{\cdot}COOH.$$

$\beta\gamma$-Dibromadipic acid (m. p. 190°) is formed when $\Delta^{\beta\gamma}$-hydromuconic acid is treated with bromine: if large quantities of the acid are employed the yield is very small. It crystallises in colourless needles, and is identical with the acid obtained by Limpricht by brominating $\Delta^{\beta\gamma}$-hydromuconic acid in hot acetic acid solution. The *methyl* salt, $C_8H_{12}Br_2O_4$, prepared by brominating methyl hydromuconate in chloroform solution, crystallises in long needles, and melts at 78°.

The acid (m. p. 205°) obtained by Ador (*Ber.*, 4, 627) by treating hydromuconic acid with bromine in aqueous solution is identical with $\beta\gamma$-dibromadipic acid (m. p. 190°).

Attempts to prepare the bromo-additive compound of $\Delta^{\alpha\beta}$-hydromuconic acid were unsuccessful, but the *methyl* salt, $C_8H_{12}Br_2O_4$, can be obtained by treating methyl $\Delta^{\alpha\beta}$-hydromuconate with bromine in chloroform solution; it crystallises in small needles, and melts at 84—85.

Muconic acid, $COOH\cdot CH:CH\cdot CH:CH\cdot COOH$, can be prepared by dissolving $\Delta^{\beta\gamma}$-dibromadipic acid in hot alcohol, adding to the cold solution a little more than the theoretical quantity of 22 per cent. alcoholic potash, and then boiling for five to seven minutes. The precipitated potassium salt and the potassium bromide are separated by filtration, washed with absolute alcohol, dried on a porous plate, then dissolved in water, and the muconic acid precipitated with sulphuric acid; the yield is 85 per cent. of the theoretical. It crystallises in very small, moss-like needles, turns brown at about 250°, and does not melt below 260°; it is very sparingly soluble (1 in 5000) in cold, but rather more readily in hot water, and moderately easily in hot alcohol and hot glacial acetic acid. It is immediately oxidised and completely destroyed by potassium permanganate. The *silver* salt, $C_6H_4O_4Ag_2$, is a colourless, amorphous compound, moderately stable in the light. The *copper* salt is a bluish-green, sparingly soluble, amorphous compound. The *calcium*, *barium*, and *strontium* salts are more sparingly soluble in hot than in cold water. The *methyl* salt, $C_8H_{10}O_4$, prepared from the chloride, crystallises from hot alcohol in slender needles, and melts at 154°; when treated with sodium amalgam in ice-cold alkaline solution, it is converted into $\Delta^{\beta\gamma}$-hydromuconic acid (m. p. 195°). The "muconic" acid obtained by Limpricht by treating $\beta\gamma$-dibromadipic acid with silver oxide is a monobasic acid, and has probably the constitution



$$\begin{matrix} CH_2\cdot CH \\ | \\ CO - O \end{matrix}\!\!>\!C\cdot CH_2\cdot COOH.$$

Tetrabromadipic acid, $C_6H_4Br_4O_4$, is obtained when finely divided muconic acid is treated with bromine. It crystallises from hot dilute alcohol in small plates, begins to turns brown at 230°, and decomposes completely at 250°; it is sparingly soluble in hot water, but moderately easily in hot dilute alcohol, glacial acetic acid, and ether. The *methyl* salt, $C_8H_{10}Br_4O_4$, prepared from the acid chloride, crystallises in colourless needles melting at 74°. F. S. K.

Synthesis of Diakyl-substituted Glutaric Acids and of Compounds containing closed Carbon Chains. By M. GUTHZEIT and O. DRESSEL (*Annalen*, **256**, 171—201).—Ethyl dicarboxyglutarate, prepared by the method previously described (Abstr., 1888, 1061), boils at 192° under a pressure of 12 mm., and at 300—310° under the ordinary pressure with partial decomposition; when hydrolysed with moderately concentrated (1 : 1) sulphuric acid, it is converted into glutaric acid, the yield being nearly theoretical.

A monosodium-derivative of ethyl dicarboxyglutarate could not be obtained; the disodium-derivative has been prepared by Perkin (Abstr., 1886, 691).

Ethyl dimethyldicarboxyglutarate,

$$(COOEt)_2CMe{\cdot}CH_2{\cdot}CMe(COOEt)_2,$$

is obtained when ethyl dicarboxyglutarate (1 mol.) is treated with sodium (1 mol.) and methyl iodide (2 mols.) in alcoholic solution, and the mixture warmed, if necessary, until the solution is neutral. It is a colourless oil, and boils at 191° (12 mm. pressure). The free *acid* $C_9H_{12}O_8$, prepared by hydrolysing the ethereal salt with alcoholic potash, is a colourless crystalline compound, melts at 164° with evolution of carbonic anhydride when heated quickly, and is readily soluble in water, but more sparingly in ether; it is decomposed by boiling water. In aqueous solutions of the ammonium salt, the chlorides of barium, strontium, and mercury, and silver nitrate, produce colourless precipitates, but salts of calcium and many other metals produce no precipitation.

Dimethylglutaric acid, $CH_2(CHMe{\cdot}COOH)_2$, prepared by hydrolysing ethyl dimethyldicarboxyglutarate with sulphuric acid, separates from ether in crystals, melts at about 90°, and is readily soluble in water, alcohol, and ether; in aqueous solutions of the ammonium salt, silver nitrate and mercuric chloride produce colourless precipitates, but salts of the alkaline earths and many metals give no precipitate.

Ethyl diethyldicarboxyglutarate, $C_{19}H_{32}O_8$, crystallises in large, well-defined prisms, melts at 61°, boils at 195° (12 mm.), and is very readily soluble in all ordinary solvents. The free *acid* $C_{11}H_{16}O_8$, obtained by boiling the ethereal salt for a long time with absolute alcoholic potash, is a colourless, crystalline compound melting at 163° with evolution of carbonic anhydride. In aqueous solutions of the ammonium salt, silver, mercury, lead, and iron salts produce precipitates, but the salts of the alkaline earths, and of zinc, nickel, and cobalt, are readily soluble.

Diethylglutaric acid, $C_9H_{16}O_4$, is crystalline, melts at about 63°, and is readily soluble in ether, but only sparingly in water; in aqueous solutions of the ammonium salt, silver nitrate, mercuric chloride, or lead acetate produce a colourless, and ferric chloride a brown, precipitate; the other metallic salts are readily soluble.

Attempts to prepare the monethyl-derivative of ethyl dicarboxyglutarate described by Kleber (Abstr., 1888, 1056) were unsuccessful; Kleber's compound is most probably a mixture of ethyl dicarboxyglutarate and the diethyl-derivative.

Ethyl dipropyldicarboxyglutarate, $C_{21}H_{36}O_8$, forms large crystals, melts at 42°, boils at 207—208° (12 mm.), and is readily soluble in all ordinary solvents. The free *acid*, $C_{13}H_{20}O_4$, melts at 167, with decomposition, and resembles diethyl dicarboxyglutarate very closely, except that it is more sparingly soluble in water.

Dipropylglutaric acid, $C_{11}H_{20}O_4$, crystallises from ether, melts at about 89°, and is very sparingly soluble in water. In neutral aqueous solutions, silver, mercury, lead, and zinc salts produce a colourless, copper salts a blue, and ferric chloride a yellow, precipitate; the salts of the alkaline earths are readily soluble.

Ethyl diallyldicarboxyglutarate, $C_{21}H_{32}O_8$, melts at 30—31°, and boils at 213—215° (20 mm.). *Ethyl dibenzyldicarboxyglutarate*, $C_{29}H_{36}O_8$, is a thick oil.

Ethyl trimethylenetetracarboxylate (1, 1, 2, 2,), prepared by the method described by Perkin (*loc. cit.*), crystallises in long needles, melts at 43°, boils at 187° (12 mm.), and is readily soluble in all ordinary solvents. The free *acid*, $C_7H_6O_8$, separates from cold water in large crystals, decomposes at about 200°, and is not acted on by potassium permanganate in cold alkaline solution; in concentrated aqueous solutions of the ammonium salt, precipitates are produced by salts of lead, silver, and the alkaline earths. When the acid is heated at 200—230°, and then distilled under reduced pressure (15 mm.), the anhydride of trimethylenedicarboxylic acid passes over between 170° and 180°, and quickly solidifies on cooling (compare Conrad and Guthzeit, Abstr., 1884, 991).

Ethyl tetramethylenetetracarboxylate, $C_{16}H_{14}O_8$ (1, 1, 3, 3,), is obtained when ethyl disodiodicarboxyglutarate is treated with methylene iodide in alcoholic solution; it is a thick oil boiling at 220—250° (15 mm.) with partial decomposition; on hydrolysis with alcoholic potash, it yields a small quantity of an acid melting at 115°, probably impure tetramethylenedicarboxylic acid. F. S. K.

Action of Ammonia on Lactones. By R. FITTIG (*Annalen*, **256**, 147—149; compare Abstr., 1884, 744).—Lactones combine with ammonia in alcoholic or aqueous solution yielding the amide of the corresponding γ-hydroxy-acid; the ammonium salt of the hydroxy-acid is not formed under any conditions. The presence of water is necessary in order that the reaction may take place at the ordinary temperature; when an absolute alcoholic solution of ammonia is employed, combination takes place only very slowly even at 100°.

The amides of the γ-hydroxy-acids are very unstable; they are decomposed by dilute acids or dilute alkalis at the ordinary temperature, and also when heated alone at a moderately high temperature (158—200°), yielding ammonia and the lactone. F. S. K.

γ-Hydroxyvaleramide. By R. FITTIG and H. RASCH (*Annalen*, **256**, 149—152; compare Neugebauer, Abstr., 1885, 65, and Fittig, preceding abstract).—γ-Hydroxyvaleramide, $C_5H_{11}O_2N$, is a colourless, hygroscopic compound, very readily soluble in water and alcohol, but only sparingly in chloroform and ether; on the addition of ether to a concentrated alcoholic solution, it is precipitated in plates melting at 56°.

Ammonium γ-hydroxyvalerate, $C_5H_{13}O_3N$, prepared by treating a solution of barium hydroxyvalerate with ammonium sulphate, crystallises in stellar aggregates, and is more sparingly soluble in water than the amide; it decomposes at 115° yielding ammonia, water, and valerolactone. F. S. K.

γ-Hydroxycapronamide. By R. Fittig and H. Dubois (*Annalen*, 256, 152—155; compare Fittig, this vol., p. 879).—*γ-Hydroxycapronamide*, $OH\cdot CHEt\cdot CH_2\cdot CH_2\cdot CO\cdot NH_2$, separates from chloroform in colourless, prismatic crystals, melts at 74°, and is very readily soluble in water and alcohol.

Ammonium γ-hydroxycaproate, $C_6H_{15}O_3N$, prepared from the barium salt, separates from alcohol in hygroscopic crystals, and melts at 90° with decomposition; at 100° it is converted into water, ammonia, and caprolactone. F. S. K.

ψ-Selenocarbamides. By W. Baringer (*Ber.*, 23, 1003—1006; compare preceding abstract).—On heating potassium selenocyanate with bromethylamine hydrobromide, and extracting the residue with alcohol, *ethylene-ψ-selenocarbamide hydrobromide*,

$$\begin{matrix}CH_2\text{—}Se\\ |\\ CH_2\cdot NH\end{matrix}\!\!>C{:}NH,HBr,$$

crystallises out in needles which melt at 170°. The free base is an unstable, oily liquid. The picrate crystallises from water in needles melting at 220°. The platinochloride is obtained in the form of light yellow, cubical crystals which are easily soluble in water. *Trimethylene-ψ-selenocarbamide hydrobromide*,

$$CH_2<\begin{matrix}CH_2\text{—}Se\\ CH_2\cdot NH\end{matrix}>C{:}NH,HBr,$$

is obtained in a similar manner by the action of potassium selenocyanate on γ-bromopropylamine hydrobromide; it crystallises from alcohol in white needles which melt at 133—135° The picrate is easily soluble in water, from which it is deposited in the form of concentric needles melting at 50—53°. β-Bromopropylamine and potassium selenocyanate yield *propylene-ψ-selenocarbamide hydrobromide*,  $\begin{matrix}CHMe\cdot Se\\ |\\ CH_3\cdot NH\end{matrix}\!\!>C{:}NH.HBr.$ The picrate crystallises from water in interlaced needles melting at 110°. The corresponding ψ-carbamides are obtained by the oxidation of these bases with bromine-water, the selenium being replaced by oxygen. J. B. T.

Sulphines. By G. Patein (*Bull. Soc. Chim.* [3], 3, 164—171; compare Abstr., 1889, 234).—The following double salts, which exist as crystalline, deliquescent masses, are described:—

$SMe_3\cdot CN,AgCN$, melting at 145—146°;
$SEt_3\cdot CN,AgCN$, melting at 25—26°;
$SMe_2Et\cdot CN,AgCN$, melting at 78—79°; and
$SMeEt_2\cdot CN,AgCN$, melting at 45—46°.

The author endeavoured to prepare from these double cyanides the corresponding sulphine cyanides, and in the case of the substance $SMe_3\cdot CN,AgCN$, found that potassium cyanide reacted therewith to form ammonia and methyl sulphide; hydrogen sulphide generated a sulphine thiocyanate, and acetonitrile, when heated with the double salt in sealed tubes at 120° for several hours, caused the formation of methyl sulphide. The following method succeeded:—Trimethylsulphine iodide is treated with a sufficient quantity of moist silver oxide to form trimethylsulphine hydroxide, which is taken up with water, evaporated to a syrup, and treated with alcohol; to the filtered alcoholic liquid, a strong aqueous solution of hydrocyanic acid is added, and it is then evaporated in a vacuum, yielding a crystalline mass, which, after being dissolved in alcohol, is purified by precipitation with ether, and subsequent evaporation in a vacuum. The crystals of trimethylsulphine cyanide thus obtained are small, colourless, deliquescent cubes which are soluble in water and alcohol, but are insoluble in ether; with dilute acids they yield the corresponding salts of the sulphine, and with silver iodide and cyanide form the double salts previously described; when treated with aqueous potash at 160°, it yields methyl sulphide and methylamine.

The crystalline double salt, $SMe_2,ZnBr_2$, is further described; it yields with mercuric chloride a compound $SMe_2,HgBrCl$, and precipitation of the zinc by reagents sets free methyl sulphide.

The derivative SMe_2Br_2, when heated in sealed tubes at 100° for several hours with alcohol and silver acetate, yields methyl sulphide and trimethylsulphine bromide and acetate.

Trimethylsulphine iodide and triethylsulphine iodide, when heated in sealed tubes at 100° for 12 hours with sodium ethoxide, yield respectively methyl and ethyl sulphides.

When the sulphine iodides are heated with alcoholic ammonia in sealed tubes for some hours, the corresponding alkyl sulphides are obtained, together with an amine.

The product of the reaction between ethyl sulphide (1 mol.) and bromine (1 mol.), after saturation with aqueous ammonia and distillation, yields an oily liquid which passes over with the ammoniacal distillate, and crystallises on cooling; after extraction of this substance with ether, evaporation of the solvent, and subsequent sublimation of the residue, a small amount of light, white crystals of the formula $C_7H_{16}N_2S$ (?) are obtained. These melt at 73—74°, are insoluble in water, but soluble in alcohol and in ether. They form soluble salts with acids and an unstable crystalline aurochloride.

T. G. N.

Benzene Formulæ. By A. LADENBURG (*Ber.*, **23**, 1007—1011).—This is a reply to part of Baeyer's address at the Kekulé festival. Whilst admitting that the formation of naphthalene, &c., is best represented by Kekulé's formula, the author is of opinion that the relations between terephthalic and succinic acids on the one hand, and between phthalic and adipic acids on the other, are much more clearly shown by the "prism formula" than by Kekulé's hexagonal formula with double bonds.

J. B. T.

Metamerism in Derivatives of Benzene. By A. HAND (*Annalen*, **256**, 264—268).—The "second" monobromobenzene, described by Fittica (*Ber.*, **18**, 2634), is simply a mixture of benzene and ethyl bromide.

F. S. K.

New Method of Chlorinating Aromatic Compounds. By Pétricou (*Bull. Soc. Chim.* [3], 3, 189—191).—Benzene (400 c.c.) and granulated tin (90 grams) were placed in a reflux apparatus, and chlorine was passed in for 20 hours, when more tin (150 grams) was added, and the current of chlorine continued for 90 hours. During the reaction much hydrogen chloride was evolved. The resulting solid mass, after washing and drying, was fractionated, and yielded 562 grams of chlorobenzenes fractionating at temperatures between 244—277°, and some hexachlorobenzene.

A second experiment, in which chlorine was passed into a mixture of benzene (400 c.c.) and tin (100 grams) for 36 hours, yielded 142 grams of 1 : 4-dichlorobenzene, 114 grams of 1 : 2 : 4-trichlorobenzene, 52 grams of 1 : 2-dichlorobenzene, and 86 grams of chlorinated derivatives boiling between 200 and 230°.

The chlorination is probably expressed by the following equation:—

$$C_6H_6 + SnCl_4 = C_6H_5Cl + HCl + SnCl_2,$$

the stannic chloride being regenerated continuously during the reaction by the current of chlorine. The author claims that this method is superior to the ordinary iodine process, since only substitution-products are formed, and the necessity of separating iododerivatives is avoided, whilst the time occupied in carrying out the process is shorter. T. G. N.

Conversion of Paradichlorobenzene into Metadichlorobenzene. By Istrati (*Bull. Soc. Chim.* [3], 3, 186—188).—When paradichlorobenzene (10 grams) is heated with lead peroxide (20 grams) in sealed tubes at 250—300°, oxygen is set free and oily drops of an aromatic liquid appear, which are extracted by a mixture of alcohol and ether, and separated from the unaltered paradichlorobenzene by recrystallisation. This substance, which becomes solid on standing, and melts at + 17°, is metadichlorobenzene. The conversion is also effected by heating with mercuric oxide, red lead, chromium oxide, or litharge.

Fuming nitric acid forms with the meta-derivative a resinous substance which softens at 65°, and melts at 70—75°, appearing to be the compound $C_6H_3Cl_2{\cdot}NO_2$ [1 : 3 : 5], described by Körner.

T. G. N.

Action of Fuming Nitric Acid on Hexachlorobenzene. By Istrati (*Bull. Soc. Chim.* [3], 3, 184—186).—Tetrachloroquinone is formed when hexachlorobenzene (25 grams) is treated in a reflux apparatus with a mixture of fuming nitric acid (200 c.c.) and sulphuric acid (50 c.c.). After six hours' reaction, the mixture is boiled for seven hours, and the substance is deposited as a yellow powder from the nitric acid, and may be purified by a further treatment with nitric acid, and subsequent crystallisation from alcohol or benzene. Thus prepared, it sublimes at 270° without previous fusion. T. G. N.

Ethylxylenes. By J. Stahl (*Ber.*, 23, 988—994; compare Abstr., 1887, 35).—The ethylxylenes have been already prepared by the action of ethyl iodide and sodium on the monobromo-derivatives of the three xylenes.

Ethylxylene, [Me : Me : Et = 1 : 3 : 4], boils at 185—186°, and is soluble in sulphuric acid in the cold. The *trinitro*-compound crystallises from alcohol in white needles melting at 127°. The corresponding *tribromo*-derivative crystallises from alcohol in large, white, prismatic needles melting at 94—95°. The hydrocarbon yields xylic acid on oxidation.

Ethylxylene, [Me : Me : Et = 1 : 4 : 2], boils at 185°; it easily forms a sulphonic acid of the formula [Me : Et : SO_3H : Me = 1 : 2 : 3 : 4], which yields the corresponding *ethylxylenol;* this melts at 37°, and boils at 245°; its alcoholic solution gives an intense green colour with ferric chloride. By prolonged fusion of the above sulphonic acid with potash, an acid is obtained in small quantity which melts at 140—142°, and has the constitution

[Me : COOH : OH : Me = 1 : 2 : 3 : 4]

(compare Abstr., 1884, 1347). Isoxylic acid, [Me : COOH : Me = 1 : 3 : 4], is formed by the oxidation of the hydrocarbon.

Ethylxylene, [Me : Me : Et = 1 : 2 : 4], boils at 187—188°. The trinitro-derivative crystallises from alcohol in slender needles melting at 121°. The *tribromo*-compound also crystallises in needles melting at 93°. Two ethylxylenes, [Me : Me : Et = 1 : 3 : 4] and [Me : Me : Et = 1 : 3 : 5], are formed by the action of ethyl bromide and aluminium chloride on metaxylene. The compounds were isolated by converting them into the sulphonamides, and separating the mixed crystals mechanically. J. B. T.

Action of Sulphuric Acid on Tribromophenol. By Georgesco (*Bull. Soc. Chim.* [3], 3, 193—195).—Tribromophenol (60 grams) is heated with sulphuric acid (200 c.c.) for 20 hours, and, on cooling, the mixture is poured into water, and the dark-coloured precipitate collected. This contains a mixture of bromofrancëins which contain from 42—63 per cent. of bromine, and, in addition, tri-, tetra-, and penta-bromophenols. The results obtained by Istrati (this vol., p. 51) in respect to the migration of halogen-atoms in the benzene nucleus caused by sulphuric acid are thus confirmed, although the migration appears to be more easily effected with the bromine-derivatives than with the corresponding chlorine compounds. T. G. N.

Thymol-derivatives. By G. Mazzara and E. Vighi (*Gazzetta*, 19, 335—336).—*Amidobromothymol ethyl ether*, $C_6HPrMeBr(NH_2)\cdot OEt$ [4 : 1 : 2 : 5 : 3], is prepared by reducing the ethyl ether of nitrobromothymol with tin and hydrochloric acid; on adding excess of sodium carbonate to decompose the hydrochloride formed, a liquid separates, which may be isolated by extraction with ether; it is a very heavy, red oil, which volatilises with difficulty in a current of steam. The *hydrochloride* crystallises from alcohol acidified with hydrochloric acid, in small, colourless, transparent prisms melting at 200—201°.

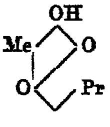
Orthobromothymol ethyl ether, $C_6H_2PrMeBr\cdot OEt$ [4 : 1 : 2 : 3], is obtained by heating amidobromothymol ethyl ether (5 grams) with alcohol saturated with ethyl nitrite (50 grams) on the water-bath until the reaction subsides. The alcohol is then removed by evaporation, and the product distilled in a current of steam, when the ether passes over as a yellowish oil with an agreeable odour.

S. B. A. A.

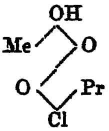
Constitution of Derivatives of Carvacrol, Thymoquinone, and Thymol. By G. Mazzara (*Gazzetta*, 19, 337—343).—*Bromonitrosocarvacrol*, $C_6HPrMeBr(NO)\cdot OH$ [$OH : Pr : NO_2 : Me = 1 : 3 : 4 : 6$], is prepared by gradually mixing strongly cooled solutions of bromine (8·20 grams) and nitrosocarvacrol (10 grams) in glacial acetic acid; after a time, the product is poured into water, and the precipitate purified by dissolving it in ammonia, reprecipitating with sulphuric acid, and recrystallising twice from alcohol. It forms large, yellow, transparent, rhombic tables which melt at 166—168°, and are soluble in ether and in benzene.

Bromamidocarvacrol is prepared by reducing the preceding compound with tin and hydrochloric acid, decomposing the hydrochloride formed with a solution of sodium carbonate, and extracting the precipitate with light petroleum. The base is a yellowish-red oil, which changes, after a few days, into a solid mass; this softens at 53° and melts at 60—61°. When bromamidocarvacrol hydrochloride is oxidised with ferric chloride, and distilled in a current of steam, a yellow solid passes over, identical with the bromothymoquinone melting at 48°.

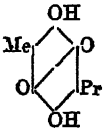
The author considers bromamidocarvacrol to have the constitution [$OH : Pr : NH_2 : Br : Me = 1 : 3 : 4 : 5 : 6$], and hydroxythymoquinone, the chloroxythymoquinone obtained by successively reducing and oxidising chlorodinitrocymene, and the dihydroxythymoquinone derived from the preceding compound to have respectively the formulæ I, II, and III:—



I.



II.



III

As the hydroxythymoquinone I may also be obtained from phenylazo- and phenyldisazo-thymol (Abstr., 1885, 1131), these compounds must respectively have the constitutions [$Me : OH : Pr : PhN_2 = 1 : 3 : 4 : 6$] and [$Me : PhN_2 : OH : Pr : PhN_2 = 1 : 2 : 3 : 4 : 6$].

S. B. A. A.

Trisubstituted Derivatives of Benzene. By V. Wender (*Gazzetta*, 19, 225—235).—Dry finely-powdered metanitracetanilide melting at 143° (10 grams) is gradually stirred into a mixture of fuming nitric acid (60 c.c. of sp. gr. 1·52) and concentrated sulphuric acid (60 c.c.), placed in a mixture of ice and salt, and allowed to remain until solution is complete. The solution is then removed from the freezing mixture, and, after the lapse of an hour, is poured on to pounded ice; the viscous mass which separates is washed with water and repeatedly crystallised from boiling alcohol, when a dinitracetanilide is obtained in needles melting at 186°. On concentrating the alcoholic mother liquors to a small bulk, separating the precipitated dinitracetanilide, evaporating the greater part of the alcohol, and diluting with water, a yellow oil is deposited, which rapidly changes into a crystalline mass When this is boiled for an hour with excess of acetic chloride, the product dissolved in alcohol and allowed to cool, the first deposit consists of the dinitracetanilide melting at 186°; subsequently, another acetanilide is deposited which, after purification, crystallises in needles melting at 121°. The last crop of crystals consists of a mixture of the preceding substance, with brown, nodular aggregates; the latter may be mechanically separated, and when crystallised from very dilute alcoholic solutions, form pale-yellow, polyhedral crystals melting at 144°. All these substances are dinitracetanilides. The yield from 100 grams of nitraniline consists of 50 grams of the product melting at 186°, 30 grams of the isomeride melting at 144°, and 6 grams of the third isomeride.

On heating a solution of these compounds in concentrated sulphuric acid for a few minutes at 110°, and diluting with water, the respective dinitranilines are precipitated. On warming with potash, ammonia is evolved, and the corresponding phenols are formed.

1.2.3-*Dinitraniline* is obtained from the acetanilide melting at 186°. It crystallises from water and alcohol in lustrous, orange-yellow needles which melt at 127°, and dissolves freely in warm alcohol and in acetic acid. It is moderately soluble in ether, sparingly so in boiling water, and only very sparingly in cold water. By treatment with acetic anhydride, it is acetylated with difficulty, but readily when boiled with acetic chloride. On heating with a solution of potash, ammonia is evolved, and the phenol-derivative is formed with partial resinification. It readily dissolves both in concentrated and in boiling dilute sulphuric acid. The *sulphate* is obtained in lustrous, colourless needles and slender prisms on adding an excess of sulphuric acid to the acetic acid solution of the dinitraniline. The *hydrochloride* is obtained as a white powder by passing a current of dry hydrogen chloride into an ethereal solution of the base; both these salts are decomposed by cold water. As this dinitraniline yields orthonitrobenzene when treated with ethyl nitrite, its constitution must be either $NH_2:(NO_2)_2 = 1:2:3$ or $1:3:4$; the latter supposition is inadmissible, as it would require the formation of a dinitrobromobenzene melting at 59·4° when bromine is substituted for amidogen.

1.2.3-*Dinitracetanilide*, $C_6H_3(NO_2)_2\cdot NHAc$, crystallises from alcohol in flattened or prismatic, lustrous, colourless needles which melt at 186°, and are freely soluble in boiling alcohol, but only sparingly in cold alcohol, ether, chloroform, or benzene. When heated with potash, it loses ammonia. It is easily saponified by hot concentrated sulphuric acid.

1.2.3-*Dinitrobromobenzene* is obtained by mixing a solution of the dinitraniline melting at 127° (5 grams) in boiling sulphuric acid

(50 per cent.) with a boiling strongly acid solution of cuprous bromide, gradually adding a saturated aqueous solution of potassium nitrite (2·5 grams), heating for a few minutes, and diluting with water. The product is distilled in a current of steam, and crystallises from alcohol in lustrous, pale-yellow laminæ having an odour of bromonitrobenzene; it melts at 101·5°, and distils over unchanged at about 320°. It is freely soluble in boiling alcohol, only moderately so in cold alcohol and in ether; it dissolves very sparingly in boiling water. On heating dinitrobromobenzene with alcoholic ammonia in a sealed tube for four hours at 160°, a substance is obtained which crystallises from alcohol in yellow needles; this melts at 65—75°, and, probably, consists of a mixture of a bromonitraniline and a dinitraniline.

1 . 2 . 3-*Dinitroiodobenzene.*—Concentrated sulphuric acid (6 c.c.) is added to a solution of the dinitraniline melting at 127° (5 grams) in hot glacial acetic acid (70 c.c.); the whole is cooled down to 0° and constantly agitated to separate the sulphate of the base in a finely divided state; a cold saturated solution of potassium nitrite is now stirred in, and the solution of the diazo-salt is diluted with a little ice-cold water, and poured into a solution of potassium iodide acidified with hydriodic acid; the mixture is then heated in the water-bath for several hours, and, after standing for 12 hours, collected, washed, and freed from iodine with sodium hydrogen sulphite. By repeated crystallisations from alcohol it is obtained in flattened, lustrous, pale-yellow needles which melt at 138°, and can be distilled without decomposition. It is freely soluble in warm alcohol, but only very moderately in ether; it dissolves in concentrated sulphuric acid or nitric acid without undergoing any change, and it is only very slowly acted on by a boiling solution of potash.

1 . 3 . 6-*Dinitraniline*, prepared from the acetanilide melting at 121°, crystallises from boiling water and from alcohol in slender, lustrous, orange-yellow needles which melt at 137°, and are freely soluble in warm alcohol, but only sparingly in boiling water, and very slightly in cold water. In other respects, it closely resembles the 1 . 2 . 3-compound; its constitution is established by the formation of paradinitrobenzene when it is treated with ethyl nitrite

1 . 3 . 6-*Dinitracetanilide*, obtained as previously described by the nitration of metanitracetanilide, crystallises from alcohol in beautiful white or slightly yellowish, silky needles, which melt at 121°, and dissolves freely in warm alcohol, and moderately in boiling water. It is easily attacked by aqueous potash, ammonia being evolved.

1 . 3 . 4-*Dinitraniline*, obtained from the acetanilide melting at 144°, crystallises from boiling water in slender, bright, lemon-yellow needles, and from alcohol in lustrous or brownish-yellow, prismatic needles. It melts at 154°, and dissolves very freely in alcohol and in acetic acid, but only sparingly in ether. It gives off ammonia when heated with potash, dissolves in concentrated sulphuric acid, and is precipitated unchanged on dilution. The *sulphate* is precipitated in beautiful, lustrous, colourless prisms by adding sulphuric acid to the acetic solution of the base, and allowing the whole to remain. It is decomposed by cold water. The base cannot be acetylated by the

action of boiling acetic chloride. Its constitution is demonstrated by the formation of orthodinitrobenzene when it is treated with ethyl nitrite.

1.3.4-*Dinitracetanilide* is obtained in hard nodules consisting of slender needles when its solution in boiling alcohol is rapidly cooled; when the solution is slowly cooled or allowed to evaporate, lustrous, yellowish, rhombic crystals are obtained, which melt at 141°, dissolve freely in warm alcohol, and moderately in boiling water.

1.3.4-*Dinitroiodobenzene* is prepared like the 1.2.3-compound. It crystallises from alcohol in thin, lustrous, canary-yellow needles which melt at 74·4°; it dissolves very freely in hot alcohol, ether, and chloroform, but only very sparingly in boiling water. When heated in a sealed tube with alcoholic ammonia for four hours at 170°, an iodonitraniline is obtained in pointed, brown needles, with violet lustre. This compound melts at 174°, dissolves freely in warm alcohol, and has very feeble basic properties. It appears to have the constitution $NH_2 : I : NO_2 = 1 : 3 : 6$, since it is converted into pariodonitrobenzene by boiling with ethyl nitrite and alcohol. S. B. A. A.

Action of Benzylamine on Methylene Chloride. By K. Kempff (*Annalen*, **256**, 219—232).—Methylenedibenzylamine, $CH_2(NH\cdot CH_2Ph)_2$ is formed when methylene chloride is heated with benzylamine at 100° for 12 hours. The product is treated with water to free it from benzylamine hydrochloride, the insoluble oil extracted with ether, and kept for some time over sulphuric acid, whereon the methylenedibenzylamine separates in crystals. It forms colourless, rhombic prisms, melts at 45—46°, and boils at 225—230° with partial decomposition; it is insoluble in water, but readily soluble in alcohol and ether; it reduces silver and mercury salts at the ordinary temperature. The *hydrochloride*, $C_{15}H_{18}N_2,2HCl$, crystallises from hot water in colourless, monoclinic plates, and melts at 240—242°. The *hydrobromide*, $C_{15}H_{18}N_2,2HBr$, crystallises from alcoholic ether in silky plates. The *hydriodide*, $C_{15}H_{18}N_2,2HI$, crystallises from benzene in colourless plates, and is more sparingly soluble in water and alcohol than the two preceding salts. The *sulphate*, $C_{15}H_{18}N_2,H_2SO_4 + 2H_2O$, crystallises in colourless prisms which effloresce on exposure to the air; the acid sulphate and the nitrate are deliquescent. The *phosphate*, $C_{15}H_{18}N_2,2H_3PO_4$, crystallises in needles, and melts at 228—233°. The *platinochloride*, $C_{15}H_{18}N_2,H_2PtCl_6$, crystallises in pale-yellow, monoclinic plates; the *aurochloride*, $C_{15}H_{18}N_2,2HAuCl_4$, in golden needles. The *oxalate*, $C_{15}H_{18}N_2,2C_2H_2O_4$, forms colourless crystals, and melts at 133—136°. The *picrate*, $C_{15}H_{18}N_2,2C_6H_3N_3O_7$, crystallises in light-yellow needles, and is very sparingly soluble in alcohol and water.

When methylenedibenzylamine hydrochloride is treated with potassium nitrite, the nitrite of the base seems to be formed.

F. S. K.

Action of Methylene Chloride on Para- and Ortho-toluidine. By H. Grünhagen (*Annalen*, **256**, 285—313).—A solid and a liquid methylenediparatoluidine are formed, together with a small quantity of dimethylenediparatoluidine (see below), when paratoluidine is heated with methylene chloride at 100° for about 34 hours. The product is treated with water to dissolve the hydrochlorides of paratoluidine and dimethylenediparatoluidine, and the two compounds in the residual oil are partially separated by treatment with ether, in which the solid methylenediparatoluidine is only sparingly soluble; the liquid compound, on keeping, deposits more of the solid substance.

The liquid *methylenediparatoluidine*, $C_{15}H_{18}N_2$, boils at 350° with decomposition, and is readily soluble in most ordinary solvents except water; it dissolves in sulphuric acid with a green coloration. The basic *hydrochloride*, $C_{15}H_{18}N_2,HCl$, is a brown, amorphous, unstable compound, readily soluble in alcohol, but only sparingly in water; all the other salts are likewise amorphous. The *platinochloride*, $(C_{15}H_{18}N_2)_2,H_2PtCl_6$, and the *aurochloride*, $C_{15}H_{18}N_2,HAuCl_4$, were analysed.

The solid *methylenediparatoluidine*, $C_{15}H_{18}N_2$, is a colourless, amorphous compound, melts at about 156°, and boils above 350° with decomposition; it is only sparingly soluble in ether and alcohol, and insoluble in water. It dissolves in warm dilute acids, but separates unchanged on cooling, or on adding alkalis; its solution in sulphuric acid shows a green fluorescence. All the salts except the acid oxalate are amorphous and unstable. The *hydrochloride*, $C_{15}H_{18}N_2,2HCl$, is soluble in alcohol and water. The *platinochloride*, $C_{15}H_{18}N_2,H_2PtCl_6$, *aurochloride*, $C_{15}H_{18}N_2,2HAuCl_4$, and the *oxalate*, $C_{15}H_{18}N_2,2C_2H_2O_4$, were analysed.

Dimethylenediparatoluidine, $C_6H_4Me{\cdot}N{<}\substack{CH_2\\CH_2}{>}N{\cdot}C_6H_4Me$, separates from ether in crystals, melts at about 90° with previous softening, and is soluble in alcohol, but insoluble in water. The *hydrochloride*, $C_{16}H_{18}N_2,2HCl$, is a yellow, crystalline compound readily soluble in water and alcohol. The *aurochloride*, $C_{16}H_{18}N_2,2HAuCl_4$, is a yellow, crystalline compound readily soluble in water and alcohol. The *hydrobromide*, $C_{16}H_{18}N_2,2HBr$, is crystalline and readily soluble in water. The *sulphate*, $C_{16}H_{18}N_2,H_2SO_4$, crystallises in ill-defined plates, and is only sparingly soluble in water. The *isonitroso*-derivative, $C_{16}H_{17}N_3O$, is formed when dimethylenediparatoluidine is treated with nitrous acid. It is a yellow, crystalline powder, readily soluble in alcohol and ether, but insoluble in water, and it does not give Liebermann's nitroso-reaction. The *platinochloride*,

$$(C_{16}H_{17}N_3O)_2,HPtCl_6,$$

is a yellow, crystalline compound.

A liquid *methylenediorthotoluidine*, $C_{15}H_{18}N_2$, and the solid compound described below are formed when orthotoluidine is heated with methylene chloride at 110—115° for 10 hours. It is a thick, brown oil, boils at 350° with decomposition, and is readily soluble in alcohol and ether, but insoluble in water. The *platinochloride*

$$(C_{15}H_{18}N_2)_2,H_2PtCl_4,$$

and all the other salts are amorphous.

Solid *methylenediorthotoluidine*, $C_{15}H_{18}N_2$, separates from alcohol in rhombic crystals, *a* : *b* : *c* = 0·7181 : 1 : 1·0623, melts at about 135°, and is very sparingly soluble in water, and only sparingly in cold ether and alcohol. The salts are all readily soluble in water, moderately stable, and crystalline. The *hydrochloride*, $C_{15}H_{18}N_2,2HCl$, *hydrobromide*, $C_{15}H_{18}N_2,2HBr$, *phosphate*, $C_{15}H_{18}N_2,2H_3PO_4$. *sulphate*, $C_{15}H_{18}N_2\,H_2SO_4$, and the two *oxalates*, $C_{15}H_{18}N_2,3C_2H_2O_4$ and $C_{15}H_{18}N_2,2C_2H_2O_4$, were analysed. F. S. K.

Action of Phenylhydrazine on Acetylurethane. By A. ANDREOCCI (*Gazzetta*, 19, 448—452).—When an aqueous solution of acetylurethane (1 part), phenylhydrazine hydrochloride (1·5 parts), and sodium acetate (2·5 parts) is heated for two hours on the water-bath and allowed to remain, an oily substance is first precipitated, but subsequently a crystalline deposit is formed; the residual solution on concentration yields a further quantity of oil. The solid compound is purified by recrystallisation from water, and by precipitating its solution in ethyl acetate with light petroleum; it crystallises from ethyl acetate in colourless, hexagonal tables, melts at 166—167°, dissolves very freely in ethyl acetate and in alcohol, moderately in ether and in hot water, but only sparingly in cold water. It gives a reddish-brown coloration with ferric chloride. It has the composition $C_9H_9ON_3$, the condensation presumably taking place according to the equation $C_6H_8N_2 + C_5H_9O_3N = C_9H_9ON_3 + H_2O + C_6H_5\cdot OH$; analogous to the formation of 1-phenyl-3-methyl-5-pyrazolone from ethyl acetoacetate and phenylhydrazine (Abstr., 1887, 601). The oil above mentioned changes on standing, or on treatment with boiling water, into the crystalline compound; it is probably the real hydrazone, and is analogous to the compound  $\mathrm{CMe}<^{\mathrm{CH_2\cdot COOEt}}_{\mathrm{N_3HPh}}$, obtained by Knorr (*loc. cit.*) from ethyl acetoacetate.

The crystalline compound somewhat resembles pyrroline in its chemical behaviour; it dissolves in the cold in solutions of potash, and is reprecipitated unchanged on addition of hydrochloric acid, or even by a current of carbonic anhydride; it crystallises unchanged from a solution in concentrated hydrochloric acid. It further resembles phenylmethylpyrazolone in forming both a neutral and an acid silver salt, the former, $C_9H_8ON_3Ag$, is insoluble in water; it is very stable and is not affected by moderate heating or by light; it melts at 200° with incipient decomposition; the acid salt, $C_9H_8ON_3Ag + C_9H_9ON_3$, melts without decomposition. The author considers the new compound to be a derivative of an hypothetical pyrroline,  $\begin{matrix}\mathrm{N{:}CH}\\ \vert\\ \mathrm{N{:}CH}\end{matrix}\!>\!\mathrm{NH}$, which he terms pyrrodiazole, and accordingly to have the constitution  $\begin{matrix}\mathrm{NPh\cdot CO}\\ \vert\\ \mathrm{N : CMe}\end{matrix}\!>\!\mathrm{NH}$, 2-methyl-4-phenylpyrrodiazolone.

On heating the sodium-derivative of this substance with methyl iodide, a methylated compound is obtained which bears the same relation to it as antipyrine bears to Knorr's phenylmethylpyrazolone. It crystallises from water in long, acicular prisms which melt at 83°;

like antipyrine, it is readily soluble in water, alcohol, and chloroform, but only very sparingly in ether and in light petroleum.

S. B. A. A.

Phenyl-γ-hydroxybutyramide. By R. Fittig and L. J. Morris (*Annalen*, **256**, 155—157; compare Fittig, Abstr., 1884, 744, and this vol., p. 879).—Phenyl-γ-hydroxybutyramide, $C_{10}H_{13}O_2N$, crystallises from alcohol in large, transparent, anhydrous, monoclinic prisms melting at 86°, and from water in colourless prisms containing 1 mol. H_2O, which it loses at 50°; it is very easily soluble in alcohol and hot water, and readily in chloroform, but more sparingly in ether. The hydrochloride, $C_{10}H_{13}O_2N.HCl$, crystallises in colourless, hygroscopic needles, and is very unstable.

F. S. K.

Substituted Phthalimides and their Conversion into the corresponding Primary Amines. By A. Neumann (*Ber.*, **23**, 994—1002).—*Desylphthalimide*, $COPh{\cdot}CHPh{\cdot}N{:}C_8H_4O_2$, is obtained by the action of potassium phthalimide on desyl bromide, COPh·CHPhBr; it is deposited from hot glacial acetic acid in small, slightly yellow crystals which melt at 157—158°. *Desylphthalamic acid*, $COPh{\cdot}CHPh{\cdot}NH{\cdot}CO{\cdot}C_6H_4{\cdot}COOH$, is prepared from desylphthalimide by hydrolysis: it is best purified by dissolving in dilute ammonia, and reprecipitating with hydrochloric acid. By heating with concentrated hydrochloric acid, desylphthalamic acid is decomposed into *desylamine*, $COPh{\cdot}CHPh{\cdot}NH_2$, and phthalic acid *Desylamine hydrochloride* is precipitated from solution by the addition of concentrated hydrochloric acid; it forms small, white needles melting at 210°. Both the salt and the free base are extremely unstable. The *platinochloride*, $(C_{14}H_{13}NO)_2,H_2PtCl_6$, is obtained in yellowish-brown crystals melting at 192—193°. The picrate is very insoluble. In all probability desylamine is identical with the compound obtained by E. Braun (Abstr., 1889, 613) by the reduction of benzilmonoxime.

Isoamylphthalimide is prepared by heating together isoamyl bromide and potassium phthalimide: it is a colourless liquid boiling at 307—308°. *Isoamylphthalamic acid*, melting at 114—115°, is obtained by hydrolysis. It is decomposed by concentrated hydrochloric acid with formation of isoamylamine.

Isobutylphthalimide, $CHMe_2{\cdot}CH_2{\cdot}N{:}C_8H_4O_2$, is obtained in a similar manner from isobutyl bromide; it melts at 93°, and boils at 293—295°.

Allylphthalimide, from allyl bromide, melts at 70°, and boils at 295°; it combines directly with 2 atoms of chlorine or bromine; the dichloro-compound crystallises from hot alcohol in needles melting at 93°. By the action of nitrous acid on allylphthalimide, an exceedingly unstable compound of an intense blue colour is formed; the colour disappears on drying, and by treatment with dilute acetic acid a substance with the formula $C_{11}H_{10}N_2O_5$ crystallises out in small, white leaves melting at 172—173°. This compound is stable, and is probably *hydroxynitropropylphthalimide*, $C_8H_4O_2{:}N{\cdot}CH_2{\cdot}C_2H_3(NO_2){\cdot}OH$, formed by the action of water on dinitropropylphthalimide, with the elimination of nitrous acid.

Methylenediphthalimide, $CH_2{:}(N{:}C_8H_4O_2)_2$, is obtained from methylene iodide and potassium phthalimide; it is deposited from boiling glacial acetic acid in light-brown crystals melting at 226°, and yields phthalic acid and ammonium chloride by the action of concentrated hydrochloric acid. J. B. T.

Azocumic Chloride. By P. ALEXÉEFF (*Bull. Soc Chim.* [3], **3**, 206—207).—Azocumic acid (1 part) is heated at 50° with phosphorus pentachloride (2 parts), and the resulting crystalline mass is dissolved in ether and recrystallised. *Azocumic chloride*, $N_2(C_6H_3Pr{\cdot}COCl)_2$, thus prepared forms orange-red crystals of the monoclinic system, $a : b : c = 1{\cdot}5268 : 1 : ?$, $\beta = 53° 39'$, and melts at 135°. The substance is but slowly decomposed by water or alkalis, and yields with alcohols the salts previously described (Abstr., 1885, 390), and with ammonia an amide. The author's pupils have also prepared and are studying parazobenzoic chloride melting at 145·5°, and metazobenzoic chloride melting at 87—89°. T. G. N.

Action of Halogen Acids on Phenylbutyrolactone. By R. FITTIG and L. J. MORRIS (*Annalen*, **256**, 157—159; compare Fittig, Abstr., 1884, 744).—*Phenylchlorobutyric acid*, $C_{10}H_{11}ClO_2$, prepared by treating phenylbutyrolactone with concentrated hydrochloric acid in the cold, separates from carbon bisulphide in large, monoclinic crystals and melts at 70°. *Phenylbromobutyric acid*, $C_{10}H_{11}BrO_2$, melting at 69°, and *phenyliodobutyric acid*, $C_{10}H_{11}IO_2$, can be obtained in like manner; the iodo-compound crystallises in colourless plates, melts at 77° with decomposition, and is very unstable. F. S. K.

Preparation of Cinnamic Acid and its Homologues. By L. CLAISEN (*Ber.*, **23**, 976—978).—Ethyl cinnamate is obtained by slowly adding benzaldehyde (1 mol.) to sodium wire (1 at.), contained in excess of ethyl acetate. The mixture is allowed to remain a short time, and is then treated with water and acetic acid. After separating the aqueous solution and distilling off the unaltered ethyl acetate, an oily liquid is left which boils at 260—270°, and from which cinnamic acid is obtained by hydrolysis. The yield of ethyl cinnamate is 100—110 per cent. of the weight of the benzaldehyde employed. The same condensation is brought about by the action of sodium ethoxide in alcoholic or anhydrous ethereal solutions; the cinnamic acid obtained is however impure, and the yield is small. Ethyl benzalbutyrate is obtained in a similar manner from benzaldehyde and ethyl butyrate. This reaction may be explained by supposing that benzaldeyde, ethyl acetate, and sodium unite to form the sodium compound of ethyl phenylhydroxypropionate,

$$ONa{\cdot}CHPh{\cdot}CH_2{\cdot}COOEt,$$

and that the free ethereal salt obtained after acidifying is decomposed on distillation into ethyl cinnamate and water. J. B. T.

Preparation of Unsaturated Aromatic Acids. By L. EDELEANO and BUDISHTEANO (*Bull. Soc. Chim.* [3], **3**, 191—193).—Benzaldehyde (1 mol.), acetic chloride (1 mol.), and sodium acetate (3 mols.) are heated in a reflux apparatus at 160° for 24 hours. The mass obtained is extracted with alkali, and an almost theoretical yield of cinnamic acid is obtained on acidifying with hydrochloric acid.

This combination of the methods of Bertagnini and Perkin is thus expressed :—

$$CH_3\cdot COCl + C_6H_5\cdot COH + nCH_3\cdot COONa = C_6H_5\cdot CH{:}CH\cdot COOH + CH_3\cdot COOH + NaCl + (n-1)CH_3\cdot COONa.$$

T. G. N.

Synthesis of Thymolcinnamic Acid. By L. NICOTERA (*Gazzetta*, **19**, 357—361).—Dry sodium thymolglycollate (92 grams), benzaldehyde (43 grams), and acetic anhydride (180 grams) are heated in a reflux apparatus for six hours at 150—160°, the product which, on cooling, solidifies to a mass of brown nodules consisting of minute needles, is boiled with water, allowed to cool, and the yellowish oil which separates heated with a 20 per cent. solution of sodium carbonate, extracted when cold with ether, and the alkaline residue acidified with hydrochloric acid. A white, flocculent substance is thrown down mixed with a yellow oil; the former is treated with light petroleum, the solution distilled, and the residue boiled for a few hours with baryta-water and alcohol; the barium salt thus obtained is purified and decomposed with hydrochloric acid, and the precipitate crystallised twice from alcohol. *Thymolcinnamic acid* obtained in this manner, forms minute, colourless, odourless needles melting constantly at 136°. On heating on platinum foil, it melts and volatilises without burning. It is very freely soluble in alcohol and in ether, only moderately in hot, and very sparingly in cold water. It probably has the constitution $CHPh{:}C(COOH)O\cdot C_6H_3MePr$. The *silver salt*, $C_{19}H_{19}O_3Ag$, is white, and changes a little on exposure to light, especially when damp. The barium salt, $(C_{19}H_{19}O_3)_2Ba + 2\frac{1}{2}H_2O$, crystallises in small, yellowish needles. S. B. A. A.

Phenylsalicylic Acid. By C. ARBUNZ (*Annalen*, **257**, 76—87).—When phenylsalicylic acid, prepared by Graebe's method (Abstr., 1888, 477), is treated with phosphoric chloride (1 mol.) at 100°, it is completely converted into diphenylene ketone oxide (xanthone); concentrated hydriodic or hydrochloric acid at 180° brings about the same change.

Ammonium phenylsalicylate crystallises in long prisms, melts at 130°, and is readily soluble in water: it is decomposed by boiling water, and when heated alone, it is converted into diphenyl ether (m. p. 28°). The *potassium* salt crystallises in large rhombohedra, and is readily soluble in water. The *calcium* salt $(C_{13}H_9O_3)_2Ca + 2H_2O$, crystallises from hot water in needles, and loses its water at 150°. The *ethyl* salt, $C_{13}H_9O$ Et, boils above 360°. The *phenyl* salt, $C_{13}H_9O_2Ph$, crystallises in slender needles, melts at 109°, and boils without decomposition; it is insoluble in water, but readily soluble in most organic solvents. The *amide*, $OPh\cdot C_6H_4\cdot CO\cdot NH_2$, prepared by treating the methyl or ethyl salt with aqueous alcoholic ammonia at the ordinary temperature, crystallises from alcohol in prisms, melts at 131°, distils without decomposition, and is readily soluble in most organic solvents, but only sparingly in hot water; when treated with phosphoric anhydride, or hydrogen chloride. at 200—220°, it is converted into diphenylene ketone oxide. The *anilide*,

$$OPh\cdot C_6H_4\cdot CO\cdot NHPh,$$

is formed when the acid is heated with aniline at 110°, a little phosphorus trichloride added, and the mixture heated to 130°; it crystallises from alcohol in long needles, melts at 97°, and is very readily soluble in ether, benzene, and carbon bisulphide, but only sparingly in water and is insoluble in light petroleum; it distils without decomposition, and it is only slowly decomposed by alkalis. The *orthonitranilide*, prepared in like manner, crystallises in slender, yellow needles, melts at 121°, and is soluble in most ordinary solvents except water and light petroleum; on reduction with tin and hydrochloric acid, it is converted into the *anhydro-base*, $C_{19}H_{14}N_2O$, which crystallises from a mixture of ether and light petroleum in colourless needles, melts at 147°, and forms a sparingly soluble hydrochloride.

Dinitrodiphenylsalicylic acid, $C_{13}H_8O_3(NO_2)_2$, is obtained by nitrating phenylsalicylic acid in the cold, and purifying the product by means of the barium salt. It crystallises from benzene in colourless needles, melts at 153°, and is readily soluble in alcohol, acetic acid, and chloroform, but only sparingly in ether and benzene. The *barium* salt $(C_{13}H_7N_2O_7)_2Ba + 4H_2O$, crystallises in yellow plates, loses its water at 120°, and is only sparingly soluble (0·267 in 100 parts at 17°) in cold, but more readily in hot water and alcohol. The *calcium* salt, with $4H_2O$, crystallises in plates, and is more readily soluble in water than the barium salt. The *silver* salt, $C_{13}H_7N_2O_7Ag$, crystallises from hot water, in which it is readily soluble, in needles, and is very explosive. The *methyl* salt, $C_{13}H_7N_2O_7Me$, crystallises in prisms, melts at 126°, and is readily soluble in alcohol and ether, but insoluble in carbon bisulphide and light petroleum. The *ethyl* salt, $C_{13}H_7N_2O_7Et$, crystallises in prisms, and melts at 76°. The *amide*, $C_{12}H_7N_2O_5\cdot CO\cdot NH_2$, crystallises in prisms, and melts at 166°. When dinitrosalicylic acid is warmed with excess of fuming nitric acid, it is decomposed into dinitrophenol $[OH : (NO_2)_2 = 1 : 2 : 4]$ and nitrosalicylic acid $[COOH : OH : NO_2 = 1 : 2 : 5]$; when heated at 150° with concentrated sulphuric acid, it is converted into β-dinitroxanthone (dinitrodiphenylene ketone oxide) and a sulphonic acid.

Tribromophenylsalicylic acid, $C_{13}H_7Br_3O_3$, prepared by heating phenylsalicylic acid with excess of bromine at 150°, crystallises from glacial acetic acid in colourless needles, melts at 176°, and is readily soluble in alcohol and ether, but only sparingly in hot, and insoluble in cold water. The *silver* salt, $C_{13}H_6Br_3O_3Ag$, is amorphous and insoluble in water. The *ethyl* salt, $C_{13}H_6Br_3O_3Et$, crystallises from alcohol in prisms, and melts at 67°.

Tribromoxanthone (*tribromodiphenylene ketone oxide*), $C_{13}H_5Br_3O_2$, is obtained when the preceding compound is heated with concentrated sulphuric acid at 150°; it crystallises from benzene, sublimes in needles, and is readily soluble in chloroform and carbon bisulphide, but only sparingly in alcohol and ether, and insoluble in alkalis.

F. S. K.

Ethyl Phenylparaconate. By R. FITTIG and H. LEONI (*Annalen*, **256**, 63—87: compare preceding abstract).—*Ethyl phenylparaconate* is formed when phenylparaconic acid, prepared by the method previously described (Fittig and Jayne, *Annalen*, **216**, 100), is dissolved in alcohol and the solution saturated with hydrogen chloride; it is a heavy, colourless oil with an aromatic odour, and boils at 250—252° (25 mm.).

Phenylitaconic acid, $CHPh{:}C(COOH)\cdot CH_2\cdot COOH$, is obtained by treating ethyl phenylparaconate with sodium in dry ethereal solution, or, better, by boiling the ethereal salt (2 mols.) with an alcoholic solution of sodium (1 mol.) for three to four hours. In the latter case, as soon as the formation of a precipitate is at an end, the alcohol is evaporated, the residue treated with water, the unchanged ethyl phenylparaconate extracted with ether, and the aqueous solution boiled with soda for about half an hour, in order to hydrolyse the ethyl sodium phenylitaconate. The solution is then rendered strongly acid, and the precipitated acid separated by filtration. The acid filtrate, on evaporation, yields further quantities of phenylitaconic acid, a very small quantity of phenylparaconic acid and some succinic acid, formed by the decomposition of the phenylparaconic acid; the yield of phenylitaconic acid is about 85 per cent. of the theoretical. It separates from hot water in prismatic crystals and from very concentrated solutions in cauliflower-like aggregates, melts at 172°, and is readily soluble in hot water, but only sparingly in cold water, ether, and benzene, and very sparingly in carbon bisulphide and chloroform. The *barium* salt, $C_{11}H_8O_4Ba + 2\frac{1}{2}H_2O$, crystallises from boiling water, in which it is only very sparingly soluble with $\frac{1}{2}$ mol. H_2O, and from cold aqueous solutions with $2\frac{1}{2}$ mols. H_2O, which it loses at 110—120°. The *calcium* salt, $C_{11}H_8O_4Ca$, is a granular, crystalline compound even more sparingly soluble than the barium salt. The *silver* salt, $C_{11}H_8O_4Ag_2$, is only very sparingly soluble in hot, and almost insoluble in cold water. The *ethyl* salt, $C_{11}H_8O_4Et_2$, is a thick, colourless oil, and boils at 315°, When the acid is heated to about 181°, it is partially converted into the anhydride, which distils as a colourless oil, but on heating more strongly carbonic anhydride is evolved, and a hydrocarbon and a phenol-like substance pass over, together with unchanged phenylitaconic acid and a small quantity of a crystalline acid which is insoluble in water. When phenylitaconic acid is treated with concentrated hydrobromic acid in the cold, or boiled with concentrated hydriodic acid, only a trace of phenylparaconic acid is formed, almost the whole of the acid remaining unchanged; when boiled for half an hour with dilute (1 : 1) sulphuric acid, it yields the polymeric phenylisocrotonic acid (m. p. 179°) described by Erdmann (*Annalen*, **208**, 54), and a small quantity of phenylbutyrolactone, but about half the acid remains unchanged.

Phenylbromoparaconic acid, $C_{11}H_9BrO_4$ (14·43 grams) is obtained, together with the isomeric iso-acid (1·56 grams), when finely divided phenylitaconic acid (15·05 grams) is suspended in water and treated with bromine; the crystalline products are separated by filtration, washed with water, dried, and recrystallised from boiling chloroform, in which the iso-acid is the more readily soluble. It crystallises from chloroform in long, rhombic prisms $a : b : c = 0·6538 : 1 : 1·6223$, melts at 99°, and is readily soluble in hot ether, hot benzene, and acetic acid, but only sparingly in light petroleum and insoluble in carbon bisulphide; it is decomposed by boiling water, and by sodium carbonate, with liberation of hydrogen bromide and carbonic anhydride, yielding benzoylpropionic acid, and when reduced with sodium amalgam in acetic acid solution, it is converted into phenylparaconic acid.

Phenylisobromoparaconic acid, $C_{11}H_9BrO_4$, crystallises from chloroform in large, colourless, rhombic plates $a : b : c = 0·5998 : 1 : 0·9756$, turns brown at 135°, and melts at 144° with decomposition; it is readily soluble in ether, glacial acetic acid, and hot benzene, but only very sparingly in carbon bisulphide. When treated with sodium amalgam in acetic acid solution, it is converted into phenylparaconic acid, and when boiled with water, it is converted into benzoylpropionic acid.

Benzoylpropionic acid (m. p. 116°) does not crystallise with 1 mol. H_2O, as stated by Burcker (*Ann. Chim. Phys.* [5], **26**, 433), and the barium salt is also anhydrous, whilst the calcium salt crystallises with 4 and not with 3 mols. H_2O, as stated by Burcker. The *silver* salt, $C_{10}H_9O_3Ag$, crystallises from boiling water, and is stable in the light. When benzoylpropionic acid is treated with sodium amalgam in alkaline solution, and the whole then boiled with hydrochloric acid, it is converted into phenylbutyrolactone, but small quantities of a colourless, amorphous, neutral compound, and an acid (m. p. 165°) are also produced; the acid melting at 165° crystallises from hot alcohol in colourless needles, is only sparingly soluble in ether, and is probably identical with the compound obtained by Pechmann by boiling benzoylpropionic acid with zinc-dust and acetic acid.

Bromophenylparaconic acid,  $CO<\begin{matrix}CH_2{\cdot}CH{\cdot}COOH \\ \quad\ \ | \\ O\ -CH{\cdot}C_6H_4Br\end{matrix}$, is obtained when phenylparaconic acid is suspended in water and treated with bromine (1 mol.). It crystallises from benzene in nacreous plates, melts at 141·5°, and is readily soluble in alcohol and light petroleum, and moderately easily in hot water, but only sparingly in carbon bisulphide; it is not decomposed by boiling water, and when treated with sodium amalgam, is reconverted into phenylparaconic acid.

F. S. K.

Phenylitaconic Acid. By R. FITTIG and P. RÖDERS (*Annalen*, **256**, 87—96).—Benzylsuccinic acid, $C_{11}H_{12}O_4$, is obtained when phenylitaconic acid is reduced with sodium amalgam, the solution being kept only slightly alkaline by the frequent addition of dilute sulphuric acid. It crystallises from hot water in plates, melts at 161°, and is readily soluble in hot water and alcohol, but only sparingly in benzene, chloroform, and cold water. This acid has been previously prepared by Perkin (Trans., 1888, 11) from benzylacetylenetetracarboxylic acid. The *silver* salt, $C_{11}H_{10}O_4Ag_2$, is very sparingly soluble in hot water, and darkens on exposure to the light or when boiled with water. The *calcium* salt, $C_{11}H_{10}O_4Ca$, is very sparingly soluble both in hot and cold water. The *barium* salt, with $\frac{1}{2}H_2O$, separates as a powder when a cold concentrated aqueous solution is heated. The *anhydride*, $C_{11}H_{10}O_3$, prepared by distilling the acid, crystallises from light petroleum in needles, melts at 102°, and is readily soluble in chloroform, benzene, and ether, but only sparingly in light petroleum and carbon bisulphide.

Benzylethanetricarboxylic acid, $C_{12}H_{12}O_6$, can be prepared by treating ethyl sodiobenzylmalonate (b. p. 169°, 12 mm.) with ethyl chloracetoacetate in alcoholic solution and hydrolysing the product with alcoholic potash. It crystallises from warm water or dilute alcohol in small prisms, and is moderately easily soluble in ether, alcohol, and warm water, but insoluble in benzene, chloroform, and carbon bisulphide; when boiled with water or when heated to 130—160°, it is converted into benzylsuccinic acid (m. p. 161°). The *calcium* salt, $(C_{12}H_9O_6)_2Ca_3 + 6\frac{1}{2}H_2O$, separates from hot water in a flocculent condition, loses $4\frac{1}{2}$ mols. of water at 100°, and the remainder at 210°; it is more readily soluble in cold than in hot water. The *barium* salt, with $2\frac{1}{2}H_2O$, loses its water at 210°, and is insoluble in both hot and cold water. The *silver* salt, $C_{12}H_9O_6Ag_3$, is very sparingly soluble, and darkens on exposure to the light or when boiled with water.

A New Reaction of Tannin. By C. BÖTTINGER (*Annalen*, **256**, 341—344).—When tannin (1 part) is boiled with phenylhydrazine (1 part) in aqueous solution, a mixture of substances is obtained which is soluble in ether and hot water; on the addition of soda to the aqueous solution, phenylhydrazine is liberated, and a beautiful greenish-blue coloration is produced. The substance to which the coloration is due can be isolated as follows:—After boiling with phenylhydrazine for four hours, the solution is concentrated, the water decanted, the reddish residue dissolved in hot water, and the solution acidified with hydrochloric acid. A little ammonia is then added, the solution shaken well, decanted from impurities, concentrated by evaporation, extracted with ether, and evaporated to dryness; the residue is then extracted with boiling alcohol, and the solution mixed with ether, whereon phenylhydrazine hydrochloride is precipitated, and the new substance remains in solution. It crystallises from water in colourless stellate groups, turns yellow on exposure to the air, melts at 112°, decomposes at 130—140°, and is readily soluble in acetic acid, hot water, and alcohol, but only sparingly in ether and cold water; it is only slowly decomposed by concentrated hydrochloric acid. It is readily soluble in phenylhydrazine; if this solution is boiled with acetic acid, an oil is obtained which dissolves in soda with a beautiful greenish-blue coloration.

When tannin is boiled with phenylhydrazine and acetic or hydrochloric acid and the solution then treated with soda, the same greenish-blue coloration is produced, but on shaking the solution in a test-tube, reddish-yellow stripes are also observed, probably owing to the formation of gallic phenylhydrazide.

Ammoniacal solutions of the tannin-derivative described above rapidly darken, becoming first light-blue, and then violet. In its aqueous solutions lime-water produces a blue, and baryta-water a greenish-blue precipitate; in boiling solutions, mercuric chloride gives

a colourless, silver nitrate a black precipitate. It gives the hydrazide reaction with concentrated sulphuric acid and ferric chloride, and with ferric chloride alone, first a blue, and then a green coloration is produced, whilst ammonium carbonate produces a violet coloration. This compound occurs in the decomposition-products of benzoyltannin and phenylhydrazine, and also in the extract of Italian sumach, but it could not be detected in the extract of oak-wood or oak-tan; the phenylhydrazine-derivatives obtained from the oak-extracts have a totally different constitution, and are decomposed by concentrated hydrochloric acid at 120°.

Nitro-derivatives of the Indoles. By C. ZATTI (*Gazzetta*, **19**, 260—263).—*Dinitromethylketole*, $C_9H_7N_3O_4$, is prepared by gradually introducing methylketole (α-methylindole) into ten times its weight of concentrated nitric acid (sp. gr. 1·50) placed in a freezing mixture. When the reaction which ensues is completed, the product, which is a nearly solid, brownish-red mass, is freed from excess of nitric acid by filtration, and dried on a porous tile. It is then dissolved in alcohol, the solution decolorised with animal charcoal, concentrated, diluted with water, and allowed to remain for some time, when the dinitro-derivative crystallises out in orange-yellow needles, which blacken and decompose on warming, and deflagrate when suddenly heated on platinum foil. It is soluble in warm alcohol, ethyl acetate, and in acetic acid, less so in benzene and chloroform, and only very sparingly in boiling water. It has an acid reaction, and dissolves in the alkaline hydrates and carbonates. A silver salt can be obtained as a gelatinous, yellowish mass by dissolving the ketole in ammonia, diluting with water, and adding silver nitrate. An isomeride of dinitromethylketole is prepared by gently warming methylketole with nitric acid (sp. gr. 1·47) and diluting with water. The product, after washing and drying on a tile, is repeatedly crystallised from alcohol, decolorised with animal charcoal, and precipitated from a solution in acetic acid by largely diluting with water; it is thus obtained as a very light, white powder which decomposes on heating. It is more soluble in alcohol and ethyl acetate than its isomeride; it is sparingly soluble in benzene, and almost insoluble in water; it dissolves in acetic acid, and is reprecipitated unchanged on dilution. It dissolves in the alkaline carbonates, and forms sodium and silver salts like its isomeride.

Diphenyl-derivatives. By J. KAISER (*Annalen*, **257**, 95—102).—*Diphenylphthaloylic acid*, $C_6H_4Ph{\cdot}CO{\cdot}C_6H_4{\cdot}COOH$, can be obtained by heating phthalic anhydride with diphenyl and aluminium chloride; it is best purified by means of the calcium salt. It crystallises in colourless needles, melts at 220°, and is readily soluble in hot alcohol, benzene, chloroform, and ether; it dissolves in cold concentrated sulphuric acid, yielding a deep red solution, from which it is precipitated unchanged on the addition of water, but when warmed with concentrated sulphuric acid, it seems to be converted into a sulphonic acid. The *calcium* salt, $(C_{20}H_{13}O_3)_2Ca$, separates from hot concentrated solutions in crystals; the *barium* salt is more sparingly soluble. The *silver* salt, $C_{20}H_{13}O_3Ag$, is moderately easily soluble in hot, but only sparingly in cold water. The *methyl* salt separates from light petroleum as a colourless, crystalline powder, and melts at 85—90°.

The compound  $\begin{array}{l}C_6H_4\text{——}C{\cdot}C_{12}H_9\\ \mid \qquad\quad\ \ \| \\ CO{\cdot}NPh{\cdot}N\end{array}$, prepared by heating the acid with phenylhydrazine at 160°, crystallises from alcohol in slender, colourless needles, melts at 192—194°, and is insoluble in alkalis; it dissolves in concentrated sulphuric acid with a yellow coloration. The compound  $\begin{array}{l}C_6H_4{\cdot}C{\cdot}C_{12}H_9\\ \mid \qquad \| \\ CO{\cdot}O{\cdot}N\end{array}$, obtained by heating the acid with hydroxylamine hydrochloride in alcoholic solution, crystallises in plates, melts at 180°, and is readily soluble in chloroform, but only sparingly in alcohol; it dissolves in concentrated sulphuric acid with a yellow coloration, and it is soluble in warm alkalis.

Parahydroxydiphenyl (m. p. 160—162°) was prepared by diazotising paramidodiphenyl; it is identical with the compound obtained by Latschinoff (this Journal. 1873, 749), and also with the compound (m. p. 151—152°) obtained by Hübner (Abstr., 1882, 180). The *benzoyl*-derivative crystallises in colourless plates, melts at 150°, and is readily soluble in boiling toluene, but only sparingly in alcohol and ether. The *acetyl*-derivative, $C_{12}H_9{\cdot}OAc$, crystallises in plates, melts at 88—89°, and is readily soluble in alcohol and ether.

F. S. K.

Orthocresolbenzeïn. By O. Doebner and G. Schroeter (*Annalen*, **257**, 68—75).—*Orthocresolbenzeïn*, $OH{\cdot}CPh(C_6H_3Me{\cdot}OH)_2$, is obtained by gradually adding benzotrichloride to orthocresol, and heating the mixture at 100° for several hours. The unchanged cresol is removed by distillation with steam, the residue dissolved in dilute soda, and the dye precipitated from the filtered solution with hydrochloric acid: the precipitate is then dissolved in a hot dilute solution of sodium sulphite, and the filtered solution boiled with dilute sulphuric acid to precipitate the dye. It is a dark-red powder, melts at 220—225°, and is readily soluble in glacial acetic acid and alcohol, but only sparingly in ether and cold benzene, and almost insoluble in water; it dissolves in alkalis yielding reddish-violet solutions, which become colourless on exposure to the air, or when warmed.

Dihydroxydimethyltriphenylmethane, $CHPh(C_6H_3Me{\cdot}OH)_2$, prepared by boiling cresolbenzeïn with sulphurous acid, crystallises from dilute alcohol in light-yellow needles, melts at 170—171°, and is readily soluble in alcohol, ether, benzene, and glacial acetic acid, but only sparingly in water; it is soluble in soda, and gradually turns red on exposure to the air. The *acetyl*-derivative, $C_{21}H_{18}(OAc)_2$, crystallises from dilute alcohol in yellowish needles, melts at 94°, and is readily soluble in alcohol, ether, benzene, and glacial acetic acid; it is quickly decomposed by warm alkalis, and by concentrated acids. The *benzoyl*-derivative, $C_{21}H_{18}(OBz)_2$, crystallises from dilute alcohol in colourless plates, melts at 91·5°, and is insoluble in water, but readily soluble in alcohol, ether, benzene, and glacial acetic acid. The *dibromide*, $C_{21}H_{18}O_2Br_2$, prepared by treating cresolbenzeïn with bromine in well-cooled glacial acetic acid solution, crystallises in compact, yellowish-red needles, melts at 130°, and is insoluble in water, and only sparingly soluble in ether, but readily in alcohol, benzene, and glacial acetic acid. The *dinitro*-derivative, $C_{21}H_{18}O_2(NO_2)_2$, crystallises in bright-yellow plates, melts at 127°, and is readily soluble in benzene, alcohol, and glacial acetic acid, but only moderately easily in ether, and insoluble in water.

Dimethyldihydroxybenzophenone, $CO(C_6H_3Me\cdot OH)_2$, is formed, together with benzene, when cresolbenzein is melted with potash. It crystallises from dilute alcohol in colourless needles, melts at 138°, and is readily soluble in alcohol, ether, and glacial acetic acid, but only sparingly in benzene; it is volatile at a temperature below its melting point.

Metacresol combines with benzotrichloride yielding a dye, but paracresol gives a colourless compound. F. S. K.

Pyrogallolbenzeïn. By O. DOEBNER and A. FOERSTER (*Annalen*, **257**, 60—68).—*Pyrogallolbenzeïn*, $C_{38}H_{24}O_{11}$, is obtained by heating pyrogallol with benzotrichloride, decomposing the chloride produced by boiling it with water, and repeatedly recrystallising the product from hot glacial acetic acid. It forms small, dark-green, hygroscopic crystals, which, when seen by transmitted light, are bright-red, and is almost insoluble in water, light petroleum, benzene, and carbon bisulphide, but more readily in alcohol, ether, hot chloroform, and hot sodium acetate, forming dark-red solutions. It dissolves in alkalis, ammonia, and alkaline carbonates; the neutral solutions are bluish-violet, but if a trace of free alkali is present the solutions are deep blue. It is partially decomposed by mineral acids; in neutral solutions of the ammonium salt most metallic salts produce bluish-violet, amorphous precipitates. The *acetyl*-derivative, $C_{38}H_{20}O_7(OAc)_4$, separates from hot alcohol in well-defined, bright-red crystals, melts at 208°, and is only sparingly soluble in cold alcohol and ether, and insoluble in water; it is quickly decomposed by warm soda. The *benzoyl*-derivative, $C_{38}H_{20}O_7(OBz)_4$, crystallises from hot alcohol or acetone in thin, red prisms, with a green reflex, melts at 251°, and is almost insoluble in water and ether. The compound $C_{38}H_{18}O_6(O\cdot C_5H_9O_4)$, prepared by treating pyrogallolbenzeïn with valeric chloride at 160°, crystallises from alcohol and acetone in red needles with a green reflex, and melts at 227—228°. The *picrate* of pyrogallolbenzeïn crystallises in small, red needles.

Hydropyrogallolbenzeïn is obtained when pyrogallolbenzeïn is reduced with zinc-dust in glacial acetic acid solution. It crystallises from dilute acetic acid in reddish needles, turns red on exposure to the air, and loses 3 mols. H_2O at 110°; the anhydrous substance has the composition $C_{19}H_{14}O_5$, and is therefore an anhydride of hexahydroxytriphenylmethane. It dissolves in warm concentrated sulphuric acid with partial decomposition, yielding a violet solution of a sulphonic acid. F. S. K.

Chlorine Compounds of Tolane. By A. EILOART (*Amer. Chem. J.*, 12, 231—253).—According to Wislicenus' theory of geometrical isomerism, the central-symmetrical (β-) variety of tolane dichloride should be more stable than the plane-symmetrical (α-) variety.

To test this, the action of heat on these substances was studied. Tolane tetrachloride was prepared by treating benzile with excess of phosphorus pentachloride, and crystallising the product from light petroleum. It was converted by reduction with zinc into the dichlorides, and these were separated from each other in the manner detailed by Blank (Abstr., 1889, 261), and recrystallised from alcohol. The plane-symmetrical dichloride melted at 139·5°, the central-symmetrical at 58°. Two grams of each dichloride was placed in small tubes, and these in two larger tubes, which were sealed, and then heated side by side in an oven. The contents were dissolved in alcohol, and the solution was cooled and filtered; the crystals of the α-dichloride which collected on the filter were weighed, and so was the mixture of dichlorides obtained by evaporating the alcoholic filtrate. The weight of this latter was also ascertained, and the amount of the α-dichloride in the residue from this filtrate was then calculated, the solubility of the α- in alcoholic solutions of the β-variety having been determined by separate experiments. It was thus shown that the plane-symmetrical variety undergoes conversion much more easily than the other, as we should expect from the theory; the amount of conversion increased with the temperature and with the time, and reached a maximum at about 300°, at which temperature 68 per cent. of the α-variety was found to be converted into the β-, and only 32 per cent. of the β- into the α-variety. Moreover the relative amounts of α- and β-varieties converted at any temperature were approximately in the same ratio, namely, 68 : 32.

It is then shown that Blank's statement that a larger amount of plane-symmetrical dichloride is obtained then the theory requires (that is than one-third of the total dichlorides) is erroneous; if his results are corrected for the alteration in the solubility of the α-dichloride in alcohol caused by the presence of β-dichloride, the yield does not exceed the theoretical limit. Reasons are given for thinking that Blank's ditolane hexachloride, obtained by the action of zinc on tolane tetrachloride, was merely a mixture of tetrachloride and plane-symmetrical dichloride, which had crystallised out together.

It was further found that the plane-symmetrical dichloride is much more easily reduced with zinc-dust and alcohol than the central-symmetrical variety, and is hence the less stable variety, as Wislicenus' theory asserts. Also by chlorinating tolane, "ditolane hexachloride" was obtained; this has been shown to be a mixture of the tetrachloride and plane-symmetrical dichloride of tolane; hence the plane-symmetrical dichloride is the one obtained by the addition of chlorine to tolane, which is precisely what the theory requires. C. F. B.

Naphthylamidoacetic Acid. By O. Forte (*Gazzetta*, **19**, 361—367).—Ethereal solutions of naphthylamine (2 mols.) and chloracetic acid (1 mol.) are mixed and agitated until the mass solidifies; excess of water is added and the ether distilled off; the product is then boiled for half an hour and concentrated, when a mixture of rose-coloured crystals with a brown resin is deposited. This is collected, repeatedly boiled with barium carbonate, and the filtered solution acidified, when naphthylamidoacetic acid,

$C_{10}H_7 \cdot HN \cdot CH_2 \cdot COOH$, is precipitated as a white powder. The yield is about 50 per cent. The acid crystallises from a mixture of alcohol and water in small, pale, rose-coloured needles which melt without decomposition at 192°, dissolve very readily in alcohol, moderately in acetic acid and acetone, sparingly in ether and benzene, and only very sparingly in hot water. It undergoes alteration on exposure to light and air, and is partially resinified by recrystallisation from alcohol. The aqueous solution gives a feebly acid reaction with litmus, reduces silver nitrate and mercury salts on heating, dissolves the oxides of silver and lead with difficulty, but has no action on the oxides of mercury or zinc. The *barium salt*, $(C_{12}H_{10}NO_2)_2Ba + 2H_2O$, crystallises in hemispherical tufts of small, rose-coloured prisms soluble in alcohol; the *copper salt*, $(C_{12}H_{10}NO_2)_2Cu$, is a brownish-red powder.

Acetylnaphthylamidoacetic acid, $C_{10}H_7 \cdot NAc \cdot CH_2 \cdot COOH$, is prepared by heating naphthylamidoacetic acid (15 grams), acetic anhydride (30 grams), and benzene (100 grams) for 14 hours. The product is freed from benzene, neutralised with sodium carbonate, and the solution decomposed with hydrochloric acid; a soft mass is precipitated, part of which is soluble in boiling water; the insoluble part contains a substance which melts at 220°. After some time, the aqueous solution deposits white prisms of acetylnaphthylamidoacetic acid, which melt at 154°, and leave no residue when ignited on platinum foil. This acid is freely soluble in alcohol, benzene, acetic acid, and acetone, but only sparingly in hot water and in ether. The aqueous solution has an acid reaction, and decomposes alkaline carbonates. The *barium salt*, $(C_{14}H_{12}NO_3)_2Ba + 5H_2O$, crystallises from aqueous solutions in stellate tufts of white, prismatic needles. It is more soluble in cold than in hot water. S. B. A. A.

α- and β-Naphthylphenylene Ketone Oxide and Methyldiphenylene Ketone Oxide. By E. PHOMINA (*Annalen*, **257**, 87—95; compare this vol., p. 389).—*β-Phenylenenaphthylenemethane oxide*,

$CH_2<\begin{matrix}C_6H_4\\C_{10}H_6\end{matrix}>O$, is obtained, together with naphthalene, when β-naphthaphenone oxide (Abstr., 1887, 152) is distilled over zinc-dust; it crystallises from alcohol, in which it is readily soluble, in plates, and melts at about 80°.

Hydroxy-α-naphthylhydroxyphenyl ketone (this vol., p. 389) melts at 103—106° (not 64—66°), and is very readily soluble in most organic solvents. The *methyl*-derivative, $C_{17}H_{10}OMe_2$, is a yellow, crystalline powder, melts at 64—66°, and is readily soluble in alcohol and benzene.

When methyl diphenylene ketone oxide (methyl xanthone) is melted with potash, it is converted into dihydroxymethylbenzophenone, but this compound could not be obtained in crystals.

F. S. K.

Compounds of Benzotrichloride with Phenols. By O. DOEBNER (*Annalen*, **257**, 56—60).—Benzeïns, analogous to phenolbenzeïn (Abstr., 1883, 861), are formed by the action of benzotrichloride on phenols, but only in the case of those in which the para-position to the hydroxyl-group is unoccupied.

α-Naphthabenzeïn, $C_{54}H_{38}O_5$, is prepared by heating benzotrichloride (1 mol.) with α-naphthol (1 mol.) at 100°. As soon as the evolution of hydrogen chloride is at an end, the chloride produced is boiled with dilute soda and the filtered solution acidified, whereon the α-naphthabenzeïn is precipitated in brownish-red flocks. It is purified by dissolving it in alcohol, precipitating with hydrochloric acid, and washing the precipitate with boiling water. It is a reddish-brown, amorphous powder. soluble in alcohol, ether, benzene, and glacial acetic acid, yielding yellowish-red solutions, but insoluble in hot water. It forms dark-green, amorphous compounds both with acids and alkalis, and when melted with potash it is decomposed into benzoic acid and α-naphthol. On reduction with zinc and acetic acid, it is converted into a colourless powder which seems to be dihydroxydinaphthylphenylmethane, $CHPh(C_{10}H_6 \cdot OH)_2$. The constitution of naphthabenzeïn is probably expressed by the formula

$$CPh(C_{10}H_6 \cdot OH)_2 \cdot O \cdot CPh(C_{10}H_6 \cdot OH)_2.$$

The compound $CPh(C_{10}H_7O)_2 \cdot O \cdot CPh(C_{10}H_7O)_2$ is formed when β-naphthol is treated with benzotrichloride as described above. It crystallises from hot nitrobenzene in small, colourless needles, melts above 350°, distils with only slight decomposition, and is insoluble in water, alcohol, ether, benzene, &c.; it does not combine with acids or alkalis, and is decomposed by concentrated sulphuric acid into benzoic acid and β-naphthol. F. S. K.

Amidochrysene. By E. BAMBERGER and C. BURGDORF (*Ber.*, **23**, 1006—1007).—With reference to Abegg's statement that nitrochrysene cannot be reduced by the usual agents (this vol., p. 789), the authors state that nitrochrysene is reduced by tin and hydrochloric acid in the usual way.

Norwegian Oil of Caraway. By C. NICOLAYSEN (*Bied. Centr.*, 1890, 278—279).—Norwegian wild caraways contain more oil than the German seed (Christiania seed contains 6·1 per cent. of volatile oil, Tromsö 6·4 per cent). This oil is a mixture of carvol and carvene, the proportions varying with the locality of growth. Taking samples from three districts, the percentage of carvene averages 52, that of carvol 48, whilst the specific gravity averages 0·9053. The low specific gravity of Norwegian oil is due to the relatively high percentage of carvene. As regards rotatory power for sodium light at 16° in a tube of 10 cm., oil from Christiania gave + 8° 21′, Tromsö oil + 10° 12′, and Gudbrandsthal + 13° 6′.

Oil of juniper has also been examined; the percentage of ethereal oil in the ripe berries being 0·34 per cent. (Trondhjem), in unripe berries from Gudbrandsthal 1·73 per cent., and in sprays bearing ripe and unripe berries from Tromsö 1·91 per cent. E. W. P.

Santoninoxime and its Derivatives. By P. GUCCI (*Gazzetta*, **19**, 367—382).—Santoninoxime, $C_{15}H_{19}NO_3$, was first obtained by Cannizzaro (Abstr., 1886, 73). It is best prepared by boiling a mixture of santonin (5 parts), hydroxylamine hydrochloride (4 parts), alcohol (50 parts), and precipitated calcium carbonate (3—4 parts) for 6—7 hours on the water-bath and adding an excess of boiling water to the clear solution. The yield is 80 per cent. of the santonin employed. It crystallises from alcohol in white, lustrous needles which melt at 216—219° with incipient decomposition, dissolves readily in alcohol and ether, but only very sparingly in boiling water, which, however, has no chemical action on it; it dissolves in hot solutions of the alkaline hydrates and carbonates, forming colourless solutions, from which it is precipitated unchanged on the addition of an acid. It is only very partially resinified by boiling with acetic acid, or dilute sulphuric acid, or concentrated hydrochloric acid, and the solution treated in this way has no reducing action on Fehling's solution. It is split up into its constituents on warming with very dilute hydrochloric acid, the santonin being quantitatively reproduced.

The *acetyl-derivative*, prepared by the action of acetic chloride or anhydride on the oxime, crystallises in minute needles which change in colour on heating to 70°, and decompose at 201—203°. It is soluble in warm glacial acetic acid, but is almost insoluble in the cold in that solvent and in alcohol, ether, benzene, &c. It dissolves in hot baryta-water, and on treating the solution with carbonic anhydride, filtering, and acidifying, the oxime is reprecipitated in a state of great purity. The pure oxime so prepared is lævogyrate, the specific rotatory power being $[\alpha]_D = -80.83$; for the crude oxime $[\alpha]_D = -82.47$.

The molecular weight of the oxime was confirmed by Raoult's method. The mother liquors from the oxime obtained in the ordinary way (from hydroxylamine and sodium acetate) also contain a substance which crystallises from absolute alcohol in thin, white aggregates which change colour at 210° and decompose at 228—231°. When sodium amalgam is gradually added to a solution of the oxime (20 grams) in 50 per cent. acetic acid (2½ litres), care being taken that the temperature does not rise above 50°, and the cold solution treated with ether, the extract only contains some acetic acid and resinous matters; the aqueous solution, however, after being heated to remove the ether, and concentrated in a vacuum, yields a deposit of iridescent plates and slender needles which may be separated by fractional crystallisation from 90 per cent. alcohol. The first deposit obtained is repeatedly crystallised from alcohol, and forms large, iridescent plates which melt at 152—153°; the subsequent deposit, similarly treated, yields opaque, white crystals which melt at 167·5—168·5°. These substances are isomerides, and have the molecular formula $C_{15}H_{18}O_2$; the isomeride crystallising in plates is produced alone if during the preparation heating is discontinued as soon as the crystallisation commences and the solution is then strongly agitated; protracted heating, on the other hand, leads to the formation of an excess of the second isomeride; this conversion may be directly effected by heating the plates with dilute acetic acid at 100°. Acetic anhydride has no action on either of the isomerides; hot solutions of the alkalis dissolve them both, and on prolonged heating the substance melting at 152—153° is converted into its isomeride. The former is dextrogyrate, $[\alpha]_D = +30{\cdot}75$; the latter is lævorotatory, $[\alpha]_D = -73{\cdot}73$. S. B. A. A.

Santoninphenylhydrazone. By G. GRASSI-CRISTALDI (*Gazzetta*, **19**, 382—395).—*Santoninphenylhydrazone*, $C_{14}H_{18}O_2{:}C{:}N_2HPh$, is best prepared by boiling phenylhydrazine with an acetic solution of santonin for about 10 minutes; the deposit is purified by dissolving it in dilute hydrochloric or sulphuric acid and reprecipitating with an alkali. After repeated crystallisation from alcohol, it forms straw-coloured, shining needles which melt at 220—221° with decomposition. On gradually heating to 100°, it turns red, and is resinified; if plunged into sulphuric acid heated to 210°, its melting point rises to 224—225°. It is almost insoluble in the cold in the ordinary solvents, but dissolves on heating with alcohol, benzene, or glacial acetic acid, but only sparingly in ether. It is dextrogyrate, $[\alpha]_D = +152{\cdot}42$. It dissolves in boiling solutions of the alkaline hydrates or carbonates, and is reprecipitated unchanged on acidification; it also dissolves in cold concentrated sulphuric and hydrochloric acids; from the latter solution an orange-coloured *hydrochloride* is deposited on standing. This compound is unstable, turns yellow on exposure to the air, and is decomposed by contact with alcohol. The *platinochloride* $(C_{21}H_{24}O_2N_2)_2,H_2PtCl_6$, is a yellow, amorphous powder. These reactions show that santoninphenylhydrazone combines the basic properties of a hydrazone with the lactonic properties of santonin.

Hyposantonin, $C_{15}H_{18}O_2$, is prepared by reducing an alcoholic solution of the preceding compound with sodium amalgam. Santoninphenylhydrazone (10 grams) is dissolved in 80 per cent. alcohol (1500 c.c.), the solution is acidified with acetic acid, care being taken that the temperature does not exceed 50°; sodium amalgam is then gradually added. The solution becomes first red, then yellow: at this stage two-thirds of the alcohol is distilled off under reduced pressure and the reduction continued; more alcohol is then removed, &c. The product is poured into a large excess of water, the precipitate separated by filtration, the solution shaken with ether, and, after separation of the ethereal solution, concentrated on the water-bath; colourless, shining plates of hyposantonin then separate on the surface of the liquid. After recrystallisation from alcohol, this substance melts at 152° without decomposition, and sublimes unaltered in a current of carbonic anhydride. It is very freely soluble in benzene and in warm alcohol, ether, or acetic acid, but insoluble in water. Unlike santonin, it is not affected by exposure to light. It is dextrogyrate, the specific rotatory power $[\alpha]_D = +30{\cdot}06$. When the ethereal extract mentioned above is evaporated and the residue made alkaline and distilled in a current of steam, aniline passes over, and the residue consists of resinous matter and of a solution of the sodium salt of an acid, $C_{15}H_{24}O_4$; this acid crystallises from water in shining scales which melt at 152—153°, and can be volatilised unchanged in an atmosphere of carbonic anhydride. It is very freely soluble in ether, alcohol, benzene, acetic acid, or hot water, but only sparingly in cold water. It is dextrogyrate, the specific rotatory power $[\alpha]_D = +34{\cdot}64$. Hyposantonin is insoluble in cold solutions of the alkaline hydrates and carbonates, but dissolves when heated with them; when a crystal is heated with a mixture of equal parts of sulphuric acid and very dilute ferric chloride, it dissolves, and after a time the liquid acquires a violet coloration, changing to green (distinction from santonin). When santonin-phenylhydrazone is reduced with zinc and sulphuric acid, the product contains, besides hyposantonin, aniline, and resins, a compound which forms small, white crystals, melts at 235°, dissolves in hot ether and in alcohol, but is insoluble in acids and in alkaline carbonates.

Isohyposantonin is an isomeride of hyposantonin which is formed when that compound is heated with an excess of sulphuric acid, or precipitated from its alkaline solution by hydrochloric or sulphuric acid; it is best prepared by acidifying a hot solution of hyposantonin in baryta-water with hydrochloric acid. It crystallises from alcohol in shining, white pyramids belonging to the rhombic system, melts at 168·5°, and sublimes unchanged in a current of carbonic anhydride. It is less soluble in benzene and in alcohol than hyposantonin, but it is more soluble in hot water, and equally soluble in hot alkaline hydrates and carbonates. It is lævogyrate, the specific rotatory power $[\alpha]_D = -70° 31'$. S. B. A. A.

Alcoholic Extract of Yeast. By J. DE REY-PAILHADE (*Bull. Soc. Chim.* [3], 3, 171—174).—In previous communications (Abstr., 1888, 1101), the author has indicated the existence of a principle, philothion, occurring in alcoholic extract of yeast and in most animal and vegetable tissues. 1 litre of the extract prepared as previously described, when shaken with finely divided sulphur (1 gram), causes the formation of 10 milligrams of hydrogen sulphide. At 40°, the oxygen dissolved by the alcoholic extract (4 5 c.c. per litre) is absorbed in 4 to 5 hours, and the peculiar property of the liquid disappears. The extract when acidified with hydrochloric or sulphuric acid loses its properties, which are restored on neutralisation. Animal charcoal almost entirely removes the philothion. Carmine and indigo-carmine are decolorised by the alcoholic extract, the rapidity of the effect being increased by a previous addition of alkali. T. G. N.

Action of Chlorine on Hæmatoxylin and Logwood Extract. By W. W. MACFARLANE and P. S. CLARKSON (*Chem. News*, 61, 160—162).—Logwood when "cured," that is, wetted and fermentation allowed to take place, is more active tinctorially, especially on wool, than the uncured wood. Various workers have investigated the cause of this, but without success. The authors now show that hæmateïn is produced, and doubtless accounts for the improvement. Experiments made by the authors indicate that when solutions of logwood extract are acted on by chlorine, the depth of colour obtained on wool mordanted with potassium dichromate and potassium hydrogen tartrate, increases with the quantity of chlorine used, up to a maximum, after which a dull and grey shade is produced. Less chlorine is required at 80° than at ordinary temperatures, and the colour intensified by chlorine is quite as lasting as that from "cured" wood.

Experiments with hæmatoxylin gave similar results, and it was found that the best tinctorial development was obtained when the proportion of chlorine was 2 mols. to 1 mol. hæmatoxylin, or when the former amounts to 47 per cent. of the latter; with bleaching powder, however, half this quantity suffices. The product, by treatment with ether and chloroform, yielded a white, crystalline substance soluble in ether, chloroform, water, and acetic acid; a brownish, resinous substance readily soluble in ether, alcohol, and water, seemingly a chlorine substitution-product of hæmatoxylin or hæmateïn, which takes no part in the dyeing; and bright, bronzy-greenish scales with physical and chemical properties identical with those of hæmateïn. Salting out the product from the action of chlorine on hæmatoxylin yields resinous matters only.

Colouring matter from "cured" logwood, separated by means of alcohol and hydrochloric acid, is the same as hæmateïn obtained by the oxidation of hæmatoxylin in presence of ammonia. In comparative dyeing experiments on wool made with this colouring matter, hæmateïn prepared with chlorine, and hæmatoxylin, the shades from the two former were twice as full as that from the last mentioned, and the wood colouring proved slightly duller than the chlorine-hæmateïn. On cotton, with a bath containing 5 per cent. of colouring matter, 44 of sodium carbonate, 5 of sodium hydroxide, 1 of sodium sulphite, and 16 of copper sulphate, the reverse was the case; the hæmateïns being of little practical value with abundant precipitation in the bath, whilst hæmatoxylin gave darker shades with little or no precipitate. Hæmatoxylin reduces Fehling's solution more strongly, but more slowly than hæmateïn. D. A. L.

The Molecular Weight of Pyrrolene-derivatives. By G. MAGNANINI (*Gazzetta*, 19. 251—260).—*αβ′-Dimethylpyrroline*, prepared from αβ′-dimethylpyrrolinedicarboxylic acid and purified by boiling with barium oxide for 12 hours, boils at 165·7 (corr.) at 765·0 mm. pressure. It gives normal results in dilute benzene solutions (up to about 3 per cent.), but rather high values with acetic acid or concentrated benzene solutions. The results are much closer when calculated by Arrhenius's method.

α-Acetylpyrroline melts, when pure, at 90·5° (corr.). Normal results were obtained from aqueous and from acetic acid solutions; benzene solutions, when not extremely dilute, gave very high values.

α-Pyrrolenecarboxylic acid is too sparingly soluble in benzene for the use of that solvent; the figures obtained from an acetic acid solution show a normal molecular weight, but are somewhat irregular on account of the marked exhibition of surfusion phenomena.

Methyl α-pyrrolinecarboxylate melts, when pure, at 73·2°, and gives normal results in dilute acetic acid solution. The values obtained from the acetic acid solutions of all the above compounds are normal when calculated according to Arrhenius.

Iodole (*tetriodopyrroline*) is only very sparingly soluble in acetic acid; the solution, however, gives normal results; extremely dilute (under $\frac{1}{4}$ per cent.) solutions in ethylene dibromide likewise give normal values, but these rise very rapidly with increasing concentration of the solution. Curves are given showing the relation between the molecular weight and the depression of temperature for all the above compounds. From the foregoing results, it appears that all the pyrrolene-derivatives examined follow Raoult's law.

S. B. A. A.

Action of Ethyl and Propyl Iodides on Potassium Pyrroline.

By C. W. ZANETTI (*Gazzetta*, 19, 290—297).—In a preceding communication (Abstr., 1889, 727, 1208), the author showed that the action of alcoholic iodides on potassium pyrroline resulted in the simultaneous formation of tertiary pyrrolines and of derivatives in which the alcohol radicle is united with carbon; the action of ethyl iodide thus gives rise to the compounds C_4H_4NEt, C_4H_3EtNH, and C_4H_3EtNEt. The following results were obtained from the further investigation of these compounds:—

1. *Ethylpyrroline*, C_4H_4NEt, obtained by the action of ethyl iodide on potassium pyrroline, and purified from traces of pyrroline and its higher homologues by boiling with freshly fused caustic potash, boils at 129—130° (corr.) at 762 mm.

Ethyldibromomaleïmide, $C_4Br_2O_2NEt$, is prepared according to the method indicated by De Varda (Abstr., 1889, 57), from the tetrabromo-1-ethylpyrroline described by Bell (Abstr., 1879, 525). The latter compound, which crystallises from alcohol in small, white needles melting at 83°, is very gradually added to three times its weight of nitric acid (sp. gr. = 1·49) cooled down to 0°; a brisk reaction takes place, and fumes of bromine are evolved, leaving a clear solution. On pouring the latter into excess of water, ethyldibromomaleïmide is deposited. By repeated crystallisation from dilute boiling alcohol, it may be obtained in small, yellowish needles which melt at 93—94°.

To determine whether the portion of the product of the action of ethyl iodide on potassium pyrroline, which combines with potash and boils at 150—190°, contains one or more ethylpyrrolines, it was heated in a reflux apparatus for 10 hours with sodium acetate and acetic anhydride. The product, after removal of the excess of acetic anhydride, yields a heavy oil, from which fractions were separated distilling over between 210—235° and 240—255° respectively.

The first fraction volatilises in a current of steam, and contains only 1-acetylpyrrolines, since no silver compounds are obtainable. A portion of this product distils over between 225° and 228°, and has the composition $C_4H_3EtN{\cdot}Ac$.

The fraction boiling between 240° and 255°, when strongly cooled in a mixture of ice and salt, yields a deposit which crystallises from alcohol in scales melting at 42—44°; it is probably identical with the ethylacetylpyrroline described by Dennstedt and Zimmermann (Abstr., 1886, 1043). The silver compound of this substance has the composition $C_4H_2EtAcNAg$. The liquid residue is freed from traces of 1-acetyl compounds and of pyrroline, and extracted with ether;

the extract contains an oil, soluble in water, which does not solidify when placed in a freezing mixture, and forms a silver compound also having the formula $C_4H_2EtAcNAg$.

The 1-*diethylpyrroline*, C_4H_3EtNEt, previously described by the author (*loc. cit.*), boils at 165—175° when pure.

The action of propyl iodide on potassium pyrroline resembles that of ethyl iodide, the only difference being that a smaller quantity of 1-propylpyrroline is formed. The portion of the product which combines with potash contains a mixture of propyl- and dipropylpyrrolines. Potassium pyrroline (20 grams) and propyl iodide (48 grams) are boiled together for three hours; after removing the excess of propyl iodide, an oil is obtained only a portion of which combines with caustic potash when boiled with it: the 1-propylpyrroline, which is not affected, is a colourless liquid boiling at 145·5—146·5° at 755·8 mm pressure. On decomposing the potassium compound with water, distilling in a current of steam, and extracting the distillate with ether, an oil is obtained boiling at 140—220°; this can be separated by fractional distillation into a propylpyrroline, C_4H_3PrNH, passing over at 160—180°, and a mixture of a propylpyrroline with a dipropylpyrroline.

From the above experiments, it seems that the action of alcoholic iodides on potassium pyrroline is similar to that of the acid chlorides. The yield of tertiary pyrroline obtained with propyl iodide is smaller than that obtained with ethyl iodide, and this again smaller than that with methyl iodide; this probably depends on the temperature at which these iodides respectively boil, and renders it probable that no 1-pyrroline at all would be obtained if an iodide of a higher alcohol radicle were employed. S. B. A. A.

The Induline Group. By O. Fischer and E. Hepp (*Annalen*, 256, 233—263; compare Abstr., 1888, 1291 and 1890).—*Rosinduline*  $\overset{4}{N}H{:}C_{10}H_5{<}\begin{matrix}\overset{1}{N}\text{—}\\ \underset{2}{N}Ph\end{matrix}{>}C_6H_4$, is obtained when benzeneazo-α-naphthylamine hydrochloride (1 part) is heated with aniline (2 parts) and alcohol (4 parts) under pressure at 160—170° for six to eight hours. The alcohol is evaporated, the aniline distilled with steam, the solution filtered, and the residue, which also contains rosindone (see below) repeatedly extracted with boiling water; the combined filtrates are kept for a few days, decanted from resinous products, the solution acidified with hydrochloric acid, and carefully precipitated with sodium chloride. The *hydrochloride*, $C_{22}H_{15}N_3,HCl + 3\frac{1}{2}H_2O$, which separates from the solution in long, red needles, is decomposed with soda, and the base extracted with ether. It separates from cold ether in reddish-brown plates, melts at 198—199°, and is readily soluble in ether, benzene, and alcohol, but insoluble in water; its solutions absorb carbonic anhydride from the air.

Ethylrosinduline, $C_{24}H_{19}N_3$, prepared from benzeneazo-α-ethylnaphthylamine in like manner, crystallises in slender, green prisms, and melts at 184°.

Rosinduline and ethylrosinduline dissolve in concentrated sulphuric acid, yielding green solutions, the colour of which changes to red on the addition of water; alcoholic solutions of the bases show a yellowish-red fluorescence, and aqueous alcoholic solutions of the salts are fiery-red; both compounds are good dyes. When rosinduline is heated with concentrated hydrochloric acid at 160—180°, it is decomposed into ammonia and rosindone.

Rosindone, $C_{10}H_5O<\genfrac{}{}{0pt}{}{N—}{NPh}>C_6H_4$, crystallises from a mixture of alcohol and toluene in red, hexagonal plates with a slight green fluorescence, and melts at 259°; it is insoluble in alkalis, but soluble in concentrated acids, and when distilled over zinc-dust in an atmosphere of hydrogen, is converted into α-naphthaphenazine (m. p. 142°), identical with the compound prepared by Witt.

Phenylrosinduline, $C_{28}H_{19}N_3$, has been previously described (Abstr., 1888, 1291) under the name of rosinduline. In addition to the methods already given, it can be prepared from the nitrosodimethyl-α-naphthylamine described by Friedländer and Welmans (Abstr., 1889, 150), and also, very conveniently, by mixing benzeneazo-α-naphthylamine hydrochloride (1 part) with hot aniline (2 parts), and immediately heating the mixture at 140—150° for four to five hours; if the mixture is first heated at 100—110° for some time, the principal product is tetranilidonaphthalene (see below). The product is treated with sodium carbonate, the aniline separated by distillation, and the residual phenylrosinduline extracted with boiling alcohol in order to free it from α-naphthaquinonedianil (see below). When heated with hydrochloric acid and a little glacial acetic acid at 200°, phenylrosinduline is converted into rosindone (m.p. 259°) and aniline; when rosindone is heated with aniline and a little aniline hydrochloride at 120—140°, it is reconverted into phenylrosinduline.

Paratolylrosinduline, $C_6H_4Me{\cdot}N{:}C_{10}H_5<\genfrac{}{}{0pt}{}{N—}{NPh}>C_6H_4$, can be prepared from rosindone and paratoluidine in like manner; it crystallises from a mixture of chloroform and alcohol in brown needles, melts at 212—213°, and resembles phenylrosinduline in its properties. Its salts are of nearly the same shade as those of the phenyl-base. When heated at 200° with concentrated hydrochloric acid, it is decomposed into rosindone and paratoluidine.

Isoparatolylrosinduline, $NPh{:}C_{10}H_5<\genfrac{}{}{0pt}{}{N—}{NPh}>C_6H_3Me$, is obtained when benzeazoparatolyl-α-naphthylamine hydrochloride (1 part) is heated with aniline (2 parts) and alcohol (4 parts) for several hours at 160—170°. It crystallises in reddish-brown plates, and melts at 231—232°; its salts resemble those of rosinduline.

Methylrosindone, $C_{23}H_{16}N_2O$, is formed, together with aniline, when isoparatolylrosinduline is heated with concentrated hydrochloric acid at 200°; it crystallises from boiling toluene in reddish-brown plates, melts at 255°, and is very similar to rosidone in its properties.

Trimethylphenylrosinduline, $C_6H_4Me{\cdot}N{:}C_{10}H_5<\genfrac{}{}{0pt}{}{N{\cdot}C_6H_3Me_2}{N(C_7H_7)}$, is formed when nitrosoethyl-α-naphthylamine is treated with paratoluidine and its hydrochloride, as described in the preparation of phenylrosinduline (*loc. cit.*) It crystallises from toluene in dark, bronze-coloured plates, and dissolves in concentrated sulphuric acid yielding a green solution which turns red on diluting; the red solutions of the salts have a shade more blue in them than those of phenylrosinduline.

Triparatoluidonaphthalene [$(NHC_7H_7)_3 = 1:2:4$] is obtained as a bye-product in the preparation of the preceding compound, and can be isolated by extracting the melt first with sodium carbonate and then with alcohol; it crystalises from alcohol or from a mixture of benzene and light petroleum in colourless needles, melts at 159—160°, and turns reddish on exposure to the air; it has only feeble basic properties. When boiled with mercuric oxide in benzene solution, or when treated with some other oxidising agent, it is converted into trimethylphenylrosinduline.

Toluidonaphthaquinoneditoluide, $C_{31}H_{27}N_3$, is formed as an intermediate product in the oxidation of triparatoluidonaphthalene to trimethylphenylrosinduline; it crystallises in orange-yellow plates and melts at 147°.

Naphthylrosinduline, $C_{10}H_7\cdot N\colon C_{10}H_5<\overset{N}{\underset{NPh}{}}>C_6H_4$, is formed, together with the isomeride described below, when benzeneazo-α-dinaphthylamine (1 part) is heated with aniline (2 parts) and alcohol (4 parts) at 160—170° for about 8 hours; both these compounds are also produced when nitroso-α-dinaphthylamine (1 part) is heated with aniline (2 parts) and aniline hydrochloride (1 part) at 110—120.° The deep-red product is treated with sodium carbonate, the alcohol and the aniline separated by distilling with steam, and the insoluble residue extracted with boiling alcohol, whereon napthylrosinduline remains undissolved, and the isomeride passes into solution. The two compounds can be readily distinguished, as the former dissolves in concentrated sulphuric acid yielding a blue, the latter yielding a green solution. Naphthylrosinduline crystallises from toluene in almost black needles, melts at 247°, and dissolves in alcohol and dilute acids yielding reddish-violet solutions; when heated at 210° for 8 hours with concentrated hydrochloric acid and a little glacial acetic acid, it is decomposed into α-naphthylamine and rosindone.

Isonaphthylrosinduline, $NPh\colon C_{10}H_5<\overset{N}{\underset{NPh}{}}>C_{10}H_6$, crystallises from toluene or xylene in deep-red plates, melts at 256°, and is, generally speaking, much more sparingly soluble than the isomeride, the solutions being of a more distinct red shade; it is decomposed by hydrochloric acid into aniline and an *oxyphenyldinaphthazine*, of the composition $C_{26}H_{16}N_2O$. The last named compound crystallises from cumene in shining, red, hexagonal plates, melts at 295°, and yields rose-red solutions which have a yellowish fluorescence; on the addition of an acid, the colour of the solutions changes to yellow, and the fluorescence becomes more marked. When distilled with zinc-dust in an atmosphere of hydrogen, it is converted into αβ-naphthazine.

If, in preparing phenylrosinduline ("rosinduline") by the method previously described (*loc. cit.*), the reaction takes place only slowly, there is formed a considerable quantity of tri- and tetr-anilidonaphthalene; the two compounds can be separated by treatment with alcohol.

Trianilidonaphthalene [$(NHPh)_3 = 1:3\ 4$] is more readily soluble in alcohol than the tetranilido-derivative; it separates from a mixture of benzene and light petroleum in slender needles, melts at 148°, and has feeble basic properties. Its solutions show a blue fluorescence. On oxidation with mercuric oxide, it is converted into phenylrosinduline, a yellow compound melting at about 140°, probably anilidonaphthaquinonedianil, being formed as an intermediate product; this yellow substance is unstable, and on further oxidation it yields phenylrosinduline and trianilidonaphthalene.

The compound $C_{34}H_{28}N_4$ (m.p. 191°), formed in the preparation of anilidonaphthaquinoneanil (Abstr., 1888, 473), is identical with the tetranilidonaphthalene referred to above; it has the constitution [$(NHPh)_4 = 1:2:3:4$], and its solutions show a blue fluorescence.

A compound of the composition $C_{34}H_{26}N_4$, or $C_{34}H_{24}N_{44}$, is formed, together with anilidophenylrosinduline and a small quantity of a blue substance, probably dianilidonaphthaquinone, when tetranilidonaphthalene is boiled with yellow mercuric oxide (3—4 parts) in benzene solution for about half an hour; it separates from benzene in orange-yellow crystals and melts at 169°. On further oxidation, this yellow substance is converted mainly into anilidophenylrosinduline, and when heated with alcohol and concentrated sulphuric acid, it is decomposed into aniline and a compound, probably *dianilidonaphthaquinone*, which crystallises in blue needles.

Anilidophenylrosinduline, $C_{34}H_{24}N_4$, crystallises from benzene and alcohol in almost black plates, melts at 192°, and dissolves in concentrated sulphuric acid yielding a dark-green solution which turns red on diluting.

α-Naphthaquinonedianil, $C_{22}H_{16}N_2$, separates in crystals when the alcoholic solution obtained in the purification of phenylrosinduline (see above) is evaporated, and on further concentration, a brown substance melting at 171° is obtained. α-Naphthaquinonedianil crystallises in golden plates, melts at 187°, and is sparingly soluble in alcohol, but more readily in benzene; it resembles Bandrowski's diphenylparazophenylene in its properties.

The brown substance (m. p. 171°) is a molecular compound of naphthaquinonedianil and phenylrosinduline; it crystallises from benzene in shining plates, and is decomposed into its constituents by boiling alcohol or glacial acetic acid.

Diphenylparanaphthalenediamine, $C_{22}H_{18}N_2$ (*paradianilidonaphthalene*), is easily obtained by treating an alcoholic solution of α-naphthaquinonedianil with zinc-dust and glacial acetic acid; it crystallises from alcohol in colourless prisms, and melts at 144°.

The following azo-dyes employed in this investigation were prepared by the well-known method (Fischer and Hepp, Abstr., 1886, 1041).

Benzeneazoethyl-α-naphthylamine crystallises in red plates, or prisms, with a blue reflex, melts at 76°, and is readily soluble in alcohol and benzene; it dissolves in concentrated sulphuric acid and in alcoholic hydrochloric acid, yielding reddish-violet solutions. The corresponding *phenyl*-derivative crystallises from alcohol in scarlet plates, melts at 151°, and is readily soluble in benzene, but only moderately easily in alcohol and sparingly in light petroleum; its solutions in concentrated sulphuric acid and alcoholic hydrochloric acid are of a beautiful blue colour. The corresponding *paratolyl*-derivative crystallises from alcohol in red plates with a blue reflex, melts at 141°, and resembles the phenyl-derivative in its behaviour with the solvents mentioned above

Benzeneazo-α-dinaphthylamine melts at 128°, and is readily soluble in benzene and alcohol; it crystallises in short, orange-red prisms, and its solutions in concentrated acids are blue.

It has been previously shown by Nietzki and Schmidt (Abstr., 1888, 943) that the anilido-groups in dianilidoquinone occupy the para-position; since azophenine, on decomposition, yields aniline and the same dianilidoquinone, it must have the constitution

$$[(NPh)_2 : (NHPh)_2 = 1 : 4 : 2 : 5].$$

A further proof of this constitution is afforded by the fact that when symmetrical diamidoquinonediimide (Nietzki and Hagenback, Abstr., 1887, 476) is heated with aniline and aniline hydrochloride at 120°, considerable quantities of azophenine are formed.

Ditoluidotoluquinone, $C_{21}H_{20}N_2O_2$, prepared by boiling toluquinone with paratoluidine in alcoholic solution, crystallises in needles, and melts at 241°; it has probably the constitution

$$[O_2 : (NHC_7H_7)_2 : Me = 1 : 4 : 2 : 5 : 6].$$

Anilidotoluquinoneanil, $C_{19}H_{16}N_2O$, can be obtained by warming dianilidotoluquinoneanil with stannous chloride and glacial acetic acid until the solution becomes light-yellow; the filtered solution is diluted with water, the precipitated stannochloride dissolved in hot alcohol, decomposed with ammonia, and a stream of air passed through the filtered solution for several hours; it crystallises in red needles and melts at 151°.

Diphenyldiamidophenol hydrochloride, $C_{18}H_{16}N_2O.HCl$, is obtained when azophenine is reduced with tin and hydrochloric acid in acetic acid solution; it melts at 192° with decomposition. The *base* has probably the constitution $[(NHPh)_2 : OH = 1 : 3 : 4]$; it is very unstable, and on exposure to the air it is converted into anilidoquinoneanil.

Anilidoquinonedianil, $C_{24}H_{19}N_3$, is formed, together with various other products, when azophenine is heated at 160° with hydrochloric acid. It crystallises from alcohol in reddish-brown needles, melts at 229—230°, and dissolves in concentrated sulphuric acid yielding a blue solution which turns reddish-violet on diluting: on the addition of dilute acids to an alcoholic solution of the base, a reddish-violet solution is obtained, from which wool absorbs the colouring matter. When oxidised with potassium dichromate in acetic acid solution, it is converted into a bluish-violet induline, which probably corresponds with phenylrosinduline.

The paranitroso-derivative of methylxylidine, [NHMe : Me$_2$ = 1 : 2 : 3], is a beautiful green compound, and when heated with aniline and aniline hydrochloride, it yields a red induline. The indulines are, therefore, quinoneimide derivatives (indamines), and the safranines possibly belong to the same class of compounds.

F. S. K.

Dextrococaïne. By A. Einhorn and A. Marquardt (*Ber.*, 23, 979—988; compare this vol., 646).—The authors suggest that the "methylcocaïne" and "methylecgonine," prepared by C. Liebermann and F. Giesel (this vol. p. 647) from mother liquors obtained in the manufacture of cocaïne, are really dextrococaïne and dextroecgonine, which are formed by the action of an alkali on ecgonine during the evaporation of the mother liquors. For the better characterisation of the compounds, a number of new derivatives have been prepared. Dextrococaïne is best separated from ordinary cocaïne by means of the hydrochloride. The aurochloride of dextrococaïne, $C_{17}H_{21}NO_4,HAuCl_4$, is deposited from dilute alcohol in small, lustrous, yellow crystals melting at 149°. The platinochloride is very insoluble in water; it crystallises from dilute alcohol in pale-yellow, slender needles which melt at 218°. The hydrobromide is obtained from hot water in the form of long, prismatic needles. The iodide and nitrate crystallise in lustrous leaves; both they and the sulphate are sparingly soluble in water. Dextrococaïne is liberated from its salts by the action of sodium hydroxide; it is at first obtained as an oily liquid, which readily solidifies on adding a crystal of the substance; it crystallises in prisms melting at 43—45°. Benzoyl dextroecgonine hydrochloride, $C_{16}H_{19}NO_4,HCl$, is formed by heating dextrococaïne with water for 48 hours; the solution is freed from benzoic acid by shaking with ether, and the hydrochloride precipitated on addition of hydrochloric acid; it crystallises from water or alcohol in needles, or in short, broad, well developed crystals melting at 244—245°. The *aurochloride* of *ethyldextroecgonine*, $C_{11}H_{19}NO_3,HAuCl_4$, is deposited from dilute alcohol in orange-coloured crystals melting at 115°. The corresponding propyl compound has a similar appearance and melts at 132°. The isobutyl compound, $C_{14}H_{23}NO_3,HAuCl_4$, crystallises in orange-coloured, transparent leaves melting at 130°. The aurochloride of amyldextroecgonine is at first oily, after some time it solidifies and crystallises from absolute alcohol in yellow prisms melting at 152°. Ethereal salts of benzoyldextroecgonine are formed by the action of benzoic chloride on the above ethereal salts. *Ethylbenzoyldextroecgonine*, $C_5H_7NMe{\cdot}CH(OBz){\cdot}CH_2{\cdot}COOEt$, crystallises from ether in white prisms melting at about 57°. The hydrochloride is deposited from hot water or absolute alcohol in transparent triangular leaves melting at 215°. *Propylbenzoyldextroecgonine hydrochloride* crystallises from water or alcohol in white prisms melting at 220°. The hydrochlorides of the corresponding *isobutyl* and *amyl* compounds crystallise in interlaced needles melting at 201° and 217° respectively. *Amylbenzoyldextroecgonine hydrobromide* is comparatively insoluble in water, and crystallises in white leaves. The above salts are all dextro-rotatory, and have a physiological action similar to that of cocaïne. The authors have prepared a fresh specimen of dextroecgonine, from methyldextroecgonine; on recrystallisation from methyl alcohol it melts at 257°, instead of 254°, as previously given; Liebermann and Giesel found 264° as the melting point of their "methylecgonine." J. B. T.

Determination of the Molecular Weights of Cholic Acid, Cholesterin and Hydrobilirubin, by Raoult's Method. By J. J. Abel (*Monatsh.*, **11**, 61—70).—The author contests the validity of the results given by Nencki and Rotschy (this vol., p. 76) on the ground that unsuitable solvents were used, and that bilirubin is itself changed on solution in acetic acid. Making use of pure phenol as a solvent, numbers are obtained closely approximating to those required by the formulæ, $C_{24}H_{40}O_5.C_6H_6O$; $C_{24}H_{40}O_5$; $C_{26}H_{43}{\cdot}OH$, and $C_{33}H_{40}N_4O_7$, for the phenate of cholic acid, cholic acid, cholesterin, and hydrobilirubin, respectively. G. T. M.

Physiological Chemistry.

Human Respiration. By W. Marcet (*Proc. Roy. Soc.*, **46**, 340—345).—Experiments were conducted on human beings at different altitudes on the Swiss mountains, and to avoid the disturbing influence of reduced atmospheric temperature, on the Peak of Teneriffe, in order to investigate the effect of varying pressure on the respiratory exchange of gases. It was found:—

1. That less air (reduced to 0° and 760 mm.) is breathed at high than at low altitudes for the formation of a given weight of carbonic anhydride in the body.

2. Incidentally, that the influence of food on the formation of carbonic anhydride is that the *maximum* expired occurs two or three hours after a meal, and the *minimum* before breakfast. This is merely confirmatory of older observations.

3. That the influence of food on the relation of the volumes of air breathed, and carbonic anhydride expired is marked, the volumes following the fluctuations of the carbonic anhydride, except four or five hours after a meal, when the carbonic anhydride expired falls proportionately faster than the volumes of air breathed.

4. That local atmospheric pressure has a marked influence on respiration, less air being inspired for the formation and emission of a given weight of carbonic anhydride under lower than under higher pressures; this influence varies in degree in different persons.

5. Digestion neutralises in a great measure the effects on any local change of atmospheric pressure on respiration. W. D. H.

Chemistry of the Urine of the Horse. By F. Smith (*Proc. Roy. Soc.*, **46**, 328—340).—The chief object of this research was to ascertain the difference between the urine of work and the urine of repose. In the first case the horse was worked for several days, and the urine of the next 24 hours collected. For this purpose a special stall was constructed with sloping sides, and a drain beneath. The urines examined numbered 96, complete analyses being made of 54. Normal urine was found to be invariably turbid, with a faint ammoniacal odour even when fresh, and always alkaline. Large quantities of mucus are often contained in the urine, particularly in that of mares. The following table shows the mean composition of the 24 hours' urine of horses at rest and at work.

	Rest.	Work.
Quantity	4935 c.c.	4474 c.c.
Specific gravity	1·036	1·036
	Grams.	Grams.
Total solids	230·0713	232·157
Organic solids	146·1649	152 190
Inorganic solids	83 9064	79·967
Urea	98·5110	
Ammonium carbonate as urea	13·1185	
Ammonia	2·516	5·3000
Benzoic acid	6·530	—
Hippuric acid	—	15·5870
Phosphoric anhydride	1·3000	1·8970
Sulphuric „	10·6468	15·2890
Other sulphur compounds	7·3166	7·6902
Chlorine	31·7119	21·9806
Calcium oxide	3·4367	1·9027
Magnesium oxide	2·9750	2·6300
Potassium oxide	36·5900	27·0600
Sodium „	2·5000	1·8400

Chemistry of Vegetable Physiology and Agriculture.

Fermentation of Mannitol and Glycerol. By P. F. Frankland and J. J. Fox (*Proc. Roy. Soc.*, **46**, 345—357).—The micro-organism which produced the fermentation studied in this paper was obtained from sheep-dung by cultivation in glucose peptone solution and afterwards in gelatin-peptone solution. The inoculations into the fermentable fluids were repeated until the organism was of perfectly uniform character. It is a bacillus whose appearance varies with the medium from which it is taken, being mostly paired (from liquids), or in long threads (from solid gelatin). No spores could be discovered in any of the cultivations.

In solutions containing 60 grams of mannitol or glycerol, 2 grams of peptone, 30 grams of calcium carbonate, and the necessary salts, fermentation went on briskly, more especially with the mannitol. The chief products of the fermentation were found to be ethyl alcohol and acetic acid: hence the authors propose the name *Bacillus ethaceticus.* Smaller quantities of formic and succinic acids were simultaneously formed. The proportion of alcohol to acetic acid in the mannitol fermentation is 1·63 : 1; in the glycerol fermentation it is 2·11 : 1. The action in both cases is incomplete. Solutions of glucose, cane-sugar, milk-sugar, starch, and calcium glycerate are fermented by the bacillus, but it has no action on dulcitol, erythritol, glycol, calcium lactate, tartrate, citrate, or glycollate. J. W.

Ferment-action of Bacteria. By T. L. BRUNTON and A. MACFADYEN (*Proc. Roy. Soc.*, **46**, 542—553).—This research was directed to determine in what way certain micro-organisms liquefy gelatin. The bacteria used were (1) Koch's comma spirillum (2) Finkler's comma spirillum, (3) a putrefactive micrococcus, (4) scurf bacillus, (5) Klein's "Welford" bacillus.

The liquefaction of the gelatin might be caused by the bacteria secreting some fluid which would simply dissolve it mechanically; or the solution might be effected by the gelatin being first altered chemically by a specific enzyme secreted by the bacteria. It was found that a temperature of 100° destroyed both the bacteria and the power of liquefaction, whilst a temperature of 50° destroyed neither. Exposure to temperatures between 60° and 75° killed the various organisms, but (in all cases except organism No. 3) did *not* affect the liquefying power, although active bacteria were proved to be absent. These circumstances seem to show that the bacteria which liquefy gelatin do so by means of a soluble enzyme. The authors succeeded in isolating this enzyme, and in demonstrating its peptonising action apart from the bacteria which produce it. They sum up their further results as follows:—

The most active enzyme is that formed in meat broth.

Acidity hinders, alkalinity favours its action.

The bacteria which form a peptonising enzyme on proteid soil can also produce a diastatic enzyme on carbohydrate soil.

The diastatic enzyme is not so readily separated from the microbes which produce it, but where that has been accomplished its action on starch can still be demonstrated.

The diastatic enzyme has no effect on gelatin, and *vice versâ.*

The bacteria are capable of evincing an adaptiveness to the soil in which they grow.

The microbes are capable of digesting other similar bodies such as dextrose and muscle.

Fatty matter is not affected. J. W.

Gases contained in the Bladders of Fucus vesiculosus and Ozothellia nodosa. By N. WILLE (*Bied. Cent.*, 1890, 252–253).—The gas was collected under water, and was found to contain 35·0—37·57 per cent. of oxygen, but no carbonic anhydride under any conditions.

If the plants were dried for 10 hours in the air in the dark, the bladders contained 20·76—20·84 per cent. of oxygen. When the plants had been left in the dark for 12 hours, then the percentage was reduced to 2·68, whilst after 24 hours all the oxygen had disappeared. The gas, therefore, which is contained in those bladders which have been kept in water closely resembles in composition the air dissolved in sea water. E. W. P.

Rôle of Potassium in Plants. By R. Lupke (*Ann. Agronom.*, **16**, 96; from *Landw. Jahrb.*, **17**, 887—913).—Growing the common haricot and the Spanish haricot in complete nutritive solutions, and also in the same solutions with potassium compounds only omitted, the author finds that the absence of potassium does not affect any one function or organ in particular, but that the general development of the plant is injured; all the organs are formed in turn, starch and other products of assimilation are produced, but the plants are smaller and fuller than those grown in the complete solutions.

As the cotyledons contain a store of potassium compounds, they should be removed as soon as practicable. The author's results are not in accord with those obtained by Noble some years ago on buckwheat, from which he concluded that without potassium no starch granules are formed. J. M. H. M.

Soluble Carbohydrates in Seeds of Legumes. By W. Maxwell (*Amer. Chem. J.*, **12**, 265—269).—The author has previously discovered in the seeds of *Pisum sativum*, *Faba vulgaris*, and *Vicia sativa*, both cane-sugar and a substance ("galactan") which yields galactose when boiled with dilute mineral acids, and mucic acid when oxidised with strong nitric acid (this vol. p. 544).

He has recently detected the same substances, together with dextrin, in the seeds of *Phaseolus vulgaris*. The seed material was repeatedly extracted with 75 per cent. alcohol, and the extract boiled and saturated with strontium hydroxide. The strontium carbohydrate compounds thus formed were suspended in water and decomposed with carbonic anhydride, and the resulting solution evaporated to a syrup and extracted with alcohol. From the alcoholic extract, good crystals of cane-sugar were obtained; the residue, which was of a whitish yellow colour, was dissolved in water, and the solution was purified from colouring matters, concentrated, and allowed to drop into absolute alcohol. A white, flake-like substance separated, which yielded galactose when boiled with dilute mineral acids, and mucic acid when heated with concentrated nitric acid; it was therefore a "galactan."

A quantitative estimation was made by extracting the seed material with water at 37—40°, inverting the solution with hydrochloric acid, and estimating the products of inversion gravimetrically. In this way it was found that the seeds of *Phaseolus vulgaris* contain 5·36 per cent. of soluble carbohydrates. Some of the seeds were then allowed to germinate, and when the radicle was 15 mm. long the development was arrested by drying the seeds at 100°, and an estimation of the soluble carbohydrates was made as before. Only 3·35 per cent. of these was now found; hence 32 per cent. of the soluble carbohydrates in the mature seed had been used up by the embryo plant in the earliest stage of its development, during the short time necessary for the protrusion of the radicle, and before the appearance of the plumule. C. F. B.

Bark of Xanthoxylon Senegalense (Artar Root). By P. Giacosa and M. Soave (*Gazzetta*, 19, 303—333).—After a description of the known species of *Xanthoxylon* and of the literature of the subject, the following results are given of the examination of artar root, which presumably belongs to *X. Senegalense*, D.C.

The root is generally cylindrical, somewhat contorted, and covered with bark, the underlying wood is pale yellow with minute white spots, the annual rings are barely visible, the medullary rays are very fine and waving, and meet at the centre, where, however, there is no pith; the wood is very close, tough, hard, and heavy, and has neither taste nor smell. The bark is covered with waving, longitudinal furrows; in colour it is reddish-brown, with bright, yellow spots, or yellow with greyish patches; it has a peculiar aromatic odour, and a taste which is aromatic at first, then burning, and causes itching of the tongue.

The authors have previously mentioned (Abstr., 1888, 167) the occurrence in a specimen of this bark of a fixed oil, of a neutral, crystalline substance melting at about 120°, and of two alkaloïds, the more abundant of which is amorphous; the other, which occurs only in small quantity, crystallises in large, blood-red needles soluble in hot water.

To isolate the alkaloïds from fresh specimens of the bark, they are powdered, extracted with 94 per cent. alcohol, the extract condensed by distillation and evaporation to a syrupy consistency, made alkaline with soda, and extracted with ether; on treating the washed and concentrated ethereal solution with hydrochloric acid, it yields an abundant deposit of minute needles soluble in cold water. On the addition of ammonia or soda to the cold, aqueous solution of this hydrochloride, the base is precipitated as a light, amorphous, reddish-yellow, flocculent powder, the hot aqueous solution of which on evaporation does not yield the alkaloïd previously mentioned as crystallising in red needles. It would therefore appear that the latter is not a constant constituent of the bark. On purifying the alkaloïd by repeatedly combining it with hydrochloric acid, recrystallising, and decomposing the salt, the first portions of the hydrochloride which separate were found to be more insoluble than the succeeding portions. On collecting the former apart and treating them with alkalis, a perfectly white base is obtained. This appears to be crystallisable, and dissolves in acids forming pale-yellow salts; the *hydrochloride* dissolves with difficulty in water and alcohol, and crystallises out in pale, yellowish needles which, on heating at 200° darken, and melt at 270°.

Artarine is the principal alkaloïd in the bark of artar root, of which it forms 0·4 per cent. It is an amorphous, uncrystallisable, rose-grey powder which darkens a little on exposure to light; it turns brown on heating to 210°, and melts with decomposition at 240°: when heated on platinum foil, it melts, decomposes, gives off white fumes having an odour of quinoline, chars, and is finally burnt away with difficulty, but without leaving any ash. It shows an alkaline reaction to damp reddened litmus paper, and is converted by acids into golden-yellow salts; it undergoes no change by prolonged keeping over sulphuric acid. It dissolves readily in ether, boiling amyl alcohol, and warm acetone, and also, when freshly precipitated, in warm methyl alcohol, only with difficulty in warm chloroform, and not at all in water or benzene. It is sparingly soluble in boiling 98 per cent. alcohol. The *hydrochloride*, $C_{21}H_{23}NO_4HCl$, may be purified by precipitating its alcoholic solution with an excess of ether. It crystallises in large, slender needles, occasionally forming tufts or nodules; it is blackened on heating to 60—70°, and melts at 189° with decomposition. It is freely soluble in methyl alcohol and in acetone, readily in warm chloroform and in amyl alcohol, moderately in warm alcohol, less so in warm water (0·514 per cent. at 14° C.), but is altogether insoluble in ether and in benzene. The presence of free acid considerably diminishes the solubility of the hydrochloride, and of all the other artarine salts. Solutions of the hydrochloride in water or alcohol are inactive to light. There are probably three hydrates of this compound, containing 2, 3, and 4 mols. H_2O respectively; the last of these is obtained by cooling an aqueous solution saturated in the cold; it melts at 194°. The *platinochloride* crystallises in slender, pale yellow needles which do not melt at 290°, and are insoluble in water and alcohol. The *hydriodide* is obtained by the action of potassium iodide on the hydrochloride; it crystallises in very slender, interlaced, yellow needles which dissolve freely in warm water and alcohol.

Another iodine-derivative, $C_{21}H_{23}NO_4HI_3$ is obtained by treating the cold alcoholic solution of artarine with a solution of iodine in potassium iodide; it forms aggregates of greenish-brown, microscopic needles which are insoluble in water, and only dissolve with difficulty in boiling absolute alcohol. The *sulphate* is a white powder, consisting of microscopic needles; it darkens on heating to 60—70°, and melts at 240°. The *nitrate*, obtained by adding potassium nitrate to an aqueous solution of the hydrochloride, is a thick, gelatinous, yellow mass containing a few microscopic crystals. It crystallises from alcohol in thin plates, a little longer and thinner than those of uric acid, and melts at 212°. The *phosphate* and *arsenate* crystallise in dirty yellow aggregates of microscopic prisms which are only very sparingly soluble in water; the *chromate* forms very long, reddish-yellow needles grouped in tufts; the *hydrobromide*, *molybdate*, *benzoate*, and *salicylate* are yellow, semi-crystalline powders; the *oxalate* and *tartrate* occur in hemispherical aggregates of needles; the *picrate* forms dendritic groups of very bright yellow needles.

The analyses of the compounds of artarine agree equally well with the formulæ $C_{21}H_{23}NO_4$ and $C_{20}H_{17}NO_4$ (berberine); other points of resemblance and distinction between artarine and berberine are as follows:—

Artarine forms yellow salts, the solubility of which is diminished by the presence of acids: it also forms a periodide, and generally resembles berberine in its reactions. It differs from berberine in being colourless, uncrystallisable, and in the solubility, melting points, and crystalline character of its salts. It also dissolves in sulphuric acid without any discoloration, and is coloured blood-red by the action of potassium nitrate and concentrated sulphuric acid. The hydrochloride acquires by the action of chlorine-water at most a yellowish tinge which is dissipated on addition of ammonia. The double iodides of potassium and mercury or cadmium give yellowish, flocculent precipitates, and the iodide of potassium and bismuth gives a similar red precipitate, all of which are insoluble in excess of the reagent; phosphantimonic acid only occasions a slight turbidity which disappears in excess. If the formula $C_{21}H_{23}NO_4$ is adopted for artarine, its constitution is probably that of a methylhydroberberine.

The red alkaloid, previously obtained from a specimen of the bark, crystallises in blood-red needles readily soluble in water, and forms yellow salts when heated with acids; the *hydrochloride* melts at 170°, the *sulphate* at 265°, and the *platinochloride* at 290°. Besides these alkaloids, the authors previously isolated from the light petroleum extract of the bark a neutral crystalline substance which is either identical with cubebin ($C_{10}H_{10}O_3$), or has the formula $C_{11}H_{11}O_4$. This substance crystallises in transparent, colourless prisms which melt at 123°, and dissolve readily in warm ether, chloroform, alcohol, and light petroleum, but are insoluble in water. Like cubebin, it is coloured dark-red by concentrated sulphuric acid; on the other hand, neither acetic nor pyrocatechuic acid was detected among the products of its fusion with potash. It is first coloured wine-red by concentrated sulphuric acid and then dissolved; in the presence of potassium chromate it acquires a dull violet colour; it is not affected by potash or ammonia, even on heating. A mixture of sulphuric acid (4 vols.) and water (1 vol.) colours the crystals red and partially dissolves them in the cold; on gently warming, the liquid becomes violet, and the crystals are charred. If sulphuric acid is added to the chloroform solution of the substance, an intense purple-red coloration is produced at the points of junction of the two liquids.

A neutral nitrogenous substance of unknown composition has also been isolated: it forms pale-yellow crystals melting at 170°, and its alcoholic solution is coloured bright-green by ferric chloride.

Analytical Chemistry.

Direct Estimation of Chlorine in Mixtures of Alkaline Chlorides and Iodides. By F. A. Gooch and F. W. Mar (*Amer. J. Sci.* [3], 39, 293—302).—The authors have shown, in a great number of experiments, that hydrochloric acid is stable under the conditions of the methods described below. In fact, no significant loss of chlorine by volatilisation or otherwise took place in the following cases, selected from the numerous examples given in the paper:—

1. When a solution containing 10 c.c. of sulphuric acid (1 to 1) and 1 gram of potassium chloride is concentrated from 400 c.c. to 300 c.c. by boiling for about half an hour.

2. Or when a solution containing 10 c.c. of sulphuric acid (1 to 1), 5 grams of iron-alum, and 5 c.c. of nitric acid, sp. gr. 1·40, is treated in a similar manner.

3. Or when a solution containing 10 c.c. of sulphuric acid (1 to 1), 2 grams of ferric sulphate, 5 c.c. of nitric acid, about 0·5 gram of potassium chloride, and 1 gram of potassium iodide. Or when nitrous fumes were substituted for the ferric sulphate.

On the other hand, iodine is fully expelled from hydriodic acid in the presence either of nitrous acid or ferric sulphate. It was found that without some agent to regenerate the ferrous sulphate produced in the reaction, an equilibrium was established before all the iodine was expelled, and the nitric acid was added for this purpose. The methods suggested are as follows:—

1. 10 c.c. of sulphuric acid (1 to 1), 2 grams of ferric sulphate (either as iron-alum or ferrous sulphate oxidised in concentrated solution by about 0·3 c.c. of nitric acid), and 3 c.c. of nitric acid are added to the solution of the alkaline iodide and chloride, diluted to 400 c.c., and the whole boiled until the steam ceases to colour red litmus paper greyish-blue, a reaction found by the authors to be characteristic for iodine and very delicate; the chlorine is then determined in the residue. In the second method, the iodine is expelled by passing in the gases evolved from 2 grams of sodium nitrite by the action of dilute sulphuric acid. A trap is used to prevent mechanical loss of liquid during boiling. D. A. L.

Estimation of Sulphur in Iron. By L. BLUM (*Zeit. anal. Chem.*, 29, 138—139).—Lucion having ascertained that the presence of bromine has no influence on the precipitation of barium sulphate, it might be supposed that when estimating sulphur in iron by dissolving in hydrochloric acid, and passing the gases through brominated hydrochloric acid, time would be saved without any compensating disadvantage by omitting the usual evaporation. Where hydrocarbons are evolved during solution, this is, however, not the case. There are formed oily brominated hydrocarbons, which, becoming entangled in the precipitated barium sulphate, retard the filtration so much that more time is consumed than would suffice for the evaporation. When evaporating the liquid to a small bulk, these brominated products remain adherent to the basin, and at the same time the further advantage is gained of expelling most of the hydrochloric acid, which, if retained, would lower the result by its solvent action on the barium sulphate. M. J. S.

Estimation of the Total Nitrogen in Manures. By E. AUBIN and J. QUENOT (*Bull. Soc. Chim.* [3], 3, 322—326).—Several determinations have been made by the authors, using different methods, and in all cases where nitrates are mixed with ammonium compounds Kjeldahl's method gives very low results. The estimation of the total nitrogen in such mixtures by treatment with sulphuric acid, phenylsulphuric acid, zinc, and mercury, gives numbers which are approximately correct. The authors consider that the treatment of manures with ferrous sulphate in order to destroy the nitrates (which are determined in a further sample by Schloesing's method), before applying Kjeldahl's method, is satisfactory, except that no separation of organic nitrogen as existing apart from ammonium salts is possible. They have devised the following process, in which use is made of the fact that tannic acid precipitates the albumin contained in the manure, and thus renders the organic nitrogen insoluble:—1 gram of the manure is placed on a small filter, and is exhausted with 30—40 c.c. of a 2 per cent. tannin solution. The nitrogen contained in the residue is estimated by Kjeldahl's method, and is the organic nitrogen, whilst the filtrate similarly treated gives that existing as ammonium salts; the nitrogen present as nitric acid being determined by Schloesing's method. In the case of manures containing ammonium-magnesium phosphate, 1 gram of manure should be digested with 0·5 gram of tannin in 150 c.c. of carbonic acid water for 15 hours; the residue and filtrate are to be treated as above described. The results published point to the accuracy of the method.

T. G. N.

Test for Nitrous Compounds in Sulphuric Acid. By J. H. Wilson (*J. Pharm. Trans.* [3], 20, 541).—Resorcinol is a delicate and convenient test for nitrous compounds in sulphuric acid, as it immediately produces a more or less intense yellow colour, according to the quantity of these compounds present in the acid. 1 c.c. of the acid is added to 5 c.c. of water, allowed to cool, and a minute portion of resorcinol dropped in, and stirred with it until dissolved. The test can be made a quantitative one by using Nesslerising glasses as in Wanklyn's method of estimating ammonia.

R. R.

Use of the Induction Spark for Detecting Traces of Arsenic. By N. Klobukow (*Zeit. anal. Chem.*, 29, 129—133).—Ogier has shown that hydrogen arsenide is gradually but completely decomposed into its elements at ordinary temperatures by the induction spark. If, therefore, the gaseous mixture from a Marsh's apparatus is passed slowly through a narrow tube, into which are inserted from the opposite ends two platinum wires, forming the terminals of an induction coil, the whole of the arsenic will be deposited on the glass in the immediate neighbourhood of the sparks; even so small a quantity as 0·01 milligram forming a distinct metallic mirror. The tube should be about 0·7 to 0·8 mm in internal diameter, the wires 0·5 to 0·6 mm. diameter and 3 to 4 mm. apart; about 10—15 c.c. of gas may be passed per minute, and a small induction coil capable of giving sparks of 16—17 mm. with the current of two large Bunsen cells will suffice.

M. J. S.

Estimation of Arsenic. By R. C. CANBY (*Zeit. anal. Chem.*, 29, 187; from *Journ. Analyt. Chem.*, 2, 411).—About a gram of the pulverised ore is mixed in a porcelain crucible with 4 or 5 parts of sodium carbonate and the same weight of potassium nitrate, and heated gradually to fusion. After 3 to 5 minutes it is cooled, dissolved in warm water, filtered, and the residue washed with warm water. The filtrate is acidified with nitric acid and boiled, then cooled and mixed with an excess of levigated zinc oxide. Should this produce a precipitate of silica or alumina, it is filtered off, then a further quantity of zinc oxide is added, and the arsenic acid precipitated by a small excess of silver nitrate whilst stirring vigorously. The washed precipitate, consisting of silver arsenate and the excess of zinc oxide, is dissolved in hot, dilute nitric acid, the solution cooled, mixed with a little ferric sulphate, and titrated with ammonium thiocyanate. M. J. S.

Estimation of Carbon in Graphite. By J. WIDMER (*Zeit. anal. Chem.*, 29, 160—163).—The defect pointed out by Cross and Bevan (Trans., 1888, 889) in the chromic acid oxidation process, namely, that part of the carbon is oxidised only to monoxide, is found to exist also in the oxidation of graphite by the same reagent, about 5 per cent. of the carbon being evolved as monoxide, but in this case the remedy suggested by them is inapplicable, since with the larger excess of chromic acid, greater strength of sulphuric acid, and higher temperature requisite for oxidising graphite, an evolution of oxygen cannot be prevented. The author finds it necessary to pass the gases over heated copper oxide before collecting and weighing the carbonic anhydride. The apparatus used consists of a round-bottomed flask of 200—300 c.c. capacity, with a long neck placed obliquely, so that the acid mixture may not spurt up to the rubber stopper, then a Liebig's condenser and a U-tube containing glass beads moistened with strong sulphuric acid. This is followed by a large U-tube containing calcium chloride, and pumice soaked in cupric sulphate, then a combustion tube 40 cm. long, containing granular cupric oxide, of which at least 15 cm. should be heated to redness. The gases then pass through another calcium chloride tube, and then into the absorbing tubes containing soda lime and calcium chloride. A guard tube and an aspirator of 6—8 litres capacity complete the apparatus. Air is admitted to the flask through potash, soda lime, and a cotton-wool filter. The author's experiments were made with about 0·3 gram of graphite, 10 grams of chromic acid, and 65 c.c. of sulphuric acid, which should not be of greater strength than 2 vols. of concentrated acid to 1 vol. of water. The mixture in the flask is to be heated to gentle boiling, whilst about 6 litres of air is slowly aspirated through the apparatus. M. J. S.

Estimation of Graphite in Minerals. By J. B. MACKINTOSH (*Zeit. anal. Chem.*, 29, 205).—A few fragments of potash are heated to tranquil fusion in a silver crucible. The weighed substance, which should not be very finely powdered, is added, and stirred from time to time with a silver wire, the temperature being somewhat raised, and the fusion continued until sandy particles are no longer perceptible. After cooling, the mass is digested with cold water. The graphite will be left in the insoluble residue, together with lime, magnesia, ferric oxide, &c., whilst other carbonaceous substances will have been destroyed. The residue is collected in a Gooch crucible, washed with water, and treated with dilute hydrochloric acid, then with ammonia, and finally washed, by which means all foreign matter is removed, and the pure graphite remains.

M. J. S.

Volumetric Estimation of Carbon in Iron. By J. WIBORGH (*Zeit. anal. Chem.*, **29**, 198—204; from *Berg. Hütt. Zeit.*, **46**, 223, 233).—The carbon in iron can be completely oxidised to carbonic anhydride if the iron is treated with a sufficiently concentrated solution of chromic acid in sulphuric acid, at a temperature near its boiling point. At lower temperatures, hydrocarbons are evolved. If, however, the iron is first treated with a neutral solution of cupric sulphate (which, except in rare cases, can be done without the loss of more than traces of hydrocarbons), the copper protects the iron from the action of the acid mixture until the temperature is reached at which oxidation to carbonic anhydride will occur. The iron must be in filings or borings fine enough to pass through holes 1·5 mm. in diameter. About 0·2 gram of wrought iron or of steel, or 0·1 gram of cast iron should be used. It is placed in a vessel like a test-tube and treated with 4 c.c. of a saturated solution of cupric sulphate. After stirring for 10 minutes (or only three or four if any smell of carburetted hydrogen is observed), 1·2 gram of chromic acid is added and well mixed in, keeping the mixture cool by immersing the cylinder in cold water. The tube is then closed with a rubber stopper carrying a stopcock funnel and a narrow tube for conveying the gases into a gas-burette. A special form of gas-burette is described, which has a total capacity of about 60 c.c., and at its lower part consists of a tube about 200 mm. long, 9 mm. diameter, and graduated in twentieths of a c.c. To the contents of the reaction tube, 8 c.c. of sulphuric acid of sp. gr. 1·7 is now added, and the mixture boiled for 10 minutes, after which the whole of the gaseous contents are driven over into the burette by filling the cylinder with water through the stopcock funnel. The total volume is read, and the carbonic anhydride is then absorbed by introducing potash solution into the burette through a funnel at the top. It is stated that in consequence of a small loss of carbonic anhydride by absorption in the water with which the burette is filled, 1 c.c. measured at 18°, is equal to 0·29 per cent. of carbon when 0·2 gram of iron is used, and that a variation of 2° or 3° may be neglected. M. J. S.

Separation of Barium and Strontium. By R. FRESENIUS (*Zeit. anal. Chem.*, **29**, 143—160; continued from this vol., p. 826).—In connection with the separation by means of hydrofluosilicic acid, the following points have been investigated:—

Solubility of Barium and Strontium Silicofluorides.

Percentage composition of solvent by volume	water	100	50	74·1	70·8	77·95	73	97·09	75	95·24
	alcohol (96 per cent.)	0	50	25	25	20	25	0	25	0
	hydrochloric acid (20 p. c.)	0	0	0·9	4·2	0·9	0·9	1·25	0	2·04
	hydrofluosilicic acid (3·7 p. c.) .	0	0	0	0	1·15	1·1	1·66	0	2·72
1 part of barium silicofluoride requires ...		—	37219	5263	2860	39061	70679	3247	16914	—
1 part of strontium silicofluoride requires		31·06	1529	82·93	50·9	55·0	82·97	—	147·4	7·3

Barium silicofluoride dried at 100° retains a variable quantity of water (0·78 to 1·16 per cent. have been observed), the amount of which more than compensates for the loss due to its solubility, so that when the silicofluoride is dried at 100° and weighed, the results are high, but when it is converted into sulphate, a low yield is obtained. By using a considerable excess of hydrofluosilicic acid (which reduces the solubility of the precipitate) and converting into sulphate for weighing, passably good results may be obtained. On attempting to separate barium from strontium by precipitation with hydrofluosilicic acid in presence of alcohol, the separation is incomplete, whichever metal predominates; strontium is retained by the precipitate, and barium passes into the filtrate. The error due to this cause can be greatly diminished by conducting the process as follows. The solution containing the barium and strontium is mixed with excess of hydrofluosilicic acid, stirred, and allowed to remain for 30 minutes, after which alcohol (4 vols. to 10 vols. of the solution) is added, and the mixture again allowed to repose for two hours. The precipitate is first washed with dilute alcohol (1 : 1), and then several times with small quantities of cold water. The aqueous washings are concentrated to a small bulk, mixed with a few drops of hydrofluosilicic acid and $\frac{1}{3}$ volume of alcohol, and the small precipitate obtained filtered off after two hours. The filtrates are all united, and the strontium precipitated by sulphuric acid and alcohol. For a more perfect separation, the following method is recommended:—The aqueous solution of the barium and strontium chlorides is precipitated with hydrofluosilicic acid without addition of alcohol, and the precipitate is washed with cold water. Only when strontium largely predominates in the mixture will the precipitate retain traces of it. The filtrate and washings are measured, and a quantity of N/2 sulphuric acid added sufficient to precipitate five or six times the quantity of barium corresponding with the solubility of barium silicofluoride. The small precipitate obtained will contain all the barium together with a little strontium. It is to be fused with sodium carbonate, the barium and strontium carbonates washed with ammoniacal water, converted into chlorides, and separated by hydrofluosilicic acid in presence of alcohol. Although this last separation is a somewhat imperfect one, yet, as the errors fall upon only a very small part of the original mixture, they may safely be neglected. Test analyses gave unexceptionable results.

In the above process it is necessary to ascertain the strength of the hydrofluosilicic acid by titrating it with soda; using phenolphthaleïn or litmus (with heating), 1 equivalent of hydrofluosilicic acid requires 3 equivalents of soda, but if ethyl-orange is used, only 1 equivalent of soda is required. The total amount of the bases to be separated is then regarded as baryta, and a few grams more than the corresponding quantity of hydrofluosilicic acid is added. The dilution must be such that if the bases consisted entirely of strontia, the whole would remain dissolved. For 1 gram there must therefore be about 150 c.c. when alcohol is not used, and 200 to 250 c.c. when $\frac{1}{3}$ or $\frac{1}{4}$ of the liquid consists of alcohol. Free acids must be completely absent. M. J. S.

Volumetric Analysis of Copper. By R. A. Fessenden (*Chem. News*, **61**, 183).—The author finds that the titration of copper with potassium cyanide can be conducted more quickly and accurately by neutralising with sodium carbonate instead of ammonia, and taking care to have sufficient nitric acid present; neither the presence of sulphuric acid nor varying the proportions of the reagents affects the results. D. A. L.

Detection of Mercury in Organic Liquids. By E. Brugnatelli (*Gazzetta*, **19**, 418—422).—50—100 c.c. of the liquid is acidified with a few drops of hydrochloric acid, heated with purified copper foil or wire to 50—60°, agitated for five minutes, the copper removed, washed with distilled water, transferred to a glass vessel, and a porcelain lid on which a drop of a dilute solution of gold chloride is spread is placed over or beside it, the whole is covered with a watch glass, and heated on the water-bath. The gold chloride is reduced by the mercurial fumes, and the metal is deposited on the porcelain lid as a bluish-violet film or stain. One-tenth of a milligram of mercury may in this way be detected in a litre of liquid.

The precautions to be observed are to use only copper which has been calcined and then reduced in hydrogen, and to render the porcelain lid chemically free from organic matter. Both copper and lid must not be handled otherwise than with perfectly clean forceps. S. B. A. A.

Combustion with Lead Chromate. By R. de Roode (*Amer. Chem. J.*, **12**, 226—228).—A mixture of 4 parts of finely divided lead chromate and 1 part of red lead is washed thoroughly and dried by the pump; the moist mass is then divided into small lumps and ignited in a porcelain crucible, and the lumps are finally broken up in a mortar to the size of grains of wheat. In the fore part of the combustion-tube is placed a roll of reduced copper gauze; this the author finds to be necessary whether the substance to be analysed contains nitrogen or not. Then comes a plug of asbestos, then the coarse grains of the above preparation filling about two-thirds of the rest of the tube, then another asbestos plug, then a mixture of the substance to be analysed with some of the above preparation in a state of fine powder, and finally some more of this latter in coarse grains. The fore part of the tube is connected with the calcium chloride tube and potash bulbs, the other end with an apparatus furnishing pure dried air; and the combustion is carried out as usual. The mixture of lead chromate and oxide does not fuse at a red heat, and the same tube may be used over and over again, except that the finely powdered portion of the mixture must be renewed every time, and occasionally the reduced copper gauze. C. F. B.

Estimation of Ethyl Nitrite in Spirit of Nitrous Ether. By J. C. THRESH (*J. Pharm. Trans.* [3], 20, 752—755).—In estimating nitrous compounds by titration of the iodine they liberate from hydriodic acid, the author prevents access of air by conducting the operations in an atmosphere of coal-gas, instead of using a vacuous flask, as Dunstan and Dymond do in the same process. The apparatus is simply a bottle or flask of 350 c.c. capacity, provided with a rubber stopper having two openings with tube connections for the introduction of the gas, and the burettes, &c. Certain precautions are pointed out, such as the avoidance of violent agitation of the liquid, previous boiling of the water to expel air, and, if necessary, making a slight allowance for the oxygen contained in the volumetric solution. The small quantity of oxygen usually contained in coal-gas is eliminated from the atmosphere in the flask before the introduction of the spirit to be tested, by adding 2 or 3 c.c. of spirit of nitre, passing a current of coal-gas, and allowing the apparatus to stand a short time and then adding enough thiosulphate to destroy the colour. The measured quantity of spirit of nitre is then added and titrated. Tables are given to show the accuracy of the results, which are always slightly higher than those given by Allen's method with the nitrometer.

R. R.

Reagents for α- and β-Naphthol. By — YVON (*J. Pharm.* [5], 21, 465—468).—10 c.c. of an aqueous solution of β-naphthol containing 0·2 gram per litre when mixed with 2 c.c. of 90 per cent. alcohol, 2 c.c. of nitric acid, and 10 drops of mercuric nitrate solution (Codex), gives an intense orange-red colour, unaltered on boiling, which imparts a rose-red tint to gun-cotton. Sulphurous acid does not destroy the colour, or but slowly; the mixture passes to rose colour, becomes turbid, and at length gives a yellow or black deposit of mercury oxide. Chloroform takes up the original colouring matter and becomes intense ruby-red, at length turning greenish-yellow. Under the same conditions ether becomes yellow. If instead of the mercuric nitrate and nitric acid three drops of a saturated potassium nitrite solution and ten drops of pure sulphuric acid are added, an intense violet-red coloration results, which is destroyed by sulphurous acid and becomes greenish-yellow. Chloroform becomes greenish-yellow, and ether yellow. Gun-cotton assumes a wine-red tint. α-Naphthol under like conditions gives with the mercuric nitrate mixture an orange-yellow colour, not changed on heating. Chloroform agitated with this takes an orange-yellow colour, and ether a somewhat greenish-yellow; sulphurous acid produces a brick-red precipitate, which settles and leaves a partly decolorised but still yellow liquid; gun-cotton is tinted yellow. With the potassium nitrite mixture, a reddish-brown colour is produced passing to wine-brown on boiling. Chloroform agitated with the mixture takes a greenish-brown colour, and ether becomes slightly greenish-yellow, while the aqueous solution assumes a clear, rose-red tint. The coloration is rapidly destroyed by sulphurous acid, and passes to a dirty green. Gun-cotton is tinted a dirty yellow. These reactions can be employed in studying the elimination of naphthol by the urine. With this object, the urine is shaken up with ether, this is decanted, evaporated to dryness, and the residue is taken up with 2 c.c. of alcohol; 10 c.c. of water is added, and the tests are applied as above. J. T.

Estimation of Starch in Grain. By Z. v. MILKOWSKI (*Zeit. anal. Chem.*, **29**, 134—136).—The author has made numerous estimations of starch in barley by the methods of Asbóth and Märcker respectively, and concludes from the agreement between the results that both methods are entitled to confidence. In carrying out Asbóth's process, the flour was freed from fat by ether, or carbon bisulphide, and quantities of 1—2 gram, thoroughly pulverised, were taken. In Märcker's method, 3 grams of the finely powdered substance is gelatinised by heating with 50 c.c. of water in a boiling water-bath, then cooled to 70° and mixed with 5 c.c. of malt extract (100 grams of malt to 500 c.c. of water), and kept at 70° for some minutes for the liquefaction of the starch paste. To prevent darkening, the solution is acidified with 1 per cent. of tartaric acid. The liquid is now exposed to a pressure of 3 atmospheres. After cooling, 5 c.c. of malt extract is again added, and the mixture is once more warmed to 70° and kept at that temperature for 20 minutes. This completes the solution of the starch. A portion of the filtered liquid is now inverted with hydrochloric acid of 1·125 sp. gr., and finally the sugar is estimated by Fehling's solution, using either Allihn's gravimetric, or Soxhlet's volumetric, process. A deduction must be made for the 10 c.c. of malt extract added. M. J. S.

Discrimination of Jute Fibres from those of Flax and Hemp. By W. LENZ (*Zeit. anal. Chem.*, **29**, 133—134).—A fragment of the fabric is warmed with ordinary nitric acid and a trace of potassium chlorate, then washed with water, and warmed with dilute potash solution until the acid in the fibres is neutralised. The alkaline liquid is poured off and the fibres shaken vigorously with pure water. The fibres now diffuse themselves uniformly through the water, and in this condition are poured upon a glass slip and allowed to dry in a horizontal position. After adding a drop of glycerol, a cover glass is placed over the specimen, and when the glycerol has thoroughly penetrated the fibres, they are examined under the microscope. The jute fibres now exhibit with great distinctness the irregular thickness of the cell walls. If placed between the crossed Nicols, the flax and hemp fibres show an extremely rich play of colour, whilst those of jute are uniformly bluish or yellowish, except where they happen to touch or cross one another, and even there the colour is less bright.

M. J. S.

Milk Analysis. By F. Walls (*Chem. News*, 61, 162).—The author finds it advantageous to replace the paper coil of the Adam's process by a bottomless test-tube, filled about one-third with freshly ignited asbestos. The upper opening may be closed with a cork fitted with a tube in connection with an aspirator, by which means the evaporation to dryness is greatly aided. D. A. L.

Melting and Solidifying Points of Fats and of their Mixtures. By A. Terreil (*Bull. Soc. Chim.* [3], 3, 195—200).—The author considers that the solidifying point of a fat, as determined by the slow cooling of the melted substance on an enlarged thermometer bulb, should alone be recognised as a test of purity. This point is always from 4—5° below the melting point. He describes a thermometer adapted for this purpose, and gives a very complete table, which indicates the melting, clouding, and solidifying temperatures of the principal fats, and of their mixtures with other fatty substances.

T. G. N.

Analysis of Fats. By H. Noerdlinger (*Zeit. anal. Chem.*, 29, 6—13).—Attention is called to the importance of estimating the free fatty acids in oils, and in articles of food containing fatty constituents, as the freshness and quality of the substances are closely connected with the amount of free acid present. To secure uniformity, all results are stated as oleic acid. The following table shows the mean percentage of fat and free fatty acid in various seeds:—

	100 parts of seed contain		100 parts of fat contain free fatty acid.
	Free fatty acid.	Total fat.	
Turnip (*Brassica rapa*)............	0·42	37·75	1·10
Colza (*B. campestris*)	0·32	41·22	0·77
Poppy (*Papaver somniferum*).......	3·20	46·90	6·66
Earth-nut (*Arachis hypogæa*)			
a. Seed......................	1·91	46·09	4·15
b. Husk	1·91	4·43	43·10
Sesame (*Sesamum orientale*)	2·21	51·59	4·59
Castor (*Ricinus communis*)	1·21	46·32	2·52
Palm kernel (*Elais guinensis*)	4·19	49·16	8·53
Cocoa-nut (*Cocos nucifera*)	2·98	67·40	4·42

In pressing oil from seeds, the free fatty acids are not obtained *pari passu* with the neutral oils. For instance, 100 parts of poppy seed containing 46·9 parts of oil, of which 3·2 parts are free acid, will yield on first pressure 39 parts of oil containing 0·75 part of acid, on second pressure 2·5 parts of oil containing 0·38 part of acid, and will leave in the cake 5·4 parts of oil, of which 2·07 are acid. The following table gives the oil and free acid in the residue left after pressing:—

	100 parts of cake contain						100 parts of the oil contain free fatty acid.		
	Free fatty acid.			Total fat.					
	Max.	Min.	Mean.	Max.	Min.	Mean.	Max.	Min.	Mean.
Rape cake	1·02	0·72	0·93	9·70	7·67	8·81	13·23	8·39	10·55
Poppy cake....	6·86	3·72	5·66	10·34	8·92	9·63	70·70	43·70	58·89
Earth-nut cake .	4·92	0·37	1·42	12·47	5·70	7·65	39·42	6·45	18·62
Sesame cake	7·80	2·66	6·15	21·90	11·20	15·44	58·62	20·24	40·29
Palm kernel cake	3·16	0·62	1·47	14·70	8·00	10·39	26·21	6·28	14·28
Extracted palm kernel meal...	—	—	1·55	—	—	18·68	—	—	8·29
Cocoa-nut cake..	1·63	0·91	1·31	16·11	10·10	13·11	13·88	7·27	10·51
Linseed cake....	1·06	0·43	0·75	10·80	6·82	8·81	15·50	4·00	9·75
Colza cake	1·74	0·68	1·27	8·17	4·80	6·53	28·72	8·33	20·07

The fact that in the extracted palm-kernel meal the residual oil contains the same percentage of acid as the oil in the original seed, shows that the solvents used (carbon bisulphide or petroleum) exert no selective action, and this may serve as a means of distinguishing extracted from expressed oil, as well as the residual cake from the respective methods. In various specimens of deteriorated oil-cake (palm kernel and cocoa-nut), the free acid in the residual oil ranged from 17 per cent. to the whole. M. J. S.

Detection of Cotton-seed Oil in Fats and in Olive Oil. By T. Leone (*Gazzetta*, **19**, 355—357).—The author finds that 75 per cent. of the samples of lard analysed by him contain cotton-seed oil. This substance may be detected by adding a few c.c. of a 1 per cent. solution of silver nitrate in alcohol acidified with 0·5 per cent. of nitric acid, to a few c.c. of the lard, and heating on the water-bath for 5 to 6 minutes. If cotton-seed oil is present, a brownish-yellow ring is formed at the surface of separation of the two liquids. This reaction is sufficiently delicate to detect the presence of 5 per cent. of cotton-seed oil in lard. It may be used for the detection of this impurity in olive oil, in which case it is, however, preferable to heat for 10—12 minutes. The yellow ring is not given by other oils, although occasionally a white ring is observed which changes to green on prolonged heating. S. B. A. A.

Note.—This test has since been superseded by better methods.

Estimation of Fat in Feeding Stuffs. By H. J. Patterson (*Amer. Chem. J.*, **12**, 261—265).—The use of animal charcoal is recommended to remove the water, soluble acids, &c., with which the fats and oils obtained by extracting food stuffs with ether are more or less contaminated. In the percolator-tube of the extraction apparatus is placed first some pure animal charcoal, then a plug of cotton, then the substance to be extracted, and finally another plug of cotton. The latter plug distributes the ether in a uniform stream over the substance, and prevents the latter from crawling up the sides of the percolator; the first plug prevents the fat coming in contact with the charcoal before it is thoroughly in solution. With grains and meals, 1 gram of charcoal per gram of substance was used; with hay, fodders, &c., 2 grams. A set of experiments made with pure fats showed that there was no loss in passing ethereal solutions of these through animal charcoal, and another set made upon various food stuffs showed that the method always gave lower, often much lower, results than the usual method, and that therefore the oil obtained by the latter method is more or less impure. C. F. B.

Estimation of Urea. By D. B. Dott (*J. Pharm. Trans.* [3], **20**, 793).—In the estimation of urea by measurement of the volume of nitrogen evolved, calcium hypochlorite is as trustworthy a reagent as sodium hypobromite, and the former has the advantages of being more easily and conveniently prepared (by mixing 1 part of bleaching powder with 3 parts of water and filtering); of keeping for a considerable time, whilst the hypobromite rapidly deteriorates; and of being cheaper. R. R.

Volumetric Estimation of Tannin. By E. Guenez (*Compt. rend.*, **110**, 532—534).—When a solution of tannin is added to a boiling solution of tartar emetic mixed with certain coal tar colours, antimony tannate is precipitated, and carries down the colouring matter in the form of a true "lake." After a sufficient quantity of the tannin has been added, the liquid above the precipitate becomes quite colourless. Dilution of the solutions is without influence on the results, and a given quantity of antimony tannate always carries down the same quantity of colouring matter. Gallic acid also does not interfere.

Green dyes only are suitable, and Poirrier's green 4JE. gives very good results. 12 grams of tartar emetic and 1 gram of the dye are dissolved separately in water, and the solutions are mixed, filtered, and made up to 1000 c.c. This liquid is standardised by means of a solution of 5 to 6 grams of pure tannin in a litre of water mixed with a small quantity of thymol to prevent the development of mould.

A measured volume of the antimony solution is heated to boiling, and the tannin solution is added from a burette, at first in cubic centimetres at a time, and afterwards in drops, the liquid being boiled after each addition. The precipitate settles readily, and the end reaction is easily perceived.

If the solution is standardised with tannin from nut-galls, the results with all other extracts will be expressed in terms of this tannin. C. H. B.

Estimation of the Indigo in Dyed Fabrics. By A. Renard (*Zeit. anal. Chem.*, **29**, 97; from *Mon. sci.*, **28**, 1444).—A solution of sodium hyposulphite is prepared from one of sodium hydrogen sulphite of 35° Baumé, and 100 c.c. of it is mixed with 100 c.c. of milk of lime and 2 litres of water. Of this mixture, 200 c.c. is placed in a flask containing 10 grams of the dyed stuff, and warmed to 60—70° while passing a stream of coal gas. When the decolorisation is complete, the liquid is rapidly poured into a graduated cylinder, and, after cooling, is measured. The indigotin is then precipitated by hydrochloric acid, and after 12 hours' subsidence is collected on an asbestos filter, washed, dried, dissolved in 10 c.c. of fuming sulphuric acid, and titrated according to Müller's method (*Jahresb.*, 1874, 1019).

M. J. S.

Reaction of Cholesterin. By — OBERMÜLLER (*Chem. Centr.*, 1890, i, 299—300; from *Arch. Physiol.*, 1889, 556—558).—Several of the compounds which cholesterin forms with organic and inorganic substances assume characteristic colours during cooling after being melted.

In the *propionate* the author has found a most characteristic and delicate means of detecting cholesterin, the colours which this substance assumes during the process of cooling being intense and distinct, and also are of longer duration than are many of the other cholesterin reactions.

10 grams of cholesterin is melted with 5 grams of propionic anhydride. The *propionate*, $C_2H_5\cdot COOC_{27}H_{45}$, crystallises in rhombic plates resembling cholesterin, and as the substance cools it gradually assumes the colours violet, blue, green, dark-green, orange, carmine, and finally copper-red. The deep blue and the green especially remain a considerable time. If suddenly cooled, the substance assumes the copper-red colour, which also remains a considerable time. If the substance in a flask be melted in warm glycerol solution at 98°, it assumes the blue colour. The colours are seen by reflected light; if viewed by transmitted light, the complementary colours are observed. Examined under the polarising microscope with transmitted light, the melted substance becomes first blue-green, then greyish-blue, followed by light-blue, a constant motion being observed; then suddenly it remains stationary, and groups of crystals in spheroid form appear, which, under crossed Nicols, show the black cross indicative of doubly refracting crystals. The mass becomes again set in motion, the crosses vanish and it assumes a wine-yellow colour mixed with red, then a violet, blue, light-green, dark-green colour is observed; the last suddenly disappears, and again aggregates of doubly refractive crystals appear which are much larger than the first.

In applying the test for the detection of cholesterin, the latter is separated as far as possible from other substances; a small quantity is then melted carefully with two or three drops of propionic anhydride. By suddenly cooling, a lustrous fatty mass is obtained, and if a small portion of this is melted on a glass rod and held against a dark background, the colour reactions are readily observed.

General and Physical Chemistry.

Effect of the Spectrum on the Haloïd Salts of Silver. By W. DE W. ABNEY and G. S. EDWARDS (*Proc. Roy. Soc.*, **47**, 249–275).—This paper gives an account of the method employed to measure the relative sensitiveness of a photographic plate to the different parts of the spectrum. The density of the deposit at any spot is ascertained by allowing a beam from a constant light-source to pass through the plate, and cast the shadow of a rod on a screen in such a manner that it falls exactly alongside another shadow of the same rod cast by a second constant lamp. The intensity of the beam which has passed through the plate is reduced by varying the size of sectors cut out of a rotating disc placed in its path, until the two shadows are of the same degree of darkness. From the time of exposure of the different parts of the plate, and the opening of the sectors, the relative sensitiveness can be calculated. Collodion and gelatin plates of the different silver haloïds, both separate and mixed, were examined, and the results are given in numerous tables and curves. Plates dyed with cyanin and erythrosin were also investigated. J. W.

Polarisation of Electrodes. By L. POINCARÉ (*Compt. rend.*, **110**, 950—951).—The maximum polarisation which metallic plates can acquire when plunged into an electrolyte varies with the temperature, and, if the electrolyte is a fused salt, can be followed through a somewhat wide interval. Maximum polarisation is attained most quickly when the electrodes are short, slender wires.

With silver electrodes in fused sodium nitrate, the E.M.F. of polarisation is 0·33 volt at 330°, but it falls to 0·1 volt at 440°, and tends towards zero as the temperature rises to 470°, the point at which the salt begins to decompose. Similar experiments with potassium and ammonium nitrates, potassium and sodium chlorates, and mixtures of nitrates which decompose at different temperatures prove that the polarisation of silver electrodes is nil at the temperature at which the electrolyte decomposes. The same result is obtained with electrodes of iron or of gold. These results are analogous to Bouty's observation that in concentrated nitric acid, which is easily decomposed, the polarisation of platinum electrodes is very slight.

If it is assumed that the maximum polarisation is equivalent to or higher than the energy used up in the electrolytic decomposition, it follows that a rise of temperature tends to dissociate the electrolyte into its ions, and if the actual products of decomposition are not the ions, they are produced from the latter by secondary changes. Heat in fact gives rise to a dissociation similar to that which Arrhenius supposes to take place in dilute solutions. C. H. B.

Thermochemistry of Hydroxylamine. By BERTHELOT and ANDRÉ (*Compt. rend.*, 110, 830—836).—Hydroxylamine nitrate was prepared by Kahlbaum in crystals which melt at about 48° and readily remain in superfusion. They are very soluble in water and very hygroscopic; heat of dissolution at 11·3 = —5·93 Cal. Decomposition by means of sodium hydroxide showed that the heat of neutralisation of hydroxylamine by nitric acid is +9·2 Cal.

The salt was mixed with naphthalene and burnt in the calorimetric bomb: the heat of combustion for 1 gram is 535·5 cal., and hence the molecular heat of combustion at constant volume is +51·41 Cal., and at constant pressure +50·29 Cal. The heat of formation in dilute solution from the constituent gases is + 23·8 Cal.

The following table gives the heats of formation of ammonia and hydroxylamine from their constituents, and the heats of formation of their dissolved salts from the acid and the gaseous constituents of the base.

Hydroxylamine ...	+23·8 Cal.	Ammonia....	+21·0 Cal.
Hydroxm. nitrate...	+33·0 „	Am. nitrate..	+33·4 „
„ chloride.	+33·0 „	„ chloride .	+33·4 „
„ sulphate.	+2 × 34·6 Cal.	„ sulphate.	+2 × 35·5 Cal.

The heats of formation of the two bases and their corresponding salts are very nearly identical. The heat of formation of hydroxylamine is slightly higher than that of ammonia, but in the case of the salts the order is reversed, ammonia having a decidedly higher heat of neutralisation than hydroxylamine. It follows that the conversion of ammonia into hydroxylamine cannot be regarded as oxidation in the proper sense of the word, nor is it a change analogous to the formation of an alcohol or an aldehyde from a hydrocarbon. The formation of hydroxylamine from nitric oxide is accompanied by the development of +45·4 Cal. The reduction of the nitro-group to hydroxylamine develops much less heat than its reduction to the amido-group, the difference being nearly equal to the heat of formation of water. Decomposition of hydroxylamine by potassium hydroxide with formation of water and ammonia develops +52·2 Cal.; decomposition by concentrated ammonia, with liberation of dissolved nitrous oxide, develops +45·0 Cal., or if the nitrous oxide escapes as gas +43·6 Cal. Simple decomposition of the hydroxylamine into nitrogen, hydrogen, and water is accompanied by the development of +45·2 Cal., and hence the energetic reducing action of the base.

The decomposition of the nitrate by heat develops +50·3 Cal. if the water is liquid and 30·9 Cal. if the water is gaseous. It follows that the decomposition, like that of ammonium nitrate, may become explosive. As with other explosives, decomposition may take place in several different ways, according to circumstances.

The oxidation of hydroxylamine to water and nitrogen or an oxide of nitrogen corresponds to the following thermal disturbances:—nitrogen +79·7 Cal., nitrous oxide +69·4 Cal., nitric oxide +58·1 Cal., nitrous anhydride +75·5 Cal., nitrogen peroxide +77·1 Cal., and nitric anhydride +95·0 Cal. The development per atom of oxygen (16 grams) in each case is +159·4, +69·4, +38·8, +37·8, +30·8, and

+31·6 respectively. Its conversion into ammonia and water by the action of hydrogen develops +66·2 Cal. C. H. B.

Preparation and Heat of Formation of Mono-sodium Erythroxide. By DE FORCRAND (*Compt. rend.*, **110**, 859—862).—The action of one equivalent of sodium hydroxide in dilute solution on a solution of erythrol at 13° develops +0·69 Cal., a number higher than the corresponding value for glycerol (+0·37), and still higher than that for glycol (+0·28), but lower than that for mannitol (+1·05). It follows that the energy of the alcoholic function increases with the number of hydroxyl-groups. 122 grams of pure dry erythrol was dissolved in 800 c.c. of methyl alcohol, which is its best solvent, the boiling solution was mixed with a solution of 23 grams of sodium in 300—350 c.c. of methyl alcohol, and the mixture boiled for five or six hours in a flask with a reflux condenser. The alcohol was afterwards distilled off in a current of dry hydrogen, and the crystals dried on porous plates out of contact with air. When heated at 115°, they lose 18·01 per cent., which corresponds with 1 molecule of methyl alcohol.

Monosodium erythroxide is obtained in this way as a very hygroscopic white powder: heat of dissolution at 13° + 0·89 Cal. From this result it follows that—

$C_4H_{10}O_4$ solid + ½Na_2O solid = ½H_2O solid + $C_4H_9NaO_4$ solid .... develops +22·315 Cal.
$C_4H_{10}O_4$ solid + NaOH solid = H_2O solid + $C_4H_9NaO_4$ solid .... „ +5·81 „
$C_4H_{10}O_4$ solid + Na solid = H gas + $C_4H_9NaO_4$ solid .... „ +37·70 „

Comparison of these numbers with the corresponding values for glycerol shows that whilst in solution the acidic function of erythrol is more energetic than that of glycerol, in the solid state the reverse seems to be the case. The anomaly is however only apparent, and is due to the fact that the physical condition of the solid erythrol is not comparable with that of the liquid glycerol. Analogy indicates that the heat of fusion of erythrol is not less than —10 Cal.

C. H. B.

Action of Erythrol on Alkali Alkyl-oxides. By DE FORCRAND (*Compt. rend.*, **110**, 904—907).—The action of sodium methoxide on erythrol (preceding abstract) yields a compound $C_4H_9O_4Na,MeOH$, which loses methyl alcohol at 140°. The action of sodium ethoxide on erythrol in presence of ethyl alcohol yields the compound $EtONa,C_4H_{10}O_4$, or if ethyl alcohol is present in large excess, the compound $EtONa,C_4H_{10}O_4,2EtOH$. Both these compounds can be heated for several hours at 150° without undergoing any alteration, and hence, in all probability, have the constitution given. This view is confirmed by thermochemical measurements. Heats of dissolution at 13°, $C_4H_9O_4Na,MeOH$ = +0·89 Cal; $EtONa,C_4H_{10}O_4$ = —1·94 Cal.; $EtONa,C_4H_{10}O_4,2EtOH$ = —5·10 Cal.

$C_4H_9O_4Na$ solid + MeOH liquid = $C_4H_9O_4Na,MeOH$ solid .... develops +0·81 Cal.
EtONa solid + $C_4H_{10}O_4$ solid = EtONa,$C_4H_{10}O_4$ solid .... „ +10·80 „
EtONa,$C_4H_{10}O_4$ solid + 2EtOH liquid = EtONa,$C_4H_{10}O_4$,2EtOH solid.......... „ +8·24 „
EtONa,2EtOH solid + $C_4H_{10}O_4$ solid = EtONa,$C_4H_{10}O_4$,2EtOH solid.......... „ +10·17 „

As a rule, the heat of combination of ethyl alcohol with metallic alkyl-oxides is 1 Cal. less than for the corresponding combination of methyl alcohol, and it would follow that the combination of ethyl alcohol with sodium erythroxide would be endothermic. This result explains the non-formation of the compound $C_4H_9O_4Na$,EtOH, and also why the erythroxide is not formed in the solution in ethyl alcohol.

C. H. B.

Heats of Combustion and Formation of Nitrogenous Compounds derived from Albuminoïds. By BERTHELOT and ANDRÉ (*Compt. rend.*, **110**, 884—889).—The combustions were made in compressed oxygen in the calorimetric bomb.

	Per gram.	Molecular heat of combustion.		Heat of formation.	Diff.
		Constant volume.	Constant pressure.		
	cal.	Cal.	Cal.	Cal.	Cal.
Glycollamine	3133·6	235·0	234·9	126·2	+11·8
Alanine	4370·7	389·0	389·2	135·2	+2·8
Leucine	6526·1	854·9	855·9	158·4	−20·4
Asparagine	3396·8	448·4	448·1	205·1	+1·9
Aspartic acid.......	2911·1	387·2	386·8	231·9	+33 2
Tyrosine...........	5915·9	1070·8	1071·2	156·4	+50·0
Hippuric acid.......	5659·3	1013·0	1012·9	145·6	+60·7
Urea	—	—	—	80·8	−11·8
Uric acid	—	—	—	148·1	+37·0

The heats of formation of urea and uric acid are given for comparison. The last column gives the differences between the actual heats of combustion and those calculated from the composition by Dulong's method. In all cases except urea and leucine the actual values are higher than the calculated values, and in some instances the differences are very considerable.

In the following table, the total heat of combustion is compared with the heat of combustion of the various compounds, the nitrogen being supposed to be eliminated in the form of urea, the heat of dissolution of which approximately compensates for the heat of dissolution of the original compound and the heat of dissolution of the carbonic anhydride. These conditions closely resemble those actually existing in the living organism.

	Compounds, solid.	Compounds, dissolved.	Complete combustion.	Deficit, solid.	Deficit, dissolved.
Glycollamine ..	+159·2	+167·3	234·9	75·7	78·5
Alanine	+313·5	+327·5	389·2	75·7	78 5
Leucine	+780·4	+811·2	855·9	75·7	78·5
Tyrosine	+995·5	+942·6	1071·2	75·7	78·5
Asparagine....	+296·6	+314·4	448·1	151·5	156·1
Aspartic acid ..	+311·1	+330·7	386·8	75·7	78·5
Hippuric acid..	+937·2	+982·8	1012·9	75·7	78·5
Uric acid	+158·4	+175·8	461·4	303·0	314·2

The heat developed under these conditions is very considerably lower than the heat of complete combustion, and it is evident that urea plays a very important part in connection with animal heat, since 80 to 85 per cent. of the nitrogen is eliminated in this form. If the nitrogen is eliminated in the form of uric acid, the deficit is 115·2 Cal. per 14 grams, or 122·0 Cal. if the carbonic anhydride is in solution; if the nitrogen is eliminated as hippuric acid, the deficit is 1012·9 Cal. per 14 grams. In the case of herbivora, it follows that there would be a very considerable thermal deficit, if there were not compensation in the form of liberation of free nitrogen in the intestine. The high deficit in the case of uric acid explains to some extent the effect of excessive feeding on its production, and the characteristic physiological and pathological perturbations which accompany its formation. C. H. B.

Heats of Combustion of the Chief Nitrogenous Compounds in Living Organisms, and their Relation to Animal Heat.

By BERTHELOT and ANDRÉ (*Compt. rend.*, **110**, 925—934).—The heats of combustion were determined by means of the calorimetric bomb. In the table (p. 938), column 1 contains the heats of combustion of 1 gram at constant pressure; column 2 the heat of combustion of the quantity which contains 1 gram of carbon; column 3 the heat of combustion if 1 gram of the nitrogen is eliminated in the form of urea, and column 4 the heat of combustion of the quantity which contains 1 gram of carbon, the nitrogen being eliminated as urea.

The table (p. 938) gives the percentage composition of the various preparations.

The albumin was purified, and dried at 100°; the fibrin was treated with ether and dried at 115°; the muscular flesh was washed with alcohol, then with ether, and dried at 115°; the hæmoglobin was prepared from the horse, and was dried at 115°; the casein, ossein, and chrondrin were dried at 115°; the vitellin was dried in a vacuum at the ordinary temperature; the yolk of egg was hard-boiled and dried in a vacuum at the ordinary temperature, but was subjected to no other treatment; the vegetable fibrin was extracted with alcohol and ether and dried at 115°; the isinglass, fibroïn, and wool were washed with ether and dried at 115°; the chitin was purified; the tunicin was prepared from Ascidians and treated with alkalis and acids, and these two substances and the gluten were dried at 115°.

The average heat of combustion of the albuminoïds which can serve as foods is 5691 cal. for 1 gram, and 10,870 cal. for the quantity which contains 1 gram of carbon. The loss of heat resulting from elimination of the nitrogen in the form of urea is 16 per cent. The mean heat of combustion of the carbohydrates is 9470 cal. for the quantity containing 1 gram of carbon, but the value for 1 gram varies with the degree of hydration. It is about one-fifth greater than the heat of combustion of the carbon which is present, and this reserve of energy is the source of the heat developed during many fermentations. In the case of fats, the heat of combustion per gram of carbon is 12,200 to 12,500 cal., the magnitude of this number being due to the small percentage of oxygen which the compounds contain. On the other hand, they require a large amount of oxygen for complete combustion. In the case of the albuminoïds, about one-sixth of the total possible heat is not available, because the nitrogen is eliminated from the living organism in the form of urea: in the case of the fats and carbohydrates, the whole of the heat of combustion is available, provided that the organism is healthy and completely burns the food supplied.

When an organism is enfeebled, and is unable to burn completely the food which is introduced into it, various evil results follow. Fats are deposited in the form of adipose tissue, encumbering the muscles and other organs, and although they possess the highest heat-producing power, they are the first of the food-stuffs to cease to furnish their energy to an enfeebled organism. Incomplete combustion of carbohydrates results in a reduction of the quantity of animal heat, and appears to be connected with a pathological condition of certain special organs. Incomplete oxidation of nitrogenous compounds results in the elimination, chiefly through the kidneys, of unaltered albumin in severe cases, and of products of incomplete combustion, such as uric acid, in other cases, but the diffusion of such products in the organism is accompanied by serious perturbations.

C. H. B.

Thermochemistry of Wool and Cotton. By L. VIGNON (*Compt. rend.*, **110**, 909—910).—The heat developed by the action of normal solutions upon 100 grams of unbleached wool at 11—12° is as follows:—

	KOH.	NaOH.	HCl.	H_2SO_4.
Spun wool.........	1·16	1·15	0·95	0·99 Cal.
Combed wool......	1·37	1·10	1·00	1·05 Cal.

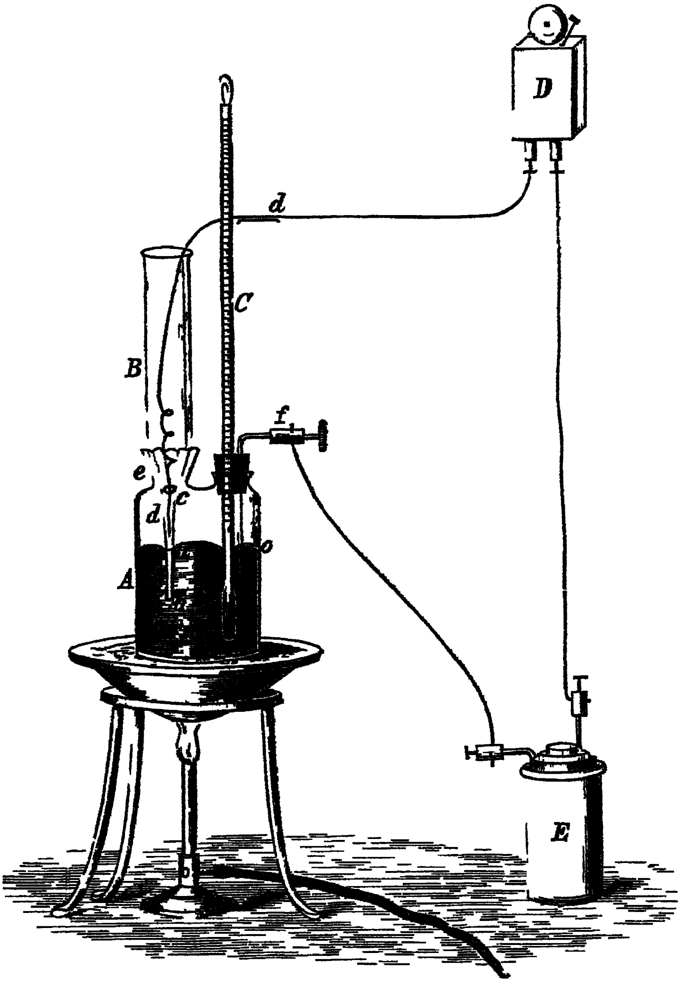
The rise of temperature ceases after about five minutes. In the case of cotton the development of heat is slower, but the rise of temperature ceases at the end of seven or eight minutes. The heat developed per 100 grams of cotton is as follows:—

	KOH.	NaOH.	HCl.	H_2SO_4.
Cotton, unbleached .	1·30	1·05	0·65	0·60 Cal.
Cotton, bleached ...	2·27	2·20	0·65	0·58 Cal.

The greater development of heat by the action of alkalis on bleached cotton is probably due to the presence of oxycellulose, which has been formed in the process of bleaching. C. H. B.

New Apparatus for Determining Melting Points. By A. C. CHRISTOMANOS (*Ber.*, **23**, 1093—1096).—The apparatus shown in the diagram (p. 940) has been devised by the author for ensuring a more correct determination of the melting point of substances.

The cylindrical vessel (*A*), which is 12 cm. in height and 6 cm. in diameter, is heated on a sand-bath or in an air-bath, and is provided with two apertures; a thermometer (*C*) and a platinum wire (*f*) pass through a cork fitting into one of the apertures, whilst the other (*e*) is conical and fluted and serves for the reception of a drawn-out test-tube (*B*). The vessel (*A*) is filled with pure mercury to such a depth that the point (*b*) of the test-tube is about 2 cm below the



surface (*w*) of the metal. The substance is introduced in a melted condition, into the point (*b*), so that it forms a layer of from 0·5 to 1·5 cm in length, and when it has completely solidified again the test-tube is placed in position and the space (*ac*) immediately above the substance filled with mercury, into which dips the platinum wire (*d*). On applying heat, the mercury in (*A*) is uniformly heated throughout its whole mass, so that the thermometer and the substance are always at the same temperature; the moment the substance melts, the two mercury columns come into contact, the circuit is completed, the bell (*D*) rings, and the temperature is noted.

F. S. K.

Boiling Points of Substances are a Function of their Chemical Nature. By M. WILDERMANN (*Ber.*, 23, 1254—1264).—In any homologous series of organic compounds, the relation between the boiling point (in absolute temperature) under a pressure of M mm., and that under a pressure of N mm. is one and the same for all members of the series. This law has been tested in a number of cases for wide limits of pressure (12 to 1500 mm.) and found correct. It may be expressed in the following manner—

$$\frac{\mathrm{T}ap}{\mathrm{T}a\mathrm{P}} = \frac{\mathrm{T}bp}{\mathrm{T}b\mathrm{P}} = \frac{\mathrm{T}cp}{\mathrm{T}c\mathrm{P}} = \mathrm{D},$$

where *a*, *b*, and *c* represent different members of any homologous series, *p* the lower, and P the higher limit of pressure. From the above it also follows that $\mathrm{T}ap : \mathrm{T}bp = \mathrm{T}a\mathrm{P} : \mathrm{T}b\mathrm{P}$, or that the ratio of the boiling points of two substances belonging to the same homologous series is the same for all pressures.

The above law does not hold, however, for members of the same series which differ in chemical nature or in the mode of arrangement of the atoms in the molecule, and, therefore, is not applicable to the various isomerides of the higher members of a homologous series. The value of D is also found to vary from one series to another, the author having determined the values of T12 mm. / T760 mm. for 150 different substances, and found the variation to be from 0·73 to 0·79. From this it follows that the change in the boiling point of a substance with change of pressure is dependent on the nature of the elements composing that substance, as also on their number and mode of arrangement in the molecule, and hence is a function of the chemical nature of any compound.

H. C.

Solution Compounds. By G. GORE (*Chem. News*, 61, 172—174).—The author has measured, using zinc-platinum couples, the voltaic energy of numerous aqueous solutions containing various proportions of all kinds of soluble elements, alkaline, neutral, and acid salts and acids, and has in all cases obtained evidence of combination by the reduction of voltaic energy. The author gives the average available voltaic energy of the ingredients used in the various solutions, and also the loss of voltaic energy which takes place when two of these substances are in the same solution, in proportions representing the formulæ of each solution compound.

The author considers that the results obtained illustrate the fact "that all kinds of chemical substances, when in neutral solution, unite with each other indiscriminately, and irrespective of the chemical nature of the substances."

D. A. L.

Sealing Tubes under Pressure. By A. RICHARDSON (*Chem. News*, 61, 255).—The following device serves for sealing tubes after gases have been admitted to them under pressure. The tube terminates in a T-piece, the lateral tube of which is constricted at places, and provided near the joint with a plug ground into a contraction of the tube, so that it acts as a valve opening inwards, yielding to the admission of gas under pressure, but closing firmly under internal pressure, and so permits of the sealing of the tube at a point further removed from the joint. D. A. L.

Inorganic Chemistry.

Spontaneously Inflammable Hydrogen Phosphide. By L. Gattermann and W. Haussknecht (*Ber.*, 23, 1174—1190).—In order to obtain more accurate details as to the composition and properties of the liquid hydrogen phosphide obtained by Thénard in 1845, the authors have prepared this substance in considerable quantities, and subjected it to a close examination. The method of preparation adopted was that originally employed by Thénard, namely, the action of calcium phosphide on water. To obtain the calcium phosphide, a strong iron tube sufficiently wide to allow of the easy passage of a stick of phosphorus was fixed vertically in a large Hessian crucible, filled with ordinary lime, broken into pieces about the size of a hazelnut. The iron tube should end 2 cm. above the bottom of the crucible, and have a wide glass tube attached to the upper portion, in order to prevent the mouth becoming too hot. The crucible is then covered, and placed in a suitable coke furnace, heated to a moderate red heat, and phosphorus, in pieces weighing about 15 grams, thrown into the tube. The process is continued until the burning of the phosphorus from the crucible opening becomes continuous. The calcium phosphide is thus obtained as a hard, dark mass, which frequently shows iridescent surface colours, and must be at once placed in a well-closed bottle.

The decomposition of the calcium phosphide is carried out in a large, three-necked Woulffe's bottle. In the centre neck is placed a wide glass tube, dipping under the surface of the water, for the introduction of the phosphide; in the second is placed a tube, likewise dipping under the surface of the water, connected with an apparatus evolving hydrogen; whilst in the third is placed an exit tube connected with the condenser. The latter consists of a tube narrowed towards the bottom, the inlet and outlet tubes of which only come slightly below the cork, and are cut off obliquely. It is placed in a deep vessel of water containing sufficient ice at the top to keep the temperature at 0°. As soon as the air is driven out of the apparatus by the hydrogen, the Woulffe's bottle, which should contain 1½ litres of water, is carefully heated in a water-bath until the latter has a temperature of 60°, and the calcium phosphide, broken into pieces the size of a pea, added in portions of about 2 grams. It is preferable to proceed at such a rate that 50 grams are added in

15 to 20 min. After a quarter of that amount has been added, the condensation commences, and the liquid collects in the narrow portion of the condenser. The gases which pass off still contain considerable quantities of the liquid phosphide, and if passed through a flask containing hydrochloric acid, may be converted into solid hydrogen phosphide, while the gaseous hydrogen phosphide passes off, and may be collected over water. Care must be taken in this case that the tubes do not get blocked by the deposition of the solid compound. From 1—2 c.c. of the liquid phosphide is obtained in a successful operation for every 50 grams of calcium phosphide employed.

In order to obtain a weighed quantity of the substance for analysis, a small bulb-tube with a narrow neck is blown on the condenser previous to its being used, and when the liquid has been collected, a sufficient amount passed into this bulb-tube by inclining the condenser, and the narrow neck of the former then carefully sealed. It was not found possible to estimate the phosphorus directly, but the hydrogen was readily estimated by burning the substance in a tube nearly filled with lead chromate, through which a current of dry carbonic anhydride was passed, the water formed being absorbed as usual by a calcium chloride tube. The quantity of the latter agreed well with the empirical formula PH_2.

Thénard drew his conclusions as to the composition of the liquid from the fact that it decomposed in sunlight, with formation of solid and gaseous hydrogen phosphide, the amount of the former obtained being about 38 per cent. The authors have repeated this experiment, the liquid being collected in a bulb-tube to the neck of which a small capillary tube drawn out to a point was horizontally attached. The weighed tube, after breaking off the capillary, was exposed to bright sunlight, and in 36 hours was completely converted into the solid phosphide, the amount of which was found to be 38·33 per cent. In a second experiment, the gaseous hydrogen phosphide evolved was collected over mercury and measured, the liquid being both exposed to light and heated. The quantity found was 61·28. These quantities agree well with Thénard's equation, $5PH_2 = 3PH_3 + P_2H$, and form, therefore, a further confirmation of the empirical formula PH_2.

The sealed tubes containing the liquid phosphide must not be kept for any length of time, as the decomposition commences immediately, and, after a time, the pressure becomes so great that the tubes explode with an exceptionally loud report. No deposition of the solid takes place for some time, but the liquid becomes yellow, whence it would appear that solid hydrogen phosphide is soluble in liquid phosphide.

Attempts were made to obtain the vapour-density of the liquid without success, the substance being in all cases decomposed. The comparison of the physical properties of the liquid and gaseous compounds makes the formula PH_2 improbable, and the authors, therefore, regard the formula P_2H_4 as preferable. The boiling point was found to be 57—58° under 735 mm. pressure, no residue remaining, provided the temperature of the heating bath does not rise above 80°, but the distilled compound is even more unstable than the original substance. The specific gravity of the liquid was found in two cases to be 1·016 and 1·007, and is, therefore, slightly greater than that of water.

Unsuccessful attempts have also been made to obtain compounds of liquid hydrogen phosphide with aldehydes and ketones similar to those yielded by hydrazine. H. G. C.

Carbon Tetrafluoride. By H. MOISSAN (*Compt. rend.*, **110**, 951—954; compare Chabrié, this vol., p. 558).—Carbon fluorides are gaseous, closely resemble one another in many of their properties, and at comparatively low temperatures decompose and polymerise easily. Their preparation in a pure state is consequently difficult.

Carbon tetrafluoride can be obtained by the action of fluorine on purified carbon at the ordinary temperature; by passing fluorine into gently heated carbon tetrachloride; by passing fluorine heated to 100° into chloroform; by the action of fluorine on methane; by the action of silver fluoride on carbon tetrachloride.

Silver fluoride is heated at 195—200°, and the vapour of carbon tetrachloride is passed over it. The product is passed through a serpentine tube cooled to −23°, and is collected over mercury. The last traces of vapour of carbon tetrachloride are removed by allowing it to remain in contact with fragments of caoutchouc for some time. The gas still contains small quantities of a carbon fluoride of higher sp. gr., but can be obtained quite pure by agitating with absolute alcohol, in which the tetrafluoride is readily soluble, and from which it is expelled by heating. Alcohol vapour is finally removed by sulphuric acid. The preparation must be conducted in metal apparatus; otherwise a mixture of silicon fluoride, carbonic anhydride, carbon tetrafluoride, and a carbon fluoride of higher sp. gr. is obtained.

Carbon tetrafluoride has a sp. gr. of 3·09; it liquefies at −15° under ordinary pressure, or under 4 atmos. at 20°. It is only slightly soluble in water, and is not absorbed by sulphuric acid, aqueous potash, or aqueous baryta, but dissolves readily in ether, and especially in absolute alcohol. When heated in contact with glass, it yields carbonic anhydride and silicon tetrafluoride. When heated with sodium, it yields sodium fluoride and carbon, and it dissolves readily in alcoholic potash, which gradually converts it into potassium fluoride and carbonate. C. H. B.

Composition of Boiler Scale. By T. B. STILLMAN (*Chem. News*, **61**, 258).—An analysis of boiler scale, from a portion of the boiler exposed to direct heat, yielded the following numbers per cent.; the water of hydration being determined by igniting the scale, dried at 100°, in a tube, and collecting the water in a tared calcium-chloride tube:—

SiO_2 and clay.	Fe_2O_3; Al_2O_3.	CaO.	MgO.	CO_2.	SO_3.
11·70	2·81	11·62	41·32	6·92	0·96

Moisture.	H_2O (of hydration).	Undetermined.
0·69	21·78	0·2

The numbers show insufficient sulphuric and carbonic acids to satisfy the bases, whereas the water of hydration exactly corresponds with that required for the unsatisfied magnesium and calcium oxides, thus indicating the presence of 13·70 per cent. of calcium hydroxide and 56·37 of magnesium hydroxide. This is regarded as the result of the decomposition of the scale by heat, and was confirmed by an examination of the scale layer by layer, when it was found that the portion next to the iron, and nearest the fire, contained only traces of carbonic anhydride, but consisted principally of hydroxides; the intermediate portion was a mixture of hydroxides and carbonates; whilst the upper portion contained carbonates, but not hydroxides.

D. A. L.

Lead Phosphites and Pyrophosphite. By L. AMAT (*Compt. rend.*, **110**, 901—904).—*Normal Lead Phosphite.*—This salt is practically insoluble in water: Na_2HPO_3 diss. + $Pb(NO_3)_2$ diss. = $PbHPO_3$ pptd. + $2NaNO_3$ diss., develops + 0·65 Cal.

Lead Nitrophosphite.—If sodium hydrogen phosphite is used instead of the normal salt, part of the lead is precipitated as normal phosphite, and the liquid becomes acid. In presence of excess of lead nitrate, the normal lead phosphite combines with it, and forms a nitrophosphite, $PbHPO_3,Pb(NO_3)_2$, which can be recrystallised from dilute (1 : 10) nitric acid. The crystals are stable when exposed to air, and do not alter at 100—110°. When more strongly heated, the salt decomposes explosively, nitrogen oxides being evolved, and a white residue being left. In contact with water, the crystals are decomposed and become opaque, lead nitrate being dissolved, and the normal phosphite left. Lead nitrophosphite is also formed when lead phosphite is treated with nitric acid.

Lead hydrogen phosphite is obtained by dissolving the normal salt in a very concentrated solution of phosphorous acid, and separates on cooling in fine, transparent crystals which can be dried at 100°, and have the composition $PbH_4(PO_3)_2$. When treated with water, they become opaque, the normal phosphite being formed, whilst phosphorous acid passes into solution.

Lead pyrophosphite, $PbH_2P_2O_5$, is obtained by heating the acid phosphite at about 140° in a dry vacuum. In contact with water, it remains undissolved, but is gradually converted into the normal phosphite and phosphorous acid. The addition of lead nitrate to sodium pyrophosphite yields a precipitate of lead nitrophosphite and not of the pyrophosphite, a result due to the hydration of the pyrophosphite. The hydration takes place most rapidly in concentrated and acid solutions, and, hence, on addition of lead nitrate to the sodium pyrophosphite, precipitation of the nitrophosphite begins almost immediately, but in very dilute solutions precipitation is very slow indeed. This reaction may be utilised to distinguish between phosphites and pyrophosphites, since the former give an immediate precipitate with lead nitrate in the cold, whilst the latter, in very dilute solutions, give no precipitate until boiled. If a phosphite and pyrophosphite are mixed, the precipitate which forms in the cold is filtered off, and the filtrate is then boiled, when a further precipitate shows the presence of a pyrophosphite. C. H. B.

The Relation of the Hydrated Sesquioxides to the Salts of Iron and Aluminium.

By E. A. SCHNEIDER (*Ber.*, **23**, 1349—1354).—Freshly precipitated aluminium hydroxide readily acts on a hot concentrated solution of ferric sulphate, and precipitates the whole of the iron as a basic salt. The solution of ferric sulphate, as is well known, readily dissociates into free acid and a basic salt, and in this reaction the aluminium hydroxide unites with the free acid as it is formed, and thus accelerates the precipitation. The action likewise takes place in the cold. The duration of the reaction has very little influence on the amount of alumina dissolved, but the reaction takes place more slowly in cold dilute solutions. In hot solutions the concentration is without effect on the result.

Aluminium hydroxide dissolves quickly and completely in cold solutions of normal and basic ferric chloride, aluminium chloride being formed, and colloïdal ferric hydroxide remaining in solution. The latter coagulates immediately on addition of a little sulphuric acid. A solution of ferric nitrate behaves in a similar manner.

Freshly-precipitated ferric hydroxide dissolves in a concentrated solution of aluminium sulphate in considerable quantity, forming a dark-brown solution which may be evaporated to dryness without decomposition, and yields a basic salt on addition of water, having the formula $SO_3,3Fe_2O_3,3H_2O$.

The hydroxide also dissolves in considerable quantity in aluminium chloride solution. The undissolved portion, when collected and washed, dissolves readily in large quantities of water forming a reddish-brown solution, which appears cloudy in reflected light, and shows a blue fluorescence. The solution containing the iron and aluminium loses most of its iron on addition of a trace of sulphuric acid. A solution of aluminium nitrate also takes up the ferric hydroxide, but in much smaller quantity.

Aluminium hydroxide may be partially precipitated not only from basic but also from acid solutions by means of sulphuric acid, the amount precipitated in one experiment being 25·6 per cent. Further, aluminium chloride solutions prepared from hydrochloric acid, and aluminium hydroxide which has remained for a long time under aqueous ammonia, are coagulated to a greater extent by sulphuric acid than those prepared from the freshly-precipitated hydroxide.

H. G. C.

Action of Hydrogen Peroxide on Oxygen Compounds of Manganese.

By A. GORGEU (*Compt. rend.*, **110**, 857—859).—It is generally believed that when hydrogen peroxide is brought in contact with manganese peroxide, the former is rapidly decomposed into water and oxygen, whilst the latter remains unaltered. The exact nature of the change, however, depends on the conditions.

Pure crystallised manganese peroxide, obtained by heating manganous nitrate at 158—170°, decomposes hydrogen peroxide comparatively slowly, and if the latter is slightly alkaline, the manganese peroxide undergoes no change at all. If, however, the hydrogen peroxide is slightly acid, the proportion of peroxide in the manganese compound may be reduced by several per cents.

Hydrated manganese peroxide prepared in the cold immediately decomposes hydrogen peroxide, and the former also undergoes profound alteration to an extent depending on the proportion of the hydrogen peroxide. In one case the action of 1, 2, and 3 equivalents of hydrogen peroxide containing 4 to 5 vols. of oxygen on hydrated manganese peroxide containing 97·5 per cent. of the dioxide, reduced the proportion of the latter to 75, 73, and 70 per cent.

It follows that in the estimation of hydrogen peroxide, hydrated manganese peroxide should not be used; and even with the anhydrous manganese compound, there is risk of error unless the hydrogen peroxide is slightly alkaline.

The limit at which hydrogen peroxide has no action on manganese peroxide is represented by the basic manganite $MnO_2,2MnO,\frac{1}{4}H_2O$, which can be obtained by the prolonged action of a current of air on manganous hydrate suspended in its own mother liquor. Since hydrogen peroxide reduces only the oxides above this limit, it would seem that the oxidising action of the peroxide on manganous hydroxide ought to cease at the same point. This, however, is not the case; the manganous hydroxide can be oxidised even to a higher degree than the acid manganite MnO_2,MnO. The decomposition of hydrogen peroxide is more rapid in presence of a strong base, and the oxidation of the manganese is at first partly determined by the influence of the basic function of the manganous hydroxide, assisted afterwards by the acid function of the peroxide which is formed The higher oxidation may be regarded as due to the action of nascent oxygen. The author has previously shown that in contact with moist air the oxide $MnO_2,2MnO$ is converted into the compound MnO_2,MnO.

C. H. B.

Compounds of Ammonia with Metallic Permanganates. By T. Klobb (*Bull. Soc. Chim.* [3], 3, 508—510; compare Abstr., 1886, 983). By the action of ammoniacal solutions of copper, zinc, cadmium, and nickel sulphates on a saturated solution of potassium permanganate at 5—10°, the compounds $Cu(MnO_4)_2,4NH_3$, $Zn(MnO_4)_2,4NH_3$, $Cd(MnO_4)_2,4NH_3$, and $Ni(MnO_4)_2,6NH_3 + 2H_2O$ are obtained. These compounds exist either as minute, dark-violet crystals or powders, are very unstable, and explode on percussion, evolving ammonia, and leaving finely-divided oxides. They dissolve in water to dark-violet solutions which decompose rapidly with separation of manganese dioxide. Their solutions in dilute sulphuric acid are unstable.

T. G. N.

Liquation of Gold and Platinum Alloys. By E. Matthey (*Proc. Roy. Soc.*, 47, 180—186).—The author has investigated the composition of different parts of alloys containing gold and platinum, with or without admixture of copper and silver. He finds in the case of cast spheres containing respectively 88 per cent. of gold and 5 of platinum, and 70 per cent. of gold and 12 of platinum, that the platinum liquates from the gold on cooling, and becomes concentrated towards the centre of the spheres. Assays of the outer portions of such alloys are thus faulty. The same results were obtained whether the alloy consisted entirely of gold and platinum, or whether it contained in addition silver, or copper, or both. J. W.

Iridium Dioxide. By G. GEISENHEIMER (*Compt. rend.*, **110**, 855—857).—When potassium iridate is heated to redness in a gold crucible for about an hour with 15 times its weight of a mixture of potassium chloride and bromide in equivalent proportions, it is almost completely transformed into slender, microscopic needles with a very high lustre. The product is washed first with water and then with aqua regia, and can be dried at 100° or even 150° without decomposition. It consists of pure iridium dioxide, and when heated in hydrogen yields metallic iridium free from any trace of alkali.

The dioxide can also be obtained in an amorphous condition by heating iridium to bright redness in contact with the air or with oxygen. Whether crystallised or amorphous, iridium dioxide which has been prepared at a high temperature is not attacked by ordinary solvents.

Hydrated iridium dioxide is obtained (1) by boiling a 30 per cent. solution of potassium iridate with a large excess of ammonium chloride; (2) by boiling the blue basic iridate obtained in the preparation of potassium iridate with excess of ammonium chloride, a method which has the disadvantage that any silica, iron, or ruthenium present is precipitated at the same time; (3) by heating three parts of iridium to redness for 2 or 3 hours in a gold crucible with 10 parts of sodium hydroxide and 3 parts of sodium nitrate. The product seems to be sodium iridate, but is very unstable, and when boiled with water rapidly decomposes, oxygen being evolved and iridium dioxide precipitated. The dioxide is rapidly washed with ammonium chloride solution and dried at 100°; it is dissolved even by dilute acetic acid. A similar result is obtained with barium hydroxide and barium nitrate, but the separation of barium carbonate during subsequent operations is very inconvenient. C. H. B.

Mineralogical Chemistry.

Eukairite from Argentine. By R. OTTO (*Ber.*, **23**, 1039—1041). —The author has analysed a mineral obtained from Rioja, in the Argentine Republic, and finds it to be identical with eukairite, which occurs in small quantities in Småland, Sweden. The analysis showed that the mineral contains an equal number of atoms of silver, copper, and selenium, and agreed to a certain extent with Berzelius' analysis of the Swedish mineral. F. S. K.

Chemical Constitution of Talc. By F. W. CLARKE and E. A. SCHNEIDER (*Ber.*, **23**, 1537—1540).—Talc has usually been regarded as a magnesium hydrogen metasilicate, $H_2Mg_3(SiO_3)_4$, but lately Groth has proposed to regard it as a basic pyrosilicate, $Mg(Si_2O_5)_2(MgOH)_2$. The authors think Groth's formula incorrect because talc is scarcely attacked by hydrochloric acid; when heated for 15 hours at 400° in a current of hydrogen chloride, only 0·23 per cent. of magnesia is converted into chloride, and when digested with aqueous hydrochloric acid of sp. gr. 1·14 for 32 days, only 4 per cent. is converted. But minerals which contain the group $—Mg{\cdot}OH$ are easily decomposed by hydrochloric acid.

Further, if Groth's formula is correct, the molecule of talc should not be decomposed when heated, but should simply lose a molecule of water between the two (MgOH) groups. According to the usual formula, the following decomposition should take place:—

$$H_2Mg_3(SiO_3)_4 = H_2O + SiO_2 + 3MgSiO_3;$$

and, as a matter of fact, it is found that, after talc has been heated for half an hour over the blowpipe, it loses one fourth of its silica when boiled with aqueous soda, although before ignition it is unattacked by this agent. C. F. B.

Organic Chemistry.

Vapour-density and Melting Point of Cyanogen Iodide. By K. Seubert and W. Pollard (*Ber.*, 23, 1062—1065).—Vapour-density determinations of cyanogen iodide in V. Meyer's apparatus at 183° and 250° gave results which agree well with those required by molecular formula CNI; the compound undergoes slight dissociation, and iodine is deposited on the cooler portions of the tube. Cyanogen iodide melts at 146·5°, and solidifies again at 142·5°. F. S. K.

Thiocyano- and Selenocyano-derivatives. By L. Hagelberg (*Ber.*, 23, 1083—1092).—*Trimethylene thiocyanate*, $CH_2(CH_2{\cdot}S{\cdot}CN)_2$, is formed when trimethylene bromide is boiled with potassium thiocyanate in alcoholic solution. It crystallises in colourless plates, melts at 23°, and is soluble in alcohol, ether, and hot water. The *sulphide*, $C_3H_6S_2$, is obtained when the thiocyanate is treated with 25 per cent. alcoholic potash; it is a colourless, crystalline powder, melts at 71°, and is insoluble in water, alcohol, and ether, but soluble in benzene, cumene, nitrobenzene, warm potash, nitric acid, and sulphuric acid. The constitution of this compound is probably expressed by the formula $C_3H_6{<}\genfrac{}{}{0pt}{}{S_2}{S_2}{>}C_3H_6$, as when ethylene thiocyanate is treated with alcoholic potash, it is converted into diethylene tetrasulphide, $C_2H_4{<}\genfrac{}{}{0pt}{}{S_2}{S_2}{>}C_2H_4$.

Trimethylene mercaptan, $CH_2(CH_2{\cdot}SH)_2$, prepared by reducing the thiocyanate with zinc and hydrochloric acid, or by treating trimethylene bromide with potassium hydrosulphide in alcoholic solution, is a colourless, disagreeably smelling oil boiling at 169°. In its alcoholic solution, lead salts produce a yellow, copper sulphate a green, and mercuric chloride a colourless precipitate; it combines with yellow mercuric oxide very energetically, yielding a grey mass, and on oxidation it is converted into the sulphide described above.

Propylene thiocyanate, $CN{\cdot}S{\cdot}CHMe{\cdot}CH_2{\cdot}S{\cdot}CN$, is a brown oil which is insoluble in water and cannot be distilled; when treated with alcoholic potash, it is probably converted into the sulphide, which cannot, however, be isolated.

Propylene mercaptan, $SH{\cdot}CHMe{\cdot}CH_2{\cdot}SH$, is a colourless, disagreeably smelling oil boiling at 152°. It readily oxidises when heated in the air, being converted into the sulphide, and it combines very energetically with mercuric oxide; in its alcoholic solution, lead nitrate produces a yellow, and mercuric chloride a colourless precipitate.

An oil, probably *isobutylene mercaptan*, is formed in very small quantities, with evolution of butylene and hydrogen sulphide, when isobutylene bromide is treated with potassium hydrosulphide in dilute alcoholic solution; this mercaptan is also produced, but only in small quantities, when isobutylenedisulphonic chloride is reduced with zinc and sulphuric acid.

Trimethylene selenocyanate, $CH_2(CH_2{\cdot}Se{\cdot}CN)_2$, prepared by boiling trimethylene bromide with potassium selenocyanate in alcoholic solution, is a colourless, hygroscopic, crystalline compound melting at 51°; it has a disagreeable odour, is soluble in alcohol, ether, and glacial acetic acid, and is readily oxidised by warm nitric acid. The *selenide*, $(C_3H_6Se_2)_n$, obtained by treating the selenocyanide with alcoholic potash, melts at 54·5°, and is insoluble in ether, but soluble in benzene, glacial acetic acid, and hot alcohol.

Propylene selenocyanate, $CN{\cdot}Se{\cdot}CHMe{\cdot}CH_2{\cdot}Se{\cdot}CN$, is a colourless, crystalline, disagreeably smelling compound melting at 66°; it is soluble in ether, glacial acetic acid, benzene, and acetone, and decomposes on exposure to light with separation of selenium.

When isobutylene bromide is treated with potassium selenocyanate in alcoholic solution, the compound $C_3N_3Se_4K + H_2O$, described by Verneuil (Abstr., 1884, 1109), is produced.

Ethylene selenide, $(C_2H_4Se_2)_n$, is obtained when ethylene selenocyanate (m. p. 138°) is treated with alcoholic potash; it separates from ethylene bromide in crystals, melts at 130·5°, and is insoluble in alcohol and ether, and only sparingly soluble in benzene and glacial acetic acid.

F. S. K.

Preparation of Sodium Erythyroxide; Action of Erythrol on Alkali Alkyl-oxides. By DE FORCRAND (*Compt. rend.*, 110, 859—862, and 904—907).—See this vol., p. 935.

Alcoholic Fermentation of Invert Sugar. By U. GAYON and E. DUBOURG (*Compt. rend.*, 110, 865—868).—When invert sugar is fermented with ordinary yeasts, the lævorotatory power gradually increases, attains a maximum, and then decreases, finally becoming nil. This series of changes is due to the fact that the dextrose ferments more rapidly than the levulose. Most of the pure species of commercial yeasts behave in the same way, and the relation between the rotatory power and the total quantity of sugar fermented is represented by a parabolic curve, the form of which is constant for the same yeast under the same conditions, but varies considerably with different species. In some cases, the two sugars ferment at nearly the same rate, whilst with other species the dextrose ferments much more rapidly than the levulose. The curves are therefore more or less flattened, but their curvature is always in the same direction, and the liquid is always lævogyrate. They are but slightly modified by temperature, concentration, acidity, and other conditions. There are, however, four species of yeast which ferment levulose more rapidly than glucose. One of the most active of these is *Saccharomyces exiguus*, an inversive yeast. The rotatory power of the liquid rapidly diminishes, changes in sign, reaches a maximum, and then again decreases, finally becoming nil. The curves in the four cases are parabolic, but their curvature is in the opposite direction to that of the curves in the previous cases; they are also affected to a much greater extent by differences of temperature and the constitution of the fermented liquid. C. H. B.

Indian Geranium Oil. By F. W. SEMMLER (*Ber.*, **23**, 1098—1103; compare Dodge, this vol., p. 231).—Indian geranium oil, derived from *Andropogon schœnanthus*, L., has sp. gr. = 0·8869 at 16°, and a column 100 mm. long rotates the plane of polarised light 20′ to the left. It was fractionated under a pressure of 17 mm., and the fraction boiling at 120·5—122·5°, which amounted to 92 per cent. of the whole, was examined. It has the constitution $C_{10}H_{18}O$, and an index of refraction = 1·4745 at 20°, giving a refraction-equivalent of 48·71; hence, applying Brühl's method, it contains 2 ethylene unions. This is confirmed by the fact that 1 mol. unites with 4 atoms of iodine. Now a substance of the formula $C_{10}H_{18}O$ containing 2 ethylene unions cannot be a ring compound; it is therefore a doubly unsaturated alcohol, its alcoholic properties being otherwise known. When oxidised, 1 mol. yields 1 mol. of isovaleric acid. When cautiously treated with phosphoric anhydride and distilled at 17 mm., it yields a mixture of hydrocarbons, including a terpene boiling at 60—65°, and a polyterpene boiling at 205—215°; these have not yet been fully investigated, but they are certainly ring compounds. Indian geranium oil can therefore have either of the two formulæ:—$CHMe_2{\cdot}CH_2{\cdot}CH{:}CH{\cdot}CHMe{\cdot}CH{:}CH{\cdot}OH$ if optically active, and $CHMe_2{\cdot}CH_2{\cdot}CH{:}CH{\cdot}CMe{:}CH{\cdot}CH_2{\cdot}OH$ if optically inactive. Probably the latter is correct, as the ether, $(C_{10}H_{17})_2O$, readily yields a sulphide, $(C_{10}H_{17})_2S$. C. F. B.

Stereochemistry of Nitrogen-compounds. By C. WILLGERODT (*J. pr. Chem.* [2], **41**, 526—528).—The author has already published a paper touching on this subject (*J. pr. Chem.* [2], **37**, 449; Abstr., 1888, 949). The theories of Behrend (this vol., p. 575) as to the constitution of ammonia and its derivatives are very similar to those expressed in the said paper, which, however, Behrend has failed to notice. The existence of positive and negative poles in nitrogen-compounds cannot be supported by analogy with compounds of elements of the same group as nitrogen. A. G. B.

Chloramylamines. By A. Berg (*Compt. rend.*, **110**, 862—865).—*Chloramylamine* is obtained by treating a neutral solution of amylamine hydrochloride with a neutral solution of sodium hypochlorite containing a molecule of active chlorine for each molecule of the amine. The product is washed with water and dried over anhydrous sodium sulphate. It is an oily, almost colourless liquid, with a faint, pungent odour; sp. gr. at 0° = 0·968. It gradually solidifies and yields dichloramylamine, amylamine hydrochloride, and a liquid which is also obtained by the action of amylamine on dichloramylamine, and which has not yet been investigated. The same decomposition takes place with violent ebullition if a small quantity of the liquid is heated in a tube. Acids convert the chloramylamine into amylamine and dichloramylamine.

Dichloramylamine can also be obtained by the action of sodium hypochlorite (containing 2 mols. of active chlorine) on amylamine hydrochloride mixed with 1 mol. of hydrochloric acid. It is obtained most easily by the process used by Tcherniac for the preparation of dichlorethylamine. It is washed with dilute sodium thiosulphate solution, dilute sulphuric acid, and water, and dried over anhydrous sodium sulphate. It is a golden-yellow, oily liquid with a very irritating odour, and is stable when pure; sp. gr. at 0° = 1·063. It boils at 49° under a pressure of 14 mm., and at 58° under 22 mm. Under atmospheric pressure it boils at about 142°, but the greater part decomposes, and the decomposition may become explosive. A mixture of dichloramylamine (1 mol.) and amylamine (2 mols.) develops heat, and partially solidifies, with formation of amylamine hydrochloride, and a liquid which is under investigation.

Chlorodiamylamine is obtained by treating a warm solution of diamylamine hydrochloride with sodium hypochlorite, active chlorine and the amine being present in equal molecular proportions. It is a colourless, oily liquid with a feeble odour; sp. gr. at 0° = 0·897. It solidifies to a white mass at −20°, and at the ordinary temperature slowly decomposes and deposits white leaflets. When heated under atmospheric pressure, it decomposes with violent decrepitation, but under a pressure of 12 mm. it boils at about 89°. When mixed with amylamine, there is no reaction in the cold, but the mixture solidifies if heated. C. H. B.

Action of Ammonia on Di- and Tri-halogen Substitution-products of Hydrocarbons. By P. Galewsky (*Ber.*, **23**, 1066—1069).—When ethylene bromide (30 grams) is dissolved in a saturated alcoholic solution of ammonia (10 parts), and the mixture kept for 10 days at the ordinary temperature, and then evaporated on the water-bath, a residue is obtained which contains ethylenediamine; if this residue is dissolved in water, and treated with benzoic chloride, several grams of dibenzoylethylenediamine are obtained.

Propylene bromide is not acted on by alcoholic ammonia at the ordinary temperature, but at 100° the formation of the diamine takes place.

When allyl tribromide is treated with alcoholic ammonia at the ordinary temperature, or at 100°, it is converted into a bromallylamine, identical with the compound described by Paal and Hermann (Abstr., 1889, 116). The *benzoyl*-derivative, $C_3H_4Br{\cdot}NHBz$, crystallises from hot water in plates, and from light petroleum in needles, melts at 97—98°, and is insoluble in cold water, but soluble in hot benzene, ether, chloroform, and glacial acetic acid. F. S. K.

Constitution of the Cobalt-bases. By S. M. Jörgensen (*J. pr. Chem.* [2], **41**, 429—439).—The author discusses this question in the light of his experiments on the ethylenediaminepraseocobalt salts (see next abstract); the paper does not admit of useful abstraction.

A. G. B.

Metallic Diamine-compounds. By S. M. Jörgensen (*J. pr. Chem.* [2], **41**, 440—459; compare Abstr., 1889, 351).—*Ethylenediaminedichloropraseocobalt platinosochloride*, $2CoCl_3,4C_2H_4(NH_2)_2,PtCl_2$, is precipitated when the chloride is mixed with potassium platinosochloride; it forms dark-green, microscopic tables. The *bromide*, $CoCl_2Br,2C_2H_4(NH_2)_2$, is obtained when a solution of the chloride (2·7 grams) in water (10 c.c.) is mixed with strong hydrobromic acid (10 c.c.), and the resulting *hydrobromide* dried over potassium hydroxide; it is a green powder. The *dithionate* was also obtained.

Ethylenediaminedibromopraseocobalt bromide is best obtained by triturating the dichloro-chloride (5 grams) with freshly prepared silver oxide (12 grams) and water, filtering, adding strong hydrobromic acid (10—12 c.c.) to the filtrate, and evaporating to dryness; it is green, and is less soluble in water than the dichloro-chloride. Its reactions with various reagents are described. The *hydrobromide*, $CoBr_3,2C_2H_4(NH_2),HBr + 2H_2O$, the *nitrate*, $NO_3{\cdot}CoBr_2,2C_2H_4(NH_2)_2$, the *platinochloride* (with 3 mols. H_2O), the *platinobromide*, the *mercurobromide*, and the *dithionate* are described.

A series of violeocobalt salts, isomeric with the praseo-salts, have been obtained from the latter.

Ethylenediaminedichloroviolеocobalt chloride, $CoCl_3,2C_2H_4(NH_2)_2$, is obtained by evaporating a solution of the praseochloride (5 grams) in water (50 c.c.) to dryness, and drying the residue at 102—103° until it is constant in weight. As the conversion is not quite complete, the residue is washed with a little cold water until the washings appear of a deep-violet, and then with alcohol. The air-dried salt contains 1 mol. H_2O, and is a coarse, violet powder; it is less soluble than the praseo-salt, requiring 25 parts of cold water. It is insoluble in alcohol, but is precipitated with difficulty by that liquid from its aqueous solution; ether, however, precipitates it in flat, dichroic needles. Its aqueous solution becomes red after a time, from the formation of the roseo-salt, which is converted into the praseo-salt by sodium hydroxide or silver oxide; evaporation with hydrochloric acid also converts it into the praseo-salt. Its reactions with various reagents are given. The *platinochloride*, the *platinosochloride*, the *mercurochloride*, the *nitrate*, and the *dithionate* are described.

Amine-ethylenediaminechloropurpureocobalt chloride,

$$CoCl_3,2C_2H_4(NH_2)_2,NH_3 + 2H_2O,$$

is obtained when dilute ammonia is added to an aqueous solution of the dichloropraseo-chloride, and the whole evaporated to dryness; the residue is dissolved in water and concentrated over sulphuric acid, when the salt crystallises in large, dark-red needles. Its reactions are given, and the corresponding *platinochloride*, *platinosochloride*, *nitrate*, and *dithionate* are described. When the dichlorovioleo-chloride is similarly treated with ammonia, the same compound is obtained.

A. G. B.

Dimethylethylenediamine. By A. ANGELI (*Ber.*, **23**, 1357—1359).—Diacetyldioxime, on reduction with sodium in alcoholic solution according to Ladenburg's method, is readily converted into *dimethylethylenediamine*, which may be isolated by distilling the product of the reaction in a current of steam. It forms a crystalline, very hygroscopic hydrochloride, whilst the *aurochloride*,

$$(C_4H_{12}N)_2,2HAuCl_4,$$

forms orange-yellow crystals, moderately soluble in water and melting at 238°. The *oxalate*, $C_4H_{12}N_2,C_2H_2O_4$, forms small, white crystals, which are soluble in water but are reprecipitated from the solution by alcohol; it becomes yellow at 235°, and melts at 237·5—238°.

H. G. C.

Formaldehyde. By W. ESCHWEILER (*Chem. Centr.*, 1890, i, 582—583, from *Inaug. Diss. Univ. Rostock*).—The author has employed the method of Tollens and Loew for the preparation of formaldehyde. He finds that the best yield is obtained if the copper spirals are kept at such a low red heat that they can only be seen to glow in the dark. In the first receiver a product may then be obtained containing 40 per cent. of the aldehyde; the mixed products from all the receivers contained from 17 to 18 per cent. of the aldehyde.

The unpurified aldehyde solution contains formic acid, and after neutralising this with calcium hydroxide, it still becomes acid on exposure to the air.

The determination of the formaldehyde was made according to Legler's method (Abstr., 1889, 1250), also by oxidation with chromic acid. By distilling with a long (30 cm.) dephlegmator, a solution containing 20·99 per cent. by weight of formaldehyde was obtained. This boiled at 97·5—99° and had a sp. gr. of 1·063. Experiments made with the object of obtaining a more concentrated solution of the aldehyde by fractional distillation from 50° upwards, resulted in the formation of oxymethylene. On the other hand, oxymethylene decomposes again by protracted contact with water, and the nature of the resulting product, either formaldehyde or oxymethylene, is therefore under the will of the operator. The author finds that in dilute solutions the formaldehyde is almost pure. He was not able to prepare diformaldehyde or the α-trihydroxymethylene described by Pratesi. In the more concentrated solutions of formaldehyde, methyleneglycol appears to be present.

The author has prepared the sodium hydrogen sulphite compound, $NaHSO_3,CH_2O+H_2O$, crystallising in plates which disintegrate when exposed to the air; the corresponding potassium compound, $KHSO_3,CH_2O$, forms plate-like crystals.

Methylenedipiperidine, $CH_2(C_5NH_{10})_2$, a colourless oil with alkaline reaction, is prepared by the action of formaldehyde sodium hydrogen sulphite on piperidine in aqueous solution. It is but little soluble in water, readily soluble in alcohol, ether, chloroform, &c. Its sp. gr. = 0·9132 at 24°. It does not form salts. J. W. L.

Parapropaldehyde and Metapropaldehyde. By W. R. ORNDORFF (*Amer. Chem. J.*, **12**, 352—354).—When ordinary propaldehyde, boiling at 49°, is cooled in a freezing mixture and treated with a few bubbles of hydrogen chloride, *parapropaldehyde* and a small quantity of *metapropaldehyde* are simultaneously formed. After remaining in a freezing mixture, the metapropaldehyde may be collected. It is a light, crystalline solid resembling ordinary metaldehyde very closely; is insoluble in water, but dissolves in ether, chloroform, and benzene, more sparingly in alcohol and acetic acid. It melts at 180°, and, at temperatures slightly above, sublimes readily, forming fibrous, rounded needles, which show no crystal faces. Attempts to obtain derivatives were without success. Parapropaldehyde is present in the filtrate from the metapropaldehyde, and may be obtained from it by distillation under a reduced pressure of 50 mm., when it boils at 85—86°. It is a colourless liquid, lighter than water; has the odour of ordinary paraldehyde, and if cooled to −20°, forms a mass of crystals resembling those formed on cooling paraldehyde to 0°. It is not very soluble in water, and this property may be taken advantage of to separate it from propaldehyde, which is freely soluble. Both meta- and para-propaldehydes are converted into ordinary propaldehyde on heating with sulphuric or hydrochloric acids, a small amount of a tarry product being at the same time formed. G. T. M.

α-Dichloropropaldehyde. By W. SPRING and E. TART (*Bull. Soc. Chim.* [3], **3**, 402—405).—On fractionating the product of the action of dry chlorine on propyl alcohol, in addition to propyl chloride boiling at 47—50°, an oily liquid distilling at 120—150° is obtained, from which, after a time, small, colourless needles separate. These melt at 111—112°, and do not recrystallise on cooling, are insoluble in water, but very soluble in light petroleum, chloroform, ether, and alcohol, and are purified by recrystallisation from the latter solvent; at 100°, they sublime in long, nacreous needles.

When heated with moist silver oxide at 150—170° in sealed tubes, silver is deposited as a mirror, and silver chloride, carbonate, and acetate are formed; the original substance on reduction with zinc and acetic acid yields normal propyl alcohol. The crystalline substance is therefore a polymeride of *αα*-dichloropropaldehyde, $CH_3{\cdot}CCl_2{\cdot}COH$, which is isomeric with the *αβ*-derivative, $CH_2Cl{\cdot}CHCl{\cdot}COH$, obtained, by Aronstein, from acrolein.

The liquid from which these crystals separated contains the compound $CH_3{\cdot}CH_2CCl_3$, together with other chloro-derivatives.

T. G. N.

Action of Sodium on Acetone. By P. C. FREER (*Amer. Chem. J.*, 12, 355—357).—If acetone is treated with metallic sodium, a reaction takes place resembling that of sodium on methyl and ethyl alcohols, free hydrogen is evolved, and a white, flaky solid, sodium acetonate, is produced. The best results are obtained if the metallic sodium is finely powdered and covered with a large amount of anhydrous ether, the acetone mixed with four or five times its own volume of the same medium, and then slowly added to the sodium by means of a dropping-funnel, the whole operation being conducted in a stream of pure and dry hydrogen. By this means, the reaction is rendered less violent, only slight reduction of the acetone to isopropyl alcohol takes place, and the sodium acetonate separates in white flakes and may be freed from ether by placing it over solid paraffin, in a vacuum. The compound rapidly changes in presence of air, which explains the excess of sodium experimentally found over that calculated for C_3H_5NaO. On addition to hydrochloric acid, acetone is regenerated, and on exposure to air before addition to hydrochloric acid, an oil is formed which in all probability corresponds with that obtained by Fittig (*Annalen*, **110**, 25), who did not study the properties of the sodium compound, but contented himself with the preparation of pinacone. Attempts to prove the constitution of sodium acetonate by converting it into ethyl acetoacetate by the addition of ethyl chlorocarbonate were without success, an oily compound boiling at 185—200° being the chief product. G. T. M.

Products formed in the Distillation of Wood. By VLADESCO (*Bull Soc. Chim.* [3], 3, 510—514).—The author has examined two fractions obtained from the rectification of methyl alcohol. From one, passing over at 85—140°, he separated methyl propyl ketone, boiling at 101—103°, whilst the other sample, which distilled at 70—143°, consisted to the extent of 75 per cent. of methyl ethyl ketone boiling at 79—82°, which was also contained to a smaller extent in the former fraction. Acetone, toluene, and xylene also occurred. He suggests the material as a source for these compounds. T. G. N.

Action of Ethyl Iodide on Amido-acids. By E. DUVILLIER (*Bull. Soc. Chim.* [3], 3, 503—507).—When ethyl iodide is heated in a reflux apparatus with solutions of amido-α-butyric acid or of amidopropionic acid in alcoholic potash, care being taken to keep the mixture alkaline throughout the operation, there is formed in the former case diethamido-α-butyric acid, and in the latter case diethamido-α-propionic acid, which are characterised by their copper salts (compare Abstr., 1885, 750, and 1889, 1139). The yield is almost theoretical, and no betaïne is produced. T. G. N.

Action of Trimethylamine on Ethyl Bromisovalerate. By E. DUVILLIER (*Bull. Soc. Chim.* [3], 23, 507—508).—Trimethylamine (2 mols.), and ethyl bromisovalerate (1 mol.) are heated in sealed tubes at 90° for some hours. On cooling, much trimethylamine bromide separates. The mother liquor is treated with hot baryta-water to remove trimethylamine, neutralised by sulphuric acid, and distilled. After removal of bromine from the residue by silver oxide, platinic chloride is added, and tetramethylammonium platinochloride is precipitated, and, by subsequent careful crystallisation of the mother liquor, a small quantity of minute, transparent, orange prisms of a betaïne platinochloride separate, which contain 26·64 per cent. Pt, and correspond with the formula $COOH\cdot CHPr^{\beta}\cdot NMe_3Cl,PtCl_4 + 4H_2O$, being derived from some trimethylamidoisovaleric acid or methylisovalerylbetaine produced in the reaction. The distillate above mentioned contains dimethylacrylic acid amounting to 25 per cent. of the bromo-derivative employed and some isovaleric acid.

T. G. N.

Ethoxyacrylic Acid from α-Dichloropropionic Acid. By R. Otto (*Ber.*, 23, 1108—1110).—Merz has lately obtained this substance, $CH_2{:}C(OEt)\cdot COOH$, by treating α-dibromopropionic acid melting at 60—61° with alcoholic potash. Holst has prepared the same substance by treating with alcoholic potash the α-dichloropropionic acid boiling at 185—190°, which was obtained from the corresponding α-dichloropropionitrile, and first thoroughly investigated by the author. α-Dichloropropionic acid (1 mol.) was heated for three hours with alcoholic potash (4 mols.) in a sealed tube on the water-bath. Merz's method was then followed; the solution was freed from potassium chloride, the alcohol evaporated, and the residue extracted with ether. When evaporated, the ethereal solution left an oily residue; this was repeatedly treated with light petroleum, and the solution thus obtained concentrated, when a small quantity of white crystals of ethoxyacrylic acid was obtained, melting at 110° after recrystallisation from hot benzene. The author remarks in conclusion that in a paper published in conjunction with Beckurts (Abstr., 1885, 509), and apparently everlooked by Merz, he had already anticipated a portion of the latter's work.

C. F. B.

α-Dichloro-substitution Products of Dimethylsuccinic Acid. By R. Otto and G. Holst (*J. pr. Chem.* [2], 41, 460—483).—The authors have investigated the conditions most favourable for the production of α-dichloro-symmetrical-dimethylsuccinic (dichloradipic) and pyrocinchonic acids by the action of silver on dichloropropionic acid (Otto and Beckurts, Abstr., 1878, 290; 1885, 753). They find (1) that the more finely divided the silver, the more rapid is the process and therefore the purer the product; (2) that heating under pressure at a higher temperature accelerates the process, but increases the secondary products; (3) that the dichlorodimethylsuccinic acid is somewhat freely soluble in the oily secondary products and is thereby decomposed. The acids are best separated by dissolving them from the reaction-mass with ether, evaporating, picking out the crystals of α-dichloro-symmetrical-dimethylsuccinic acid from the yellow oily residue, and then adding water to precipitate the pyrocinchonic acid.

α-Dichloro-symmetrical-dimethylsuccinic anhydride, obtained by the action of acetic chloride or phosphoric chloride on the acid, forms small crystals of the consistency of camphor; it dissolves in the usual solvents and is converted into the acid by water. No geometrical isomeride of this dichlorodimethylsuccinic acid was obtained by heating the acid with its anhydride (compare the action of reducing agents, Abstr., 1885, 755). When the anhydride is treated with alcoholic ammonia, it is converted into *ammonium α-dichloro-symmetrical-dimethylsuccinamate;* this partially crystallises from hot alcohol in white, silky spangles. The free *acid* forms a white, crystalline powder. When the ammonium salt is heated in 50 per cent. alcohol for some time, carbonic anhydride is evolved, and ammonium chloride and *chlorotiglamide* separate; the latter forms prismatic crystals which melt at 108°.

When an aqueous solution of sodium α-dichloro-symmetrical-dimethylsuccinate is heated in a reflux apparatus, two α-methyl-β-chlorocrotonic acids, $C_5H_7ClO_2$ (chlorotiglic acid; Otto and Beckurts, *loc. cit.*), are formed together with methyl ethyl ketone. The mixture of the two acids melts at 55—68°, and by fractional crystallisation can be separated into lustrous, white, large, flat needles melting at 55—63°, and large, clear, rhombic prisms melting at 63—73°. By slowly subliming the crystals of lower melting point, needles are obtained which melt at 55°.

The acid of higher melting point is obtained, together with methyl ethyl ketone when α-dichloro-symmetrical-dimethylsuccinic acid is heated with water at 120°; it melts at 73°, and is more soluble in water than the acid melting at 55°; its crystallography is given. This acid is identical with the α-methyl-β-chlorocrotonic acid obtained by Rucker from methyl ethyl acetoacetate and phosphoric chloride.

These two acids are geometrical isomerides and may be formulated thus:  $\begin{array}{c}\text{Me·C·Cl}\\ \|\\ \text{Me·C·COOH}\end{array}$ (m.p. 73°), and  $\begin{array}{c}\text{Cl·C·Me}\\ \|\\ \text{Me·C·COOH}\end{array}$ (m.p. 55°).

When α-methyl-β-chlorocrotonic acid is heated with fuming hydrochloric acid at 140—150°, carbonic anhydride is separated, and a dichlorobutane is formed. A. G. B.

The so-called Dihydroxymaleic Acid. By W. S. HENDRIXSON (*Amer. Chem. J.*, **12**, 325—329).—The announcement of the discovery of this acid was made by Bourgoin (this Journal, 1873, 1021; 1875, 356), who claimed to have prepared it by the action of water on the silver salt of dibromomaleic acid. As some doubt has been thrown on the existence of the acid by Scherks (*Annalen*, **207**, 223), the author has thought it desirable to repeat Bourgoin's work. The dibromomaleic acid needed was obtained by the oxidation of mucobromic acid with cold fuming nitric acid, and the pure silver salt prepared. This was heated with water in sealed tubes at 150°, according to the method employed by Bourgoin. On opening the tubes, which contained a considerable quantity of silver bromide, much carbonic anhydride escaped. The strongly acid contents of the tube were steam-distilled, when the whole of the acid readily volatilised, and was found to consist entirely of acetic acid. The author supposes that, in this reaction, the formation of acetic acid is preceded by that of the ketonic acid, COOH·CO·CH(OH)·COOH, which would readily give rise to acetic acid and 2 molecules of carbonic anhydride.

G. T. M.

Acetone-chloroform; Chlorisobutyric Trichloride; Ethyl Acetone-chloroform. By C. WILLGERODT and S. SCHIFF (*J. pr. Chem.* [2], **41**, 515—526).—*Chlorohydroxyoxydipropionic acid,*

COOH·CMe(OH)·O·CMeCl·COOH,

is the product of the action of sulphuric acid (100 grams) on acetone-chloroform (10 grams), and is extracted by ether from the reaction-mass; it forms large, white, feathery crystals melting at 31·5° and boiling at 183°. It is very deliquescent and soluble in all solvents. It appears to be a bibasic acid. The *barium, lead*, and *copper* salts (each with 2 mols. H_2O), and *cobalt* and *nickel* salts were obtained.

Oxydiethylidenelactic acid, O[CMe(OH)·COOH]$_2$, is obtained as its *primary potassium salt* when the above acid is neutralised with potash; the liquid becomes slightly warm and potassium chloride separates out. If the liquid is hot to begin with, the *secondary potassium salt* is formed. The free acid does not crystallise.

The action of phosphoric acid, hydrochloric acid, nitric acid, and ammonia respectively on acetone-chloroform is described, but only indefinite products were obtained. Aqueous alcoholic potash converts acetone-chloroform into α-hydroxyisobutyric acid (m. p. 79°); potassium anilide converts it into phenylcarbylamine and acetone; with iodine and potassium hydroxide, carbonic oxide, potassium formate, iodide, and chloride, iodoform and water are formed; the action of bromine is similar to that of iodine; that of sulphur at 270° produces organic sulphur compounds. The action of methyl iodide in the presence of sodium, and of zinc ethide, produced no definite results. The action of ethyl sodacetoacetate produces three *compounds:* $C_{10}H_{17}O_6Cl$ = OH·CMe$_2$·CCl(CH$_2$·COOEt)·CH$_2$·COOH, an oil which boils at 175—178°; $C_{14}H_{24}O_7$ = OH·CMe$_2$·C(CH$_2$·COOEt)$_2$·CH$_2$·COOH, slender needles melting at 62°; $C_{10}H_{16}O_7$ = OH·CMe$_2$·C(CH$_2$·COOH)$_3$, an oil.

Asymmetrical dimethyltetraphenylethane, CPh$_3$·CMe$_2$Ph, is obtained by dissolving chlorisobutyric trichloride (20 grams) in excess of benzene and decomposing it with aluminium chloride; the reaction-mass is decomposed with water, distilled, and redistilled. This hydrocarbon is a pale yellow, aromatic oil boiling at 272°.

Tetramethylhexaphenylethyl ether, O(CMe$_2$·CPh$_3$)$_2$, is obtained by heating a mixture of "acetone-chloroform ether," aluminium chloride, and a large excess of benzene for four days in a reflux apparatus. It is an aromatic oil which boils at 262° (uncorr.).

A *compound*, $C_{10}H_{17}Cl_3O_3$, is obtained when "acetone-chloroform ether" is heated with alcoholic potash in a reflux apparatus; it is an oil which boils at 166° (uncorr.).

A. G. B.

Derivatives of Furfuracrylic Acid. By H. B. GIBSON and C. F. KAHNWEILER (*Amer. Chem. J.*, **12**, 314—325).—*Methyl furfuracrylate*, $C_7H_5O_3Me$, is prepared by treating carefully dried silver furfuracrylate with excess of methyl iodide, exhausting the product with ether, and purifying by distillation under reduced pressure. It distils unchanged at 112° under a pressure of 15 mm., and the distillate, on cooling, solidifies to beautiful, rhombic crystals, which melt at 27°, dissolve readily in alcohol and ether, and have a characteristic odour.

Furfuracrylamide, $C_7H_5O_2{\cdot}NH_2$, is obtained when methyl furfuracrylate is heated at 100° in sealed tubes with aqueous ammonia. It is sparingly soluble in cold water, and crystallises from hot water in pearly scales melting at 168—169°.

Bromofurfurodibromopropionic acid, $C_7H_5Br_3O_3$, is formed when furfuracrylic acid (1 mol.), suspended in carbon bisulphide, is treated with dry bromine (2 mols.). It crystallises in small, flat, oblique prisms, which are sparingly soluble in cold benzene and carbon bisulphide, but readily dissolve in alcohol and ether. When the acid is allowed to remain suspended in water for some time, carbonic anhydride escapes, and the crystalline solid is converted into *bromofurfurobromethylene*, a colourless oil, which, on treatment with alcoholic potash, gives the corresponding acetylene-derivative, a substance which cannot be readily purified, but forms with ammoniacal silver a white, and with ammoniacal copper a green, insoluble, metallic derivative. The latter, on oxidation with potassium ferricyanide, gives rise to *dibromodifurfurodiacetylene*, $C_4H_2BrO{\cdot}C{:}C{\cdot}C{:}C{\cdot}C_4H_2BrO$, a compound dissolving readily in all ordinary solvents except water, and crystallising from alcohol in small, iridescent plates melting at 126°.

Bromofurfuracrylic acid is obtained by treating an alcoholic solution of bromofurfurdibromopropionic acid with zinc-dust, which removes the bromine attached to the side chain only. It crystallises in long, slender prisms, which are sparingly soluble in cold water, more readily soluble in hot water, and dissolve readily in other common solvents, except light petroleum. It melts sharply at 176—177°, but is somewhat blackened by long-continued heating at temperatures above 150°, may be readily sublimed, and on treatment with bromine forms the original substituted propionic acid. The barium salt, $Ba(C_7H_4BrO_3)_2 + H_2O$, is sparingly soluble in cold water, and crystallises from hot water in clusters of needles; the calcium salt, $Ca(C_7H_4BrO_3)_2 + 3H_2O$, crystallises from hot water in columnar aggregations of plates; the sodium salt crystallises from cold water, in which it is readily soluble, in anhydrous nodular aggregates; the silver salt, $C_7H_4BrO_3Ag$, is nearly insoluble in water, and seems to be amorphous; the ethyl salt, $C_7H_4BrO_3Et$, crystallises from light petroleum in large, flat prisms melting at 42°.

Bromofurfurobromacrylic Acid.—The ammonium salt of this acid is formed by heating bromofurfurodipropionic acid in shallow vessels at 130°, boiling the residue with dilute ammonia, treating the solution with charcoal, and allowing it to crystallise. It forms sparingly soluble masses consisting of slender, felted needles, and on treatment with a dilute acid, yields the free acid, which crystallises in fine needles, melts at 178—179°, and may be readily sublimed. The barium salt, $Ba(C_7H_3Br_2O_3)_2 + 2H_2O$, is only sparingly soluble in boiling water, and forms lustrous scales; the silver salt is an amorphous powder; the potassium salt, $KC_7H_3Br_2O_3$, crystallises from hot water in clusters of slender needles; the ethyl salt, $EtC_7H_3Br_2O_3$, crystallises from light petroleum in radiated groups of needles which melt at 55—56°.

The analogies offered by the derivatives of pyromucic and cinnamic acids suggest the following constitutional formulæ for the above described compounds:—For bromofurfurodibromopropionic acid,

$$\left.\begin{array}{l}CH\cdot CH\\ \|\\ CBr\cdot O\end{array}\right\rangle C\cdot CHBr\cdot CHBr\cdot COOH;$$

for bromofurfurobromethylene,  $\left.\begin{array}{l}CH\cdot CH\\ \|\\ CBr\cdot O\end{array}\right\rangle C\cdot CH{:}CHBr$; for bromofurfurobromacrylic acid,  $\left.\begin{array}{l}CH\cdot CH\\ \|\\ CBr\cdot O\end{array}\right\rangle C\cdot CH{:}CBr\cdot COOH$; and for bromofurfuracrylic acid,  $\left.\begin{array}{l}CH\cdot CH\\ \|\\ CBr\cdot O\end{array}\right\rangle C\cdot CH{:}CH\cdot COOH$.

G. T. M.

Condensation of Benzene and Acetylene under the Influence of the Silent Discharge. By P. SCHUTZENBERGER (*Compt. rend.*, 110, 889—892; compare this vol., pp. 691, 692).—The tubes containing the benzene and acetylene were hermetically sealed, and thus the contents were cut off from any possible absorption of moisture from the air. It was found that after the discharge had been continued for five or six hours, the inner tube was very liable to break, a result due, according to the author, to the fact that the prolonged action of the discharge makes the glass brittle. If the tubes are quite vacuous, fracture takes place after a very few minutes.

Under the influence of the discharge, benzene vapour gradually condenses to a pale-yellow, resinous, transparent solid, the liquid benzene gradually disappearing. The product contains C, 85·9 to 91·63; H, 7·1 to 7·81; O, 0·7 to 7·0 per cent. The oxygen could not have been absorbed during the short time between opening the tube and weighing the substance; in fact, although the product does absorb oxygen from the air, the increase in weight is only 1 to 2 milligrams in more than an hour. Moreover, the composition of the product depends on whether it is formed on the inner tube or the outer tube.

	C.	H.	O.
Inner tube.........	90·54	7·30	2·10
Outer tube	87·14	7·48	5·38

The results agree with those obtained with acetylene, which gives a product containing 2 to 5 per cent. of oxygen. In one experiment, after 250 c.c. of acetylene had been almost completely condensed over mercury, hydrogen was introduced, and the passage of the spark continued. A reduction of volume ensued equal to the volume of acetylene remaining, and the contraction then ceased. The product contained C, 75·0; H, 8·9; O, 16·1 = 100, a result which, from the quantity of acetylene used, indicates that 0·02 gram of water had passed through the glass. The product did not absorb oxygen from the air. The glass was not affected.

C. H. B.

The Second Monobromobenzene. By F. FITTICA (*Ber.*, 23, 1398—1400).—A reply to the paper of A. Hand (this vol., p. 881) on this subject. The author gives details of the method he employed for the preparation of the compound, to which he assigned the formula $(PhBr)_2,C_6H_6$. J. B. T.

Preparation of Phenyl Cyanate. By B. KÜHN and M. LIEBERT (*Ber.*, 23, 1536—1537).—Phenylthiocarbimide (50 grams = 1 mol.) was heated at 170° in a reflux apparatus with well dried red oxide of mercury (80 grams = 1 mol.) mixed with some coarse glass powder. After heating for eight hours, the liquid was fractionated; the portion coming over below 170° was pure phenyl cyanate, and amounted to 20 per cent. of the theoretical yield; the rest was unattacked phenylthiocarbimide. If a larger proportion of mercuric oxide is used, the yield is lessened. C. F. B.

Action of Lead Oxide on Toluene. By C. VINCENT (*Compt. rend.*, 110, 907—908).—When toluene is allowed to fall drop by drop on lead monoxide heated to a few degrees below its melting point (335°), the lead is reduced to the metallic state, carbonic anhydride is given off, and about 10 per cent. of benzene is formed, together with a very small quantity of stilbene, and higher products, $C_6H_5{\cdot}CH_3 + 3PbO = 3Pb + C_6H_6 + CO_2 + H_2O$.

At the melting point of the lead oxide, very little benzene is formed, and the product consists chiefly of stilbene mixed with oily hydrocarbons, the principal reaction being $2C_6H_5{\cdot}CH_3 + 2PbO = C_6H_5{\cdot}CH{:}CH{\cdot}C_6H_5 + 2H_2O + 2Pb$.

At incipient redness, diphenyl, phenanthrene, anthracene, and other pyrogenic derivatives of benzene and toluene are obtained, together with the preceding products. C. H. B.

Nitration of Propylbenzene. By R. LESPIEAU (*Bull. Soc. Chim.* [3], 3, 502—503).—From the liquid resulting from the action of a boiling mixture of nitric and sulphuric acids on propylbenzene or isopropylbenzene for several hours, small crystals of paranitrobenzoic acid separate on cooling. The liquid contains oily products which decompose even when distilled under reduced pressure, but by steam distillation, a nitropropylbenzene is obtained. By prolonged nitration of propylbenzene or isopropylbenzene, a mixture of dinitroacids melting at 176°, and containing much 1 : 2 : 4-dinitrobenzoic acid, is formed. T. G. N.

Behaviour of Sodiophenylmercaptide with Isobutylene Bromide. By R. OTTO (*Ber.*, 23, 1051—1052).—When isobutylene bromide is treated with sodiophenylmercaptide, phenyl bisulphide, isobutylene, and sodium bromide are formed; trimethylethylene bromide seems to behave in a similar manner. F. S. K.

Synthesis of Ketones from Phenol Ethers by Friedel and Crafft's Method. By L. GATTERMANN, R. EHRHARDT, and H. MAISCH (*Ber.*, 23, 1199—1210).—As already shortly mentioned (Abstr., 1889, 862), acid chlorides react with phenol ethers in presence of aluminium chloride in just the same way as with the aromatic hydrocarbons, resembling in this respect phenyl cyanate and chloroformamide. The reaction is carried out by mixing the phenol ether and chloride in equivalent proportions (unless the chloride is very volatile, in which case an excess of that constituent is taken), adding carbon bisulphide as a diluent, and then gradually adding a quantity of aluminium chloride equal to $1\frac{1}{2}$ times or twice the quantity of phenol ether. The reaction is carried out in the cold, but may, if necessary, be started by gently warming. After allowing the mixture to remain for an hour, during which time it is frequently shaken, it is warmed for a few minutes on the water-bath, and the upper layer then poured off. The black aluminium double compound is washed with carbon bisulphide, and very carefully decomposed by water, the ketone separating as an oil or in crystals. In the latter case, it is simply filtered off and recrystallised from hot water, but in the second, it must be first taken up with ether, the ether evaporated off, and the residue purified either by distillation, or allowing it to remain until it crystallises.

Anisoïl and acetic chloride yield an oil, which on treatment with alcohol leaves a small quantity of dimethoxydiphenylethylene, $C_2H_2(C_6H_4{\cdot}OMe)_2$. After evaporating off the alcohol from the filtrate, the residual oil is distilled. The fraction boiling at 250—275° solidifies on cooling almost entirely, and is separated from the adhering oil by spreading on a porous plate, and recrystallising from ether. It then forms large, tabular crystals, melting at 38—39°, and boiling without decomposition at 258°. The analysis showed that *acetylanisoïl*, $C_6H_4Ac{\cdot}OMe$, had been formed. It unites with phenylhydrazine and hydroxylamine, forming crystalline derivatives, and, like many of the ketones to be described, gives very characteristic colour reactions with concentrated mineral acids. Thus, with concentrated sulphuric acid, it forms a deep, yellowish-red coloration, and with nitric acid, gives a magenta tint. On warming with the latter, it yields a substance probably belonging to the group of "nitro-sacyls" discovered by Hollemann. On oxidation acetylanisoïl yields anisic acid, showing that, as in the case of phenyl cyanate and chloroformamide, substitution has taken place in the para-position. The *paracetylanisoïl* described by Olivieri (*Gazzetta*, **13**, 275) as boiling at 220—222° must either have been impure, or have a different constitution.

Propionic chloride and anisoïl yield also a disubstituted propylene in small quantity, but the chief product is *parapropionylanisoïl*, $COEt{\cdot}C_6H_4{\cdot}OMe$. This forms colourless tablets which melt at 27°, and boil at 273—275°. It also yields anisic acid on oxidation, and forms an oxime, which crystallises from alcohol in colourless needles melting at 67°.

Benzoic chloride and anisoïl yield parabenzoylanisoïl, which forms large crystals melting at 61—62°. This compound has been previously obtained by Rennie by the oxidation of parabenzoylphenyl methyl ether (Trans., 1882, 220).

Phenetoïl combines with acetic chloride forming *acetylphenetoïl*, $C_6H_4Ac{\cdot}OEt$, which crystallises in six-sided tablets melting at 60—61°, and yields parethoxybenzoic acid on oxidation. Phenetoïl and propionic chloride yield *propionylphenetoïl*, $COEt\cdot C_6H_4\cdot OEt$, melting at 30°. Its oxime melts at 97°. Isobutyric chloride forms *isobutyrylphenetoïl*, which also forms a crystalline oxime, the melting points of the two compounds being 41° and 110—111° respectively. Benzoic chloride yields *parabenzoylphenetoïl*, which crystallises from acetic acid in silky plates melting at 38—39°, and distils above 300° without decomposition.

Resorcinyl diethyl ether is also acted on in the same manner by acetic and propionic chlorides, *acetylmetadiethoxybenzene* and *propionylmetadiethoxybenzene* being produced. The former crystallises in large, slightly pink needles melting at 67—68°, which give a beautiful green coloration with nitric acid. The second compound forms large, lustrous crystals melting at 76°, and yields an oxime melting at 133°. In neither of these cases is any unsaturated compound formed.

In addition to the above, the following compounds have been obtained from the corresponding naphthol ethers:—*Acetyl-α-naphthyl methyl ether*, crystallising in six-sided tables which melt at 71—72°, the acetyl group probably occupying the para-position; *propionyl-α-naphthyl methyl ether*, forming large prisms which melt at 58°, and yield an oxime melting at 172°; *acetyl-α-naphthyl ethyl ether*, crystallising in prisms which melt at 78—79°; *benzoyl-α-naphthyl ethyl ether*, melting at 74—75°; *acetyl-β-naphthyl methyl ether*, which forms slender, colourless needles melting at 57—58°; and, finally, *acetyl-β-naphthyl ethyl ether*, crystallising in large tables which melt at 62—63°.

In all these cases, the crystals are sufficiently large for the measurement of the angles, and might perhaps afford material for an examination of the relation between crystalline form and constitution. The same rule also appears to hold as in the case of phenyl cyanate and chloroformamide, namely, that substitution takes place in the para-position, unless that is previously occupied. In certain cases, an unsaturated alkylene compound is also formed. H. G. C.

Hexachlor-α-diketohexene. By T. ZINCKE (*Ber.*, 23, 1334—1338).—Like the corresponding tetrachlororthoquinone, chloranil only takes up 2 atoms of chlorine on treatment with that reagent, forming a compound which has probably the formula  $\begin{array}{l} CCl\cdot CO\cdot CCl_2 \\ \| \qquad\qquad | \\ CCl\cdot CO\cdot CCl_2, \end{array}$ and may be termed for the present hexachlor-α-diketohexene. It is a colourless compound, insoluble in water, readily soluble in alcohol and ether, and melts at 88°. On further heating at the ordinary pressure, it loses chlorine, but may be distilled unchanged under diminished pressure. On reduction it yields tetrachloroquinol, and on energetic treatment with phosphorus pentachloride forms hexachlorobenzene. Less energetic treatment converts it into a compound containing phosphorus and chlorine, which is decomposed by water with formation of the compound $C_6Cl_5\cdot OPO(OH)_2$, which may also be obtained in a similar manner from chloranil. On treatment with sodium hydroxide, it is converted into dichloromaleic acid, and an oily compound, probably tetrachlorethane. Contrary to the statement of

Kauder (Abstr., 1885, 652), and Ciamician (Abstr., 1884, 293), dichloromaleic acid, although extremely soluble in water, is not hygroscopic.

By the action of aniline, the compound  $\begin{array}{lll}\mathrm{CCl_2} & \mathrm{{\cdot}CO{\cdot}} & \mathrm{C{\cdot}NHPh}\\ | & & \|\\ \mathrm{CCl_2} & \mathrm{{\cdot}CO{\cdot}} & \mathrm{CCl}\end{array}$ is formed; it is a red, crystalline substance melting at 144°, and is converted by reduction into anilidotrichloroquinone. On treatment with alkali, it yields the sodium salt of an acid having the formula $C_{12}H_6Cl_3NO_3$, which readily loses carbonic anhydride, forming an indifferent compound of the formula $C_{11}H_6Cl_3NO$. As it also contains the phenyl-group, its formula may be written $C_5Cl_3NOPh{\cdot}COOH$. It appears probable that by the action of the alkali the ring is split, with formation of the compound $CCl_2{:}CCl{\cdot}CO{\cdot}CCl{:}C(NHPh){\cdot}COOH$, and that this loses another molecule of hydrogen chloride, forming *phenyltrichloropyridonecarboxylic acid*,  $\begin{array}{lll}\mathrm{CCl} & \mathrm{{\cdot}NPh{\cdot}} & \mathrm{C{\cdot}COOH}\\ \| & & \|\\ \mathrm{CCl} & \mathrm{{\cdot}CO{\cdot}} & \mathrm{CCl}\end{array}$. This melts at 245° with evolution of carbonic anhydride, and is soluble without decomposition in hot water, cold alcohol, and cold soda solution. On heating with the latter, one chlorine-atom is replaced by hydroxyl, forming *phenyldichlorohydroxypyridonecarboxylic acid*, $OH{\cdot}C_5NPhCl_2O{\cdot}COOH$, melting at 206°, which yields a *dimethyl* salt, and a *silver* salt containing two atoms of silver. On boiling with acetic anhydride, it loses carbonic anhydride, and forms *acetylphenyldichlorohydroxypyridone* melting at 143°. The indifferent compound $C_{11}H_6Cl_3NO$, or *phenyltrichloropyridone*, melts at 245°.

Methylamine also readily acts on hexachloro-α-diketohexene, but the compound obtained is colourless, and has quite different properties to the anilide. It is now being more closely investigated.

H. G. C.

A New Hydroxythymoquinone. By G. Mazzara (*Ber.*, **23**, 1390—1392).—Two hydroxythymoquinones are theoretically possible, namely, [Me : OH = 1 : 2] and [Me : OH = 1 : 5]. The former of these, the α-compound, melting at 166—167°, has long been known; the latter, the β-compound, is obtained by reducing dinitrocarvacrol and oxidising the product with ferric chloride. The quinone is purified by distillation in a current of steam; it crystallises from dilute alcohol in long, prismatic, dark orange-yellow plates, melting at 181—183°. Hydroxythymoquinone dissolves in alkaline carbonates, the solution becoming violet in colour.

J. B. T.

Safrole. By G. Ciamician and P. Silber (*Ber.*, **23**, 1159—1164).—In the course of their investigation of apiole, it appeared to the authors advisable to examine also the properties of the analogous compounds safrole and methyleugenol. Some of the results given in this paper have also been recently published by Eykman (this vol., p. 748) in agreement with whom the authors find that the isafrole obtained by Poleck (Abstr., 1884, 1339) and Schiff (Abstr., 1884, 1338), by the action of sodium and solid potassium hydroxide on safrole under pressure, may be more readily prepared by warming safrole with alcoholic potash. It forms an oil boiling at 246—248°, remaining solid at —18°, miscible with alcohol, ether, and benzene, but insoluble in water and alkalis. Its molecular weight was found by Raoult's method to be 159, which agrees with the formula $C_{10}H_{10}O_2$. Like safrole, it dissolves in concentrated sulphuric acid with an intense red coloration.

With potassium dichromate and sulphuric acid, isafrole yields piperonal and acetaldehyde, the oxidation proceeding therefore in the same manner as with isapiole. Alkaline potassium permanganate, on the other hand, converts it into piperonylic acid, and a ketonic acid which appears to be *dioxymethylenephenylglyoxylic acid*,

$$\mathrm{CH_2}{<}\substack{\mathrm{O}\\ \mathrm{O}}{>}\mathrm{C_6H_3{\cdot}CO{\cdot}COOH},$$

which may be shortly termed *piperonylketonic acid*. It crystallises from water in pale-yellow needles which melt at 148—149°, and from benzene in needles containing benzene of crystallisation melting at 130—140°, which do not lose all their benzene at 100°. It gives a yellow compound with phenylhydrazine. The *silver* salt, $C_9H_5AgO_5$, crystallises from hot water in lustrous prisms.

Whereas safrole is scarcely acted on by reducing agents, isafrole is readily converted by sodium in alcoholic solution into dihydrosafrole, an almost colourless liquid boiling at 228°, miscible with alcohol, ether, benzene, and acetic acid. It gives with concentrated sulphuric acid, first a yellow, and then a red coloration. It is in all probability formed by the addition of two hydrogen-atoms to the allyl-group, and would thus have the constitution  $\mathrm{CH_2}{<}\substack{\mathrm{O}\\ \mathrm{O}}{>}\mathrm{C_6H_3Pr^{\alpha}}$. The aqueous alkaline solution contains a substance having the composition and properties of a propylphenol, corresponding closely with the metapropylphenol described by Jacobsen (Abstr., 1878, 732). It could only be obtained, however, as a liquid, whereas Jacobsen gives its melting point as 26°.

Its methyl ether, which boils at 212—213° (corr.), yields on oxidation with alkaline potassium permanganate metamethoxybenzoic acid. It follows, therefore, that, on reduction, isafrole loses the atom of oxygen occupying the para-position.

Bromine acts on isafrole in carbon bisulphide solution, forming monobromisafrole dibromide, $C_{10}H_9BrO_2,Br_2$, which crystallises from light petroleum in colourless, lustrous needles melting at 109—110°.

H. G. C.

Eugenol. By G. CIAMICIAN and P. SILBER (*Ber.*, 23, 1164—1167). —Unlike safrole (see preceding abstract) eugenol is not completely converted by alcoholic potash into an isomeride. The methyl ether, however, prepared by the action of methyl iodide and potash on eugenol, is readily and completely converted into isomethyleugenol. The first-named methyl ether boils at 247—248°, whilst the isomeride forms a colourless, almost odourless liquid boiling at 263°. On oxidation with sulphuric acid and potassium dichromate, it is converted into methylvanillin and veratric acid, whilst with alkaline potassium permanganate it yields the latter acid, and a new compound which has the composition $C_{10}H_{10}O_5$, and crystallises from water in white, nodular aggregates or large needles melting at 137°. It is also soluble in alcohol, ether, acetic acid, and benzene, the crystals obtained from the latter containing benzene of crystallisation. It combines with phenylhydrazine, and is probably *dimethoxyphenylglyoxylic acid*, $(CH_3O)_2{\cdot}C_6H_3{\cdot}CO{\cdot}COOH$.

Like isapiole and isafrole, the methyl ether of isoeugenol readily takes up 2 atoms of hydrogen when treated with sodium in hot alcoholic solution. The hydromethyleugenol thus obtained is an oil resembling hydrosafrole in smell, which boils at 246°, and dissolves in concentrated sulphuric acid on warming, forming a pale-red solution.

Isomethyleugenol also combines with bromine forming *isomethyleugenol dibromide*, $C_{11}H_{14}Br_2O_2$, which crystallises from light petroleum in colourless crystals melting at 101—102°. It is soluble in ether, chloroform, and benzene, and insoluble in water, but melts on boiling with the latter, and imparts to it an acid reaction. H. G. C.

Diamidoquinol Ether and Dihydroxyquinone Ether. By R. Nietzki and F. Rechberg (*Ber.*, **23**, 1211—1217).—It was shown 10 years ago, by Nietzki (Abstr., 1879, 464), that quinol diethyl ether, on treatment with nitric acid, yields a mixture of two dinitro-derivatives, which may be separated by their different solubility in acetic acid, alcohol, or ethyl acetate. As the α-compound gave on reduction a diamido-compound which could be readily converted into an azimido-derivative, it appeared probable that the nitro-groups in that compound occupied the ortho-position.

The re-examination of these compounds has shown that the dinitro-compounds may be readily reduced by a mixture of stannous chloride, concentrated hydrochloric acid, and alcohol, and the amido-compounds then obtained in the form of hydrochlorides by passing in hydrogen chloride, and decomposing the precipitated stannochloride with hydrogen sulphide. It was found that the β-compound may be readily obtained free from the α-compound, but the α-compound invariably contains small quantities of its isomeride.

α-Diamidoquinol diethyl ether hydrochloride forms large needles which become grey in the air. Nitrous acid readily converts it into the azimide previously described, and it also unites with diacetyl, benzile, and phenanthraquinone, forming quinoxalines melting at 127°, 163°, and 260° respectively. There can therefore be no doubt that the amido-groups occupy the ortho-position.

β-Diamidoquinol diethyl ether may be readily separated from the α-compound by adding sulphuric acid and alcohol to the mixture of their hydrochlorides, when the sulphate of the β-compound separates out in colourless needles. Both the hydrochloride and sulphate are converted by ferric chloride into a substance which crystallises in pale-yellow plates melting at 183°. It is free from nitrogen, and has the formula $C_{10}H_{12}O_4$, and on treatment with caustic potash is converted into the symmetrical dihydroxyquinone obtained by Nietzki and Schmidt from di-imidoresorcinol. The oxidation-product must therefore be the diethyl ether of this substance, and has the constitution $O_2 : OEt_2 = 1 : 4 : 3 : 6$. It follows, therefore, that β-diamidoquinol diethyl ether has also the symmetrical constitution.

When dihydroxyquinone diethyl ether is treated with stannous chloride, hydrochloric acid, and alcohol, it is converted into *tetrahydroxybenzene diethyl ether*, $C_6H_2(OH)_2(OC_2H_5)_2$, which crystallises from water in beautiful needles melting at 138°, and yields a diacetyl compound which melts at 148°. On treatment with the requisite quantity of sodium ethoxide and ethyl bromide or iodide, it forms *tetrethoxybenzene*, which crystallises in colourless, lustrous plates, melts at 143°, and sublimes very readily.

Dihydroxyquinone diethyl ether yields with hydroxylamine a dioxime which is as good as insoluble in all ordinary solvents, and melts above 300°.

The compound obtained by Habermann (Abstr., 1878, 728) by acting on quinol dimethyl ether with nitric acid has proved on examination to be a mixture of two isomeric dinitro-compounds, which may be separated by fractional crystallisation from ethyl acetate. The more readily soluble compound melts at 177°, and the second at 202°. The amido-derivatives obtained by Karioff by the reduction of Habermann's compound (Abstr., 1881, 272) must also be a mixture. The nitro-derivative melting at 177°, on reduction with stannous chloride, hydrochloric acid, and alcohol, yields a diamido-compound which shows all the properties of an ortho-derivative, combining with diacetyl, benzile, and phenanthraquinone to form quinoxalines.

The nitro-derivative melting at 202° on reduction gives a diamido-compound analogous in all respects to β-diamidoquinol diethyl ether, and which must therefore likewise have a symmetrical constitution. It is converted by ferric chloride into a dimethoxyquinone identical with the compound obtained by Nietzki and Schmidt by acting on the silver compound of dihydroxyquinone with methyl iodide. It is readily reduced by stannous chloride and hydrochloric acid with formation of tetrahydroxybenzene dimethyl ether, which forms small, lustrous plates melting at 166°.

The above results show that dihydroxyquinone really contains two hydroxyl-groups, and has not passed into the tautomeric tetraketohexamethylene, for the dimethyl ether obtained by direct methylation, and the compound formed from amidoquinol dimethyl ether are identical, and the latter undoubtedly contains two methoxy-groups.

H. G. C.

Derivatives of Ortho- and Para-tolubenzylamine. By T. KRÖBER (*Ber.*, **23**, 1026—1034).—Orthotolubenzylamine can be prepared by reducing orthotolunitrile with sodium and alcohol; it boils at 199·5° (corr.). The *benzoyl*-derivative, $C_6H_4Me\cdot CH_2\cdot NHBz$, crystallises from alcohol in needles, melts at 88°, and is soluble in most ordinary solvents except water.

Orthoditolubenzylthiocarbamide, $CS(NH\cdot CH_2\cdot C_6H_4Me)_2$, prepared by heating the amine with carbon bisulphide and alcohol, crystallises from dilute alcohol in colourless plates or prisms melting at 186—187°.

Diazobenzeneorthotolubenzylamine, $C_6H_4Me{\cdot}CH_2{\cdot}NH{\cdot}N_2{\cdot}Ph$, obtained by treating the amine with diazobenzene chloride in dilute alcoholic solution, crystallises from alcohol in almost colourless needles, melts at 85°, and is readily soluble in ether and chloroform, but only sparingly in dilute alcohol, and insoluble in water.

Orthotolubenzyl alcohol is obtained when the amine is treated with nitrous acid; it melts at 31°. The corresponding aldehyde boils at 198—200°.

Orthomethylcinnamic acid, $C_6H_4Me{\cdot}CH{:}CH{\cdot}COOH$, can be prepared by heating orthotolualdehyde with sodium acetate and acetic anhydride at 145—150°; it crystallises from benzene in needles, and melts at 169°.

Paratolubenzylamine (b. p. 195—196°) is formed when paratolunitrile is reduced with sodium and alcohol. The *mercurochloride* crystallises in colourless prisms and melts at 203°; the *picrate*, $C_8H_{11}N,C_6H_3N_3O_7$, separates from water in moss-like crystals, and melts at 194—199° with decomposition. The *benzoyl*-derivative, $C_6H_4Me{\cdot}CH_2{\cdot}NHBz$, crystallises from alcohol in long, colourless needles, melts at 125°, and is readily soluble in ether, but insoluble in water.

Paratolubenzylcarbamide, $C_6H_4Me{\cdot}CH_2{\cdot}NH{\cdot}CO{\cdot}NH_2$, prepared by treating the hydrochloride of the amine with potassium cyanate, crystallises from dilute alcohol in plates, and melts at 166°.

Di-paratolubenzylthiocarbamide, $CS(NH{\cdot}CH_2{\cdot}C_6H_4Me)_2$, crystallises in colourless plates melting at 124—125°.

Diazobenzeneparatolubenzylamine, $C_6H_4Me{\cdot}CH_2{\cdot}NH{\cdot}N_2Ph$, crystallises in colourless plates, melts at 60—61°, and is soluble in ether, alcohol, and light petroleum.

Paratolubenzylacetamide, $C_6H_4Me{\cdot}CH_2{\cdot}NHAc$, prepared by treating the amine with acetic chloride, is a colourless, crystalline compound melting at 106·5°.

Paramethylcinnamic acid, $C_6H_4Me{\cdot}CH{:}CH{\cdot}COOH$, prepared from paratolualdehyde, crystallises from benzene in colourless needles, melts at 197°, and is soluble in most ordinary solvents. The *dibromide*, $C_{10}H_{10}Br_2O_2$, crystallises from light petroleum in needles, and melts at 183°.

Paramethylhydrocinnamic acid, $C_{10}H_{12}O_2$, is formed when the preceding compound is reduced with sodium amalgam; it crystallises from hot water in plates, and melts at 120°. F. S. K.

Action of Orthodiamines on Phthalaldehydic Acid. By A. BISTRZYCKI (*Ber.*, **23**, 1042—1046).—*Toluyleneamidinebenzenylorthocarboxylic acid*, $C_6H_3Me\langle{}^{\underline{\;\;N\;\;}}_{NH}\rangle C{\cdot}C_6H_4{\cdot}COOH$, separates as an orange precipitate when phthalaldehydic acid (benzaldehydeorthocarboxylic acid) is treated with orthotoluylenediamine in aqueous or alcoholic solution. It crystallises from alcohol in colourless needles, melts at 258° with decomposition, and is almost insoluble in water, chloroform, acetone, ether, and toluene, and only very sparingly soluble in boiling alcohol; it dissolves freely in glacial acetic acid and in mineral acids, and also in alkalis and alkaline carbonates.

Bromotoluyleneamidinebenzenylorthocarboxylic acid,

$$C_6H_2BrMe<\begin{matrix}-N\\NH\end{matrix}>C\cdot C_6H_4\cdot COOH,$$

obtained from bromoparatoluylenediamine (see below), in like manner, melts at 267°.

Phenyleneamidinebenzenylorthocarboxylic acid,

$$C_6H_4<\begin{matrix}-N\\NH\end{matrix}>C\cdot C_6H_4\cdot COOH,$$

prepared from orthophenylenediamine, decomposses at 266°. The corresponding *naphthalene*-derivative, $C_{18}H_{12}N_2O_2$, decomposes at about 280°.

These three compounds all form microscopic crystals, and are very sparingly soluble or insoluble in most neutral solvents.

Bromotoluylenediamine [Me : $(NH_2)_2$: Br = 1 : 3 : 4 : 5] can be prepared by brominating metanitroparatoluidine in alcoholic solution and reducing the product with stannous chloride and hydrochloric acid; it crystallises in long needles, melts at 81—82° with previous softening, and is very readily soluble in alcohol, ether, chloroform, acetone, and benzene, but only sparingly in water. F. S. K.

Stereochemically Isomeric Nitrogen Compounds. By A. Hantzsch and A. Werner (*Ber.*, 23, 1243—1253; compare this vol., p. 345).—In consequence of the work of Klinger and Zuurdeeg (this vol., p. 761) on the trinitroazotoluenes, the authors regard the existence of stereochemically isomeric azo-compounds as doubtful, and acknowledge that these can no longer be cited in support of their theory. In all other points the theory is upheld, and the objections raised by V. Meyer with regard to the isomeric oximes (this vol., p. 719) are replied to. The authors point out that if Beckmann's isobenzaldoxime had the constitution  $\begin{matrix}Ph\cdot C\cdot NH\\ \vee\\ O\end{matrix}$, it would be intermediate between Ph·CH:NOH and $Ph\cdot CO\cdot NH_2$, and might, therefore, be expected to readily undergo change into the latter, which is not the case. They are, therefore, still of opinion that the structure of the isomeric benzaldoximes is similar. The fact that Auwers fails to discover an isomeride of the unsymmetrical oxime of the formula $OH\cdot N{:}CPh\cdot C_6H_4Me$ cannot be taken as any positive proof against the theory, for reasons which the authors have already given in their former paper. The absence of isomeric oximes of phenanthraquinone may, perhaps, be explained by the total difference in structure between this compound and benzile, the former containing a closed ring, which is not the case with the latter, and therefore having an essentially different structure. H. C.

Diazo-compounds. By L. Gattermann, W. Haussknecht, A. Cantzler, and R. Ehrhardt (*Ber.*, 23, 1218—1228).—Experiments made by the authors with the object of obtaining diphenyl from diazobenzene chloride by the action of finely-divided copper had not the desired result, but led to the formation of chlorobenzene. Further investigation has shown that finely-divided copper exerts generally an action on diazo-salts very similar to that of cuprous salts discovered by Sandmeyer. The new reaction has, however, many advantages over the latter method, as it takes place in the cold, and it is unnecessary to prepare a special salt containing the residue to be introduced into the benzene nucleus, it being sufficient to add copper powder and a solution of the potassium or sodium salt of the acid.

The results obtained up to the present may be divided into three groups:—

(1.) Replacement of the amido-group, by halogens, thiocyanogen, and cyanogen. The copper powder was prepared by adding zinc-dust to a saturated solution of copper sulphate until the latter has only a pale-blue colour, washing the precipitated copper by decantation, and treating with dilute hydrochloric acid to remove traces of zinc. After filtering and washing, the paste of copper powder should be placed in a well-closed bottle, as it readily undergoes oxidation.

For the preparation of chlorobenzene, aniline is diazotised in the usual manner, using an excess of acid, and the copper powder gradually added, with constant stirring; nitrogen is rapidly evolved, and the reaction is complete in 15—30 minutes. The aqueous solution is poured, as completely as possible, from the lower oily layer, and the latter distilled in a current of steam. The distillate consists of chlorobenzene and a little diphenyl.

Ortho- and para-toluene in the same manner form ortho- and para-chlorotoluene, the yield being in both cases considerably better than that given by Sandmeyer's method. β-Naphthylamine is also readily converted into β-chloronaphthalene, but a large quantity of resinous matter is also formed, the yield of pure substance being only 30 per cent. Parachloronitrobenzene has also been prepared by this method from paranitraniline.

Metachlorobenzaldehyde may be prepared from metanitrobenzaldehyde by reducing the latter with stannous chloride and hydrochloric acid, diazotising directly without removing the tin, and adding copper powder.

For the preparation of bromobenzene, aniline is diazotised by means of sulphuric acid and sodium nitrite, and mixed with an aqueous solution of potassium bromide. The copper powder is then gradually added, the appearances being the same as with the chlorine compound. On distilling in a current of steam, almost pure bromobenzene is obtained. Iodobenzene and para-iodotoluene can be prepared in an exactly similar manner. The cyanogen- and thiocyanogen-groups can also be thus substituted for the amido-group, but the reactions have not as yet been closely studied.

(2.) Replacement of the amido-group by the cyanic acid residue.—The potassium cyanate required was prepared according to the method of C. A. Bell (this Journal, 1876, i, 68), by heating a mixture of potassium ferrocyanide and potassium dichromate, and extracting the product with 80 per cent. alcohol. A concentrated aqueous solution of the salt (9 grams) was added to a solution of 10 grams of aniline, diazotised in the usual manner, and then the copper added in portions of 5 grams, with constant stirring, until no more nitrogen is evolved. The phenyl cyanate forms an oily layer on the surface, and is removed by means of a glass spoon as it is formed, ether added, the water taken with it separated, and the ethereal solution dried over ignited potassium carbonate, evaporated, and distilled. The phenyl cyanate thus obtained contains a little coloured impurity, which has not yet been removed, but which is not retained by the derivatives obtained from the phenyl cyanate, such as phenyl- and diphenyl-carbamide. A residue is also obtained from the distillation of the phenyl cyanate, probably consisting of phenyl phenylcarbamate, NHPh·COOPh.

Orthotolyl cyanate may also be obtained in this manner from orthotoluidine, the yield being better than in the foregoing case.

(3.) Conversion of aniline into diphenyl.—For this purpose aniline is diazotised with sulphuric acid and sodium nitrite, and a quantity of 90 per cent. alcohol added. Copper powder is then gradually introduced, and the mixture vigorously stirred for an hour. The whole is then distilled in a current of steam, and the distillate collected as soon as it gives a solid precipitate on addition of water. The diphenyl thus obtained is perfectly pure. Concerning the mechanism of the action, all that is known at present is that the alcohol is partially oxidised to aldehyde, and the copper also oxidised to some extent. The copper may be replaced by finely-divided zinc or iron.

Culmann and Gasiorowsky have also recently obtained diphenyl from diazobenzene chloride by the action of stannous chloride, but the action is more complicated. Better results were obtained by the action of stannous chloride on diazobenzene formate in presence of formic acid (Abstr., 1889, 1156), but the copper method is preferable as being much cheaper. H. G. C.

Piazothioles and Piaselenoles II. By O. HINSBERG (*Ber.*, 23, 1393—1397; compare Abstr., 1889, 785, and this vol., p. 160).—1 : 2-Naphthylenediamine, obtained by the reduction of benzeneazo-β-naphthylamine, yields *naphthapiazothiole*, $C_{10}H_6N_2S$, when heated to 180—200° for 6 to 8 hours with hydrogen sodium sulphite in a sealed tube. The products of the reaction are treated with dilute hydrochloric acid, and distilled in a current of steam. Naphthapiazothiole crystallises from methyl alcohol in colourless or slightly yellow needles or leaves, melting at 81°. It is a feeble base, and gives a yellow coloration with concentrated sulphuric acid; with tin and hydrochloric acid, it yields naphthylenediamine and hydrogen sulphide.

1 : 2-*Naphthaquinoxaline*, $C_{10}H_6{:}C_2N_2H_2$, is obtained by warming a mixture of 1 : 2-naphthalenediamine and glyoxal hydrogen sodium sulphite with acetic acid; after purification, the compound crystallises from dilute alcohol in small, colourless needles, melting at 62°; its salts are yellow in solution, and are not dissociated. The *platinochloride* is sparingly soluble in water. The base is stable towards oxidising agents and nitrous acid; concentrated sulphuric acid produces a deep-red coloration, which changes to yellow on the addition of water.

Experiments made with the object of ascertaining what influence, if any, the presence of alkalis or acids exerts on the formation of piaselenoles, show that alkaline selenites do not react with 1 : 3 : 4-diamidotoluene, and that dilute mineral acids do not affect the ordinary course of the reaction. On warming a mixture of equal molecular parts of 1 : 3 : 4-diamidotoluene and selenious anhydride in concentrated hydrochloric acid, the solution becomes yellowish-red in colour, and a considerable quantity of crystals are deposited which chiefly consist of *methylchloropiaselenole*, $C_6H_2ClMe{:}N_2Se$, melting at 149—150°. This compound shows all the characteristic properties of the piaselenoles; it is a feeble base, gives a yellowish-red colour with concentrated sulphuric acid, and, on reduction, yields a chlorodiamidotoluene. As selenious anhydride and concentrated hydrochloric acid have no action on methylpiaselenole, the above reaction is probably best explained by assuming that the compound $SeCl_2(OH)_2$ is first formed, and that this then unites with the diamidotoluene, giving the compound $C_7H_6{<}\genfrac{}{}{0pt}{}{NH}{NH}{>}SeCl_2$; by the loss of two hydrogen-atoms, the dichloride, $C_7H_6{:}N_2SeCl_2$, would be produced, from which methylchloropiaselenole is finally obtained by elimination of hydrogen chloride and atomic rearrangement. Selenic acid combines with diamidotoluene to form methylpiaselenole, part of the amine being simultaneously oxidised to a red-coloured compound. J. B. T.

Formation of Alkyl-derivatives of Amides. By J. Tafel and C. Enoch (*Ber.*, 23, 1550—1554; compare this vol., p. 491)—*Silver metanitrobenzamide*, $C_7H_5N_2O_3Ag$, prepared by dissolving metanitrobenzamide in dilute alcohol, precipitating with silver nitrate and soda, and carefully drying, is a grey powder, which by heating for several days at 50° with ethyl iodide, extracting the mass with ether, and precipitating by the addition of ethereal hydrogen chloride to the ether extract, yields the *hydrochloride of metanitrobenzimidoethyl ether*, $NO_2{\cdot}C_6H_4{\cdot}C(OEt){:}NH,HCl$. It forms a horny mass soluble in alcohol and water; when the aqueous solution is warmed, decomposition ensues, ammonia and ethyl metanitrobenzoate, melting at 43° (uncorr.), being formed. *Metanitrobenzimidoethyl ether* was prepared by dissolving the hydrochloride in water, and adding the calculated quantity of sodium carbonate. It is an uncrystallisable oil, but its acid oxalate, $C_{11}H_{13}N_2O_7$, forms well-developed crystals. *Metanitrobenzamidine hydrochloride*, $NO_2{\cdot}C_6H_4{\cdot}C(NH){\cdot}NH_2,HCl$, was prepared from it by Pinner's method (Abstr., 1883, 1089); it dissolves easily in water, less easily in alcohol, and is precipitated from solution in the latter solvent by the addition of ether, in white tables melting at 240°. The *platinochloride* forms small, glittering, yellowish plates. Free *metanitrobenzamidine* was obtained by decomposing the hydrochloride with excess of soda; it forms ill-defined crystals which are soluble in water and have a strongly alkaline reaction.

When mercury-acetamide is suspended in ether and mixed with iodine, a brick-red powder of the constitution $HgI_2(NHAc)_2$ is formed; when this is dissolved in hot alcohol and the solution cooled, it separates as an oil, but soon solidifies to a crystalline mass. It is insoluble in benzene, is decomposed by heat, and by dilute hydrochloric acid, but not by other dilute acids.

When mercury-benzamide is treated in the same way, a similar red powder, $HgI_2(NHBz)_2$, is formed. When this is boiled with alcohol, it is decomposed into two compounds, one not containing mercury, probably C_7H_6NOI, the other C_7H_6NOHgI, obtained in small, white needles melting at 194°, and decomposing at a higher temperature; it is insoluble in water.

When silver-carbamide, $CON_2H_2Ag_2$, is treated with iodine in the above manner, a greenish mass of $CON_2H_2Ag_2I$ is formed, extremely sensitive to light, and decomposed with liberation of silver iodide when heated alone or with alcohol, some aldehyde being formed in the latter case. Dilute hydrochloric acid liberates the iodine.

C. F. B.

A Modification of the Chloroformamide Synthesis. By L. Gattermann and A. Rossolymo (*Ber.*, 23, 1190—1199).—About two years ago, one of the authors, in conjunction with G. Schmidt, W. Hess, and E. P. Harris, described a new method of synthetically preparing aromatic carboxylic acids, which consisted in acting with chloroformamide on aromatic hydrocarbons and phenol ethers in presence of aluminium chloride (Abstr., 1887, 569; 1888, 574). For the preparation of chloroformamide in quantity, a considerable quantity of condensed carbonyl chloride is necessary, which is not always readily obtained, and moreover, the time required in the preparation of the chloroformamide is too great in comparison with the actual preparation of the carboxylic acid, when only small quantities of the latter are required. The authors have succeeded in effecting a modification of the method by which the difficulties in the preparation of small quantities have been successfully overcome. Led by the fact that chloroformamide, which appears to distil unchanged, really splits up into cyanic acid and hydrogen chloride, they have examined the effect of replacing the chloroformamide by a mixture of cyanic acid and hydrogen chloride, and find that the mixture acts in exactly the same way with the aromatic hydrocarbons and phenol ethers.

For the preparation of cyanic acid, cyanuric acid is recrystallised from water, the hydrated crystals carefully heated until anhydrous, and the acid then distilled in a suitable vessel, passing a current of carbonic anhydride through it during the operation. The vapours are led into a wide necked flask, into which also passes a tube conveying hydrogen chloride. In the flask is placed a quantity of powdered aluminium chloride equal to that of the cyanuric acid taken, and the hydrocarbon or phenol ether to be acted on, the latter being diluted with carbon bisulphide if the quantity is small, and it is to be converted as fully as possible into the amide. Through a third hole in the flask is placed a fairly wide tube, which serves to condense the carbon bisulphide boiled off during the reaction. The whole is gently warmed, and the cyanic acid vapours mixed with carbonic anhydride, and the hydrogen chloride simultaneously passed in, the flask being continually shaken. After the reaction is over, the liquid is poured off from the solid or semi-solid aluminum double salt, and the latter carefully decomposed with water, cooling well during the operation. The amide usually separates at once or, if the quantity is small, may be extracted with ether, and then crystallised from hot water after treatment with animal charcoal.

Benzene gives the worst yield of any of the hydrocarbons. The compound obtained crystallises in colourless plates melting at 128°, and is identical in every respect with benzamide. Even with a small quantity of benzene and an excess of cyanic acid and hydrogen chloride, the yield is not good.

Toluene, under the same conditions, gives a much better yield of paratoluamide, melting at 158°. As with phenyl cyanate and chloroformamide itself, the hydrogen-atom occupying the para-position to the methyl-group is replaced. Ethylbenzene yields the previously unknown *parethylbenzamide*, $C_6H_4Et{\cdot}CO{\cdot}NH_2$, which is sparingly soluble in hot water, and crystallises from it in colourless plates melting at 115—116°. The acid obtained from it by hydrolysis is identical with parethylbenzoic acid.

Metaxylene is converted by the reaction into *metaxylylamide*, $C_6H_3Me_2{\cdot}CO{\cdot}NH_2$ (1 . 3 . 4), melting at 178—179°. By means of this reaction the authors have been able to ascertain that a sample of xylene from coal-tar consisted chiefly of metaxylene mixed with a little ethylbenzene.

Anisoïl readily yields anisamide, which crystallises in white needles and melts at 162—163°, and not at 137—138°, as given by Henry.

Phenetoïl is also converted with great ease into the amide of ethoxybenzoic acid, crystallising in lustrous plates melting at 201°.

Naphthalene, acenaphthene, and α-naphthyl ethyl ether are also acted on by these reagents. The first yields the amide of α-naphthoic acid, melting at 201—202°, and the second an amide melting at 197—198°, whilst the third gives an amide for which the authors, in agreement with Hess, find the melting point 143—144°.

This reaction also permits of the detection of the constituents of a mixture of hydrocarbons. Thus, a mixture of toluene and metaxylene, treated with half the quantity of cyanic acid necessary to convert the whole into amide, yielded nearly pure metaxylylamide, and the residual hydrocarbon on further treatment yielded paratoluamide.

H. G. C.

Action of Carbonyl Chloride on Orthodiamines. By A. HARTMANN (*Ber.*, 23, 1046—1051. Orthophenylenecarbamide (m. p. 307—308°) is formed when carbonyl chloride is heated with orthophenylenediamine hydrochloride in toluene solution; orthotoluylenecarbamide (m. p. 291—292°), and orthonaphthylenecarbamide (m. p. about 380°) can be obtained in like manner.

Bromotoluylenecarbamide, $C_6H_2BrMe<\genfrac{}{}{0pt}{}{NH}{NH}>CO$, prepared from bromotoluylenediamine (m. p. 81—82°) melts at 324—325°, and is readily soluble in alcohol, but only sparingly in benzene, ether, and water.

Diacetylbromotoluylenediamine, $C_6H_2BrMe(NHAc)_2$, is obtained when bromotoluylenediamine [Me : $(NH_2)_2$: Br = 1 : 3 : 4 : 5] is boiled with acetic anhydride; it crystallises from water in needles, melts at 222—223°, and is readily soluble in glacial acetic acid and alcohol, but more sparingly in water, benzene, and toluene. The *monacetyl*-derivative, $C_9H_{11}BrN_2O$, can be prepared by reducing metanitrometabromoparacetotoluide with stannous chloride and hydrochloric acid in the cold; it separates from benzene in crystals and melts at 167—168°.

Ethenylbromotoluyleneamidine, $C_6H_2BrMe<\begin{matrix}-N\\NH\end{matrix}>CMe$, is formed when acetyl- or diacetyl-bromotoluylenediamine is heated above its melting point, and also when nitrobromacetotoluide is reduced at a moderately high temperature; it crystallises from alcohol in prisms, melts at 197—198°, and is readily soluble in alcohol, but only sparingly in benzene and water.

Dibenzoylbromotoluylenediamine, $C_6H_2BrMe(NHBz)_2$, crystallises in colourless needles melting at 244°.

Diphenylbromotoluquinoxaline, $C_6H_2BrMe<\begin{matrix}N{:}CPh\\ |\\ N{:}CPh\end{matrix}$, prepared by boiling bromotoluylenediamine with benzile in alcoholic solution, crystallises in needles, and melts at 153—154°.

Bromotoluphenanthrazine, $C_{21}H_{13}BrN_2$, is formed when bromoparatoluylenediamine is treated with phenanthraquinone in glacial acetic acid solution; it crystallises from a mixture of chloroform and alcohol in yellow needles melting at 209—210°. F. S. K.

Derivatives of Trimethylenediamine. By A. GOLDENRING (*Ber.*, **23**, 1168—1174).—Aniline readily acts on γ-bromopropylphthalimide at 150°, aniline hydrobromide separating out. On addition of aqueous ammonia and distilling in a current of steam, an oil remains which may be purified by adding boiling water and concentrated hydrochloric acid, until all but a small quantity of resinous matter is dissolved. On cooling the filtered solution, the salt formed separates in white granules, which are reconverted into the base by warming with dilute aqueous ammonia; the product thus obtained is dissolved in a small quantity of benzene, and a large excess of alcohol added. The yellow crystals which separate, melt at 144—145°, and consist of *diphthalylditrimethylenetriamine* $NPh(CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}N{:}C_8H_4O_2)_2$. On heating this compound with fuming hydrochloric acid in a sealed tube at 240°, it is converted into *di-trimethylenephenyltriamine hydrochloride*, $NPh(CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NH_2)_2,3HCl$, which yields a sparingly soluble platinochloride.

The mother liquor from the above diphthalyl compound, leaves on evaporation a yellow, resinous mass, which may be purified for analysis by recrystallisation from light petroleum. It then forms indistinct, yellow crystals melting at 87—89°, which from their composition and mode of preparation must consist of *γ-anilidopropylphthalimide*, $C_8H_4O_2{:}N{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NHPh$. Like the foregoing compound, this is converted by treatment with fuming hydrochloric acid into the *hydrochloride* of the corresponding trimethylenephenyldiamine, $NH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NHPh,2HCl$, which crystallises in small, almost white needles. The *picrate*, $C_9H_{14}N_2,2C_6H_3N_3O_7$, crystallises from 60 per cent. alcohol in greenish, feathery needles, which decompose at 195°. The free *trimethylenephenyldiamine*, $NH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}NHPh$ is prepared by decomposing a concentrated aqueous solution of the hydrochloride with solid potash. It is a colourless, strongly refractive oil, readily soluble in water, alcohol, and ether, having a strong alkaline reaction and characteristic amine smell, and boiling at 277°. It absorbs carbonic anhydride from the air, forming a liquid carbonate. This base has also been prepared in a different manner by Balbiano (Abstr., 1889, 1215). In agreement with the latter, the author finds that the amido-compound reacts with carbon bisulphide in a different manner to ethylenediamine, a *dithiocarbamate* of the constitution $NH{\cdot}Ph{\cdot}C_3H_6{\cdot}NH{\cdot}CS{\cdot}SH,NHPh{\cdot}C_3H_6{\cdot}NH_2$, being formed. It crystallises in small, white plates and decomposes on boiling with water into hydrogen sulphide, trimethylenephenyldiamine, and *trimethylenephenylthiocarbamide*,  $CS{<}^{NH-}_{N\cdot Ph}{>}C_3H_6$, the latter forming white prisms melting at 215°.

Trimethylenephenyldiamine is readily acted on by phenylthiocarbimide with formation of trimethylene, triphenyldithiocarbamide, $NHPh{\cdot}CS{\cdot}NH{\cdot}C_3H_6{\cdot}NPh{\cdot}CS{\cdot}NHPh$, which crystallises from alcohol in slender needles melting at 145°.

Trimethylenephenylcarbamide cannot be prepared in a similar manner to the corresponding trimethylenecarbamide by the action of ethyl carbonate on trimethylenephenyldiamine (compare Fischer and Koch, Abstr., 1886, 527). If, however, the monohydrochloride of the latter be treated with potassium cyanate at 100°, it is converted into *anilidopropylcarbamide*, $NH{\cdot}Ph{\cdot}C_3H_6{\cdot}NH{\cdot}CO{\cdot}NH_2$. This crystallises in rose-coloured aggregates of needles which melt at 96—98°, and at 120° give off ammonia with formation of *trimethylenephenylcarbamide*, $CO{<}^{NPh}_{NH-}{>}C_3H_6$. This crystallises from alcohol in pale yellow needles sparingly soluble in water, and melts at 213—215°.

H. G. C.

Derivatives of Paracyanobenzyl Chloride. By H. K. GÜNTHER (*Ber.*, **23**, 1058—1062).—*Paracyanobenzylphthalimide*,

$$C_8H_4O_2{:}N{\cdot}CH_2{\cdot}C_6H_4{\cdot}CN,$$

is formed when paracyanobenzyl chloride is heated with potassium phthalimide at 130°. It crystallises from boiling glacial acetic acid in yellowish-brown plates, $a : b : c = 0{\cdot}7212 : 1 : 0{\cdot}5218$, melts at 183—184°, and is almost insoluble in water, ether, alcohol, and light petroleum, but readily soluble in acetone, chloroform, and hot glacial acetic acid.

Paracarboxybenzylphthalamic acid,

$$COOH{\cdot}C_6H_4{\cdot}CO{\cdot}NH{\cdot}CH_2{\cdot}C_6H_4{\cdot}COOH,$$

is obtained when the preceding compound is warmed with soda, and the sodium salt thus produced decomposed with hydrochloric acid. It separates from alcohol in microscopic needles, melts at 255°, and is only sparingly soluble in most ordinary solvents. The *silver* salt, $C_{16}H_{12}O_5NAg_2$, crystallises in prisms.

Benzylamineparacarboxylic acid, $NH_2{\cdot}CH_2{\cdot}C_6H_4{\cdot}COOH$, can be prepared by heating the preceding compound with concentrated hydrochloric acid at 200° for three hours; the product is treated with cold water, the filtered solution evaporated to dryness, the residue dissolved in a little warm water, and the solution mixed with sodium acetate; on rubbing, the acid gradually separates in crystals. It crystallises from water and glacial acetic acid in yellow scales, and is insoluble in ether, alcohol, benzene, acetone, and light petroleum. The *hydrochloride* crystallises in long needles, $a : b : c = 0{\cdot}5742 : 1 : 0{\cdot}9630$, and is soluble in water, alcohol, light petroleum, and chloroform, but insoluble in ether, glacial acetic acid, and benzene. The *platinochloride* $(C_8H_9O_2N)_2,H_2PtCl_6$ is amorphous. The *aurochloride* crystallises in well-defined prisms.

An acid of the composition $C_{16}H_{14}O_5$ is formed when paracyanobenzyl chloride is boiled with potash, and the resulting sodium salt decomposed with hydrochloric acid; it separates from hot acetic acid in ill-defined, colourless crystals, and is insoluble in ether, acetone, chloroform, and benzene, but readily soluble in ammonia and alkalis. The *silver* salt has the composition $C_{16}H_{12}Ag_2O_5$. The constitution of the acid is probably expressed by the formula $O(CH_2{\cdot}C_6H_4{\cdot}COOH)_2$.

F. S. K.

Etard's Reaction. By W. v. MILLER and G. ROHDE (*Ber.*, 23, 1070—1079).—When propylbenzene is treated with chromyl chloride, benzaldehyde, benzyl methyl ketone, and other compounds are formed, but not a trace of hydrocinnamaldehyde is produced, as stated by Etard (Abstr., 1881, 581).

When cymene is treated with chromyl chloride, it yields about equal quantities of an aldehyde identical with the compound described as paramethylhydrocinnamaldehyde by Richter and Schüchner (Abstr., 1884, 1342), and a compound which seems to be paratolylethyl ketone. The aldehyde obtained in this way is not identical with paramethylhydrocinnamaldehyde (compare next abstract), and on oxidation with silver oxide it is converted into an acid which melts at 40—41°; paramethylhydrocinnamic acid melts at 116° (compare Kröber, this vol., p. 969). The aldehyde obtained from cymene has probably the constitution $C_6H_4Me{\cdot}CHMe{\cdot}CHO$, and the acid (m. p. 40—41°) is probably paramethylhydratropic acid.

Ethylbenzene and chromyl chloride yield acetophenone, together with an oil which combines with sodium hydrogen sulphite, and probably consists of phenylacetaldehyde and benzaldehyde.

The above experiments show that Etard's reaction takes a course different to that which it is usually supposed to take; whilst the methylbenzenes yield with chromyl chloride the corresponding aldehydes, the hydrocarbons with longer side chains give a ketone as a rule, and only in some cases the corresponding aldehyde.

Stilbene is formed when a mixture of benzyl methyl ketone and benzaldehyde is shaken with hot concentrated (3 : 1) sulphuric acid; when a mixture of benzyl methyl ketone and metachlorobenzaldehyde is treated in like manner, a crystalline compound melting at 73—74°, probably metachlorostilbene, is produced. Deoxybenzoin and benzyl methyl ketone condense together forming stilbene and benzoic acid.

F. S. K.

Hydrocinnamaldehydes. By W. v. MILLER and G. ROHDE (*Ber.*, 23, 1079—1082).—*Hydrocinnamaldehyde*, $C_6H_5{\cdot}CH_2{\cdot}CH_2{\cdot}CHO$, prepared by distilling a mixture of calcium hydrocinnamate and calcium formate, is an oil.

a-Methylhydrocinnamaldehyde, $C_6H_5{\cdot}CH_2{\cdot}CHMe{\cdot}COH$, prepared from methylhydrocinnamic acid in like manner, boils at 226—227° (corr.); the hydrazone and the anilide are oils.

Metachlorohydrocinnamaldehyde, C_9H_9ClO, boils at about 240°.

Paramethylhydrocinnamaldehyde, $C_6H_4Me{\cdot}CH_2{\cdot}CH_2{\cdot}CHO$, is an oil.

The compounds described above have a characteristic odour of jessamine, undergo oxidation on long exposure to the air, and have the generic properties of aldehydes; when treated with concentrated or moderately concentrated sulphuric acid, they yield solutions which, when seen by transmitted light, have a more or less intense rose- or carmine-red coloration. F. S. K.

Aromatic Alkyl Ketones; their Oxidation by Potassium Permanganate. By A. CLAUS (*J. pr. Chem.*, [2], 41, 483—514; compare this vol., p. 769).—*Metaxylyl methyl carbinol*,

$$[C_6H_3Me_2{\cdot}CHMe{\cdot}OH = 2:4:1],$$

is produced when metaxylyl methyl ketone (Abstr., 1886, 463) is reduced by sodium amalgam (compare the behaviour of paratolyl methyl ketone, this vol., p. 769); it is a pale-yellow oil, becoming brown in the light in presence of air; it boils above 300°.

Metaxylyl methyl ketone *phenylhydrazide* forms lustrous needles melting at 115° (uncorr.), and is insoluble in cold water and ether.

Orthoparadimethylmandelic acid,

$$C_6H_3Me_2{\cdot}CH(OH){\cdot}COOH\ [= 2:4:1],$$

is obtained when metaxylylglyoxylic acid (Abstr., 1886, 463) is reduced by sodium amalgam; it crystallises from hot water in aggregates of needles, melts at 119° (uncorr.), sublimes, and is easily soluble in alcohol and ether, but not in cold water. It gives a cherry-red colour when warmed with strong sulphuric acid, a reaction which is shared by its salts. When the glyoxylic acid is reduced by hydriodic acid, metaxylylacetic acid, $C_6H_3Me_2{\cdot}CH_2{\cdot}COOH$ [4:2:1], is obtained as well as the above; it crystallises in colourless needles or leaflets which melt at 102° (uncorr.), sublime, and are soluble in the usual solvents, except cold water. The melted acid distils about 265° (uncorr.). Its *potassium*, *barium*, and *silver* salts (each with 1 mol. H_2O), its *calcium salt* (with 4½ mols. H_2O), and its *amide* (m. p. 183°, uncorr.) are described.

Dinitrosometaxylylglyoxylic acid, $C_6HMe_2(NO)_2{\cdot}CO{\cdot}COOH$, obtained by acting on the glyoxylic acid (1 part) for a short time (two minutes) with fuming nitric acid (4—5 parts), forms colourless crystals which melt at 177° (uncorr.), and sublime with decomposition; it is soluble in the usual solvents, except water, and gives a red colour with phenol and sulphuric acid. Its *potassium* and *barium* salts (each with 1½ mol. H_2O) are described. When it is oxidised with potassium chromate (0·254 part) and sulphuric acid, it yields *dinitrosometaxylenecarboxylic acid*, $C_6HMe_2(NO)_2\cdot COOH$, which melts at 166°. When the dinitrosoglyoxylic acid is acted on by fuming nitric acid, *nitronitrosometaxylenecarboxylic acid*,

$$NO\cdot C_6HMe_2(NO_2)\cdot COOH,$$

is obtained; this crystallises in needles which melt at 256° (uncorr.), and dissolve freely in hot water, sparingly in chloroform and glacial acetic acid, but not in carbon bisulphide and benzene.

Dinitrometaxylylglyoxylic acid,

$$C_6HMe_2(NO_2)_2\cdot CO\cdot COOH\ [=2:4:3:5:1],$$

is obtained by treating xylylglyoxylic acid with nitric and sulphuric acids in the cold and pouring the mixture into water; it forms colourless needles melting at 198° (uncorr.); its *barium salt* (with 2 mols. H_2O) is described.

By nitrating metaxylyl methyl ketone (10 grams) with nitric acid of sp. gr. 1·4 (100 grams) at 65°, a nitroso-derivative,

$$(C_8H_9\cdot CO\cdot C{:}N\cdot OH)_x,$$

melting at 107—108°, was obtained; this has been described by Holleman (Abstr., 1888, 275; 1889, 49). When it is oxidised by potassium permanganate, it yields orthoparadimethylbenzoic acid (m. p. 126°), and when it is reduced by zinc and acetic acid, dimetaxylyl ethylene diketone (Abstr., 1887, 827) is obtained.

When nitric acid, of sp. gr. 1·52, is used, and the temperature kept below 30°, two mononitro-metaxylyl methyl ketones are obtained, the one (m. p. 72°) more soluble in alcohol than the other (m. p. 67°); a third product was obtained but not investigated.

5-*Nitrometaxylyl methyl ketone* forms colourless needles which melt at 67° (uncorr.) and are insoluble in dilute alcohol. When it is oxidised with dilute nitric acid, or potassium permanganate, nitrodimethylbenzoic acid (m. p. 195°) is formed; the *amido*-derivative of this acid melts at 175°. When the potassium permanganate is used in dilute aqueous solution and in sufficient quantity to supply only three atoms of oxygen, 5-*nitro*-2 : 4-*dimethylphenylglyoxylic acid* is formed; it is an oil which crystallises after a time and melts at 40° (?); its *barium salt* (with 6 mols. H_2O), *calcium salt* (with 4½ mols. H_2O), and *silver salt* are described. 5-*Amidometaxylyl methyl ketone* crystallises in small needles which quickly become coloured and melt at 88° (uncorr.); its *hydrochoride* and *platinochloride* are described.

3-*Nitrometaxylyl methyl ketone* crystallises from glacial acetic acid in columns or prisms which melt at 72°; it is unstable and gradually becomes converted into an oily substance, referred to above as the third product of the action of nitric acid on metaxylyl methyl ketone. When oxidised with four atoms of oxygen, it yields 3-*nitro*-2 : 4-*dimethylbenzoic acid*; this acid forms colourless needles or columns which melt at 135° (uncorr.), and are freely soluble, except in cold water; its *barium salt* was obtained.

When metaxylyl methyl ketone (1 part) is added by degrees to a mixture of nitric acid of sp. gr. 1·52 (3 parts) and sulphuric acid (6 parts), cooled to −10° or −15°, two products are obtained, a dinitro- and a dinitronitroso-ketone, the latter being more abundant at higher temperatures; the dinitroketone is soluble in ether, which therefore serves to separate them.

3 : 5-*Dinitrometaxylyl methyl ketone* crystallises in yellow needles which melt at 96° (uncorr.) and explode at the boiling point; it is soluble in the usual solvents. By oxidation it yields 3 : 5-*dinitro-2 : 4-dimethylbenzoic acid*, which forms small, lustrous crystals melting at 199—200° (uncorr.) and subliming in silky needles; it is freely soluble, except in cold water; its *potassium*, *barium* (with 1½ mols. H_2O), *calcium*, and *silver* salts were obtained; they are explosive when dry.

3 : 5-*Dinitrometaxylyl nitrosomethyl ketone* crystallises from nitrobenzene, or acetone, in lustrous, microscopic leaflets melting at 209° (uncorr.), and exploding when heated on platinum foil.

Mesityl methyl ketone, $C_6H_2Me_3 \cdot COMe$, is a colourless liquid of peculiar odour; it boils at 235° (uncorr.), and is specifically lighter than water. When it is oxidised by potassium permanganate, mesitylglyoxylic acid and trimethylbenzoic acid are obtained; they are separated by water at 30°, in which the latter is fairly soluble, but the former not.

Mesitylglyoxylic acid forms large, yellowish, columnar crystals melting at 118° (uncorr.), and soluble except in water. The *barium salt* (with 2½ mols. H_2O) and the *silver salt* are described.

2 : 4 : 6-*Trimethylbenzoic acid* forms crystals which melt at 155° (uncorr.); it is volatile with steam, smells of honey, sublimes, and is freely soluble in the usual solvents; it is identical with Jacobsen's β-isodurylic acid (m. p. 151°; Abstr., 1883, 53). The *barium salt* (with 2 mols. H_2O) and the *silver salt* are described. Further oxidation by potassium permanganate produces only one dibasic acid, namely, 2 : 6-*dimethylterephthalic acid;* this acid crystallises in small, white needles which melt at 206° (uncorr.) and are easily soluble; the *barium salt* (with 3 mols. H_2O) is described.

2 : 4 : 6-*Trimethylphenylacetamide*, $C_6H_2Me_3 \cdot CH_2 \cdot CO \cdot NH_2$, is obtained by the action of ammonium sulphide on mesityl methyl ketone in small, colourless crystals which melt at 208° (uncorr.) and sublime; it is soluble except in cold water. The corresponding *acid* forms a white, crystalline powder which melts at 164° (uncorr.) and sublimes in small, colourless, slender needles; it is soluble except in cold water; the *barium salt* (with 3 mols. H_2O) was obtained

Pseudocumyl methyl ketone [$Me_3 = 2 : 4 . 5$] is a colourless, strongly refracting liquid which boils at 246—247° (uncorr.); it solidifies at 0° to transparent prisms which melt at 10°; it dissolves in the usual solvents. When oxidised, it yields 2 : 4 : 5-*trimethylphenylglyoxylic acid*, which crystallises in slender, white needles melting at 75° (uncorr.), and is soluble in most solvents; its *potassium* (with 1 mol. H_2O), *sodium* (with 1½ mols. H_2O), *barium* (with 4 mols. H_2O), *calcium* (with 3 mols. H_2O), *silver*, and *lead* salts were obtained. When this glyoxylic acid is treated with ammonium sulphide, 2 : 4 : 5-*trimethylphenylacetamide* is formed; it crystallises in lustrous leaflets which melt at 174°. The corresponding *acid* forms needles which melt at 118° (uncorr.) and sublime; the *barium* salt crystallises with 2 mols. H_2O. By oxidation, the glyoxylic acid becomes 2 : 4 : 5 *trimethylbenzoic*

acid (m. p. 150°), identical with Jannasch's durylic acid (*Zeits. f. Chem.*, 6, 449), some 2 : 5-*dimethylterephthalic acid*, identical with Jannasch's cumidic acid (*loc. cit.*; Abstr., 1883, 334), being formed at the same time.
A. G. B.

Dipyrogallopropionic Acid. By C. Böttinger (*Ber.*, 23, 1093).—The compound described by the author as dipyrogallopropionic acid (Abstr., 1884, 318) has, like Doebner and Förster's pyrogallolbenzeïn (this vol., p. 899), the property of dissolving in alkalis with a beautiful blue coloration.

The so-called dipyrogallopropionic acid can be converted into a tetracetyl-derivative; when its red solution is boiled with zinc-dust and glacial acetic acid, it becomes colourless, but on the addition of soda the reduction product absorbs oxygen and the solution turns blue. The colourless reduction product is probably the true dipyrogallopropionic acid, of which the red compound is an oxidation product.
F. S. K.

Tetrabromodinitrobenzene. By C. L. Jackson and W. D. Bancroft (*Amer. Chem. J.*, 12, 289—307; compare Abstr., 1888, 821 and 1276; 1889, 696).—Tetrabromodinitrobenzene (m. p. 228°) is not acted on by alcoholic ammonia in open vessels, but if the mixture is heated in sealed tubes at 100°, it is converted into a substance (probably *bromotriamidodinitrobenzene*) which is insoluble in any ordinary solvent, and does not melt at 285°.

Bromodinitrotrianilidobenzene, $C_6Br(NO_2)_2(NHPh)_3$, is prepared by heating at 100°, a mixture of tetrabromodinitrobenzene (1 mol.) and aniline (6 mols.). It is insoluble in water and light petroleum; crystallises from alcohol, acetic acid, benzene, and chloroform in microscopic prisms; and melts at 175—176°. The compound has no basic properties.

Ethyl dibromodinitrophenylmalonate, $C_6HBr_2(NO_2)_2{\cdot}CH(COOEt)_2$, is obtained by dissolving tetrabromodinitrobenzene in benzene, and mixing the solution with ethyl sodiomalonate; the red-coloured mass formed is poured into water and the benzene separated; on adding sulphuric acid to the aqueous solution, the new compound separates out, and on crystallisation from alcohol forms colourless needles which melt at 89°. It is insoluble in water and in light petroleum, but is readily dissolved by all other common solvents, has well-marked acid properties, forms soluble salts with the alkalis, and gives various-coloured, amorphous precipitates when solutions of the heavy metals are added to aqueous solutions of its ammonium salt.

Ethyl bromanilidodinitrophenylmalonate,

$$NHPh{\cdot}C_6HBr(NO_2)_2{\cdot}CH(COOEt)_2,$$

is readily prepared by adding aniline (2 mols.) to ethyl dibromodinitrophenylmalonate (1 mol.). It crystallises from hot alcohol in slender, bright-red prisms; melts at 127°; readily dissolves in most solvents; has only feeble acid properties, but gives yellow precipitates with solutions of the heavy metals.

Bromamido-oxindole, $C_8NH_5OBr{\cdot}NH_2$, is obtained by the reduction of ethyl dibromodinitrophenylmalonate with tin and hydrochloric acid. On precipitation from a solution of its chloride, it forms colourless, microscopic needles which melt, with considerable charring, at about 212°. It is soluble in hot water and in hot alcohol, insoluble in ether and chloroform, and, in some respects, behaves as a phenol. The chloride, $C_8H_7ON_2,HCl + H_2O$, crystallises from water in needles or prisms, and does not melt within the range of the mercurial thermometer.

In preparing tetrabromodinitrobenzene for these experiments, the previously undescribed pentabromonitrobenzene, melting at 248°, was obtained. G. T. M.

Compounds Prepared from Bromonitrobenzenes. By C. L. JACKSON (*Amer. Chem. J.*, **12**, 307—313; compare preceding abstract). —The author offers an explanation of the reactions between the bromonitrobenzenes prepared by him, on the one hand, and ethyl sodiomalonate on the other hand; reviews the relative ease with which the reactions takes place, and gives inferences drawn from experiments, by which the comparative acidity of the substituted ethyl malonates, ethyl acetoacetates and ketones, prepared by him, have been determined. G. T. M.

Tautomeric Compounds. By J. U. NEF (*Amer. Chem. J.*, **12**, 379—425; compare also Abstr., 1889, 509).—The first part of the paper is devoted to a discussion of the alleged cases of tautomerism in ethyl succinosuccinate and analogous compounds, and reasons are given for believing that the polymorphism in this group is due, not to a change of position of certain groups within the molecule, but to physical isomerism. It is further deemed probable that ethyl succinosuccinate and dihydroxyterephthalate never contain a ketone-group, but that the oxygen usually assumed to exist in this condition is present rather as hydroxyl.

The author then proceeds to give in detail the results of experiments made to test this alleged tautomerism, after first mentioning that he has prepared a derivative of ethyl acetoacetate containing two acid radicles, which has not before been done. Since ethyl acetoacetate greatly resembles ethyl succinosuccinate and dihydroxyterephthalate, it seemed probable that it, too, is not a ketonic compound, and if so it ought to form alkyl and acid ethereal salts, in which the substituting group (R) is bound to oxygen, $OR\cdot CMe\dot{:}CH\cdot COOEt$, and these substances would be insoluble in alkalis. In reality, it is found that when ethyl sodacetacetate is treated with 1 mol. of benzoic chloride, a small quantity of a compound insoluble in alkalis is formed, but this was found to be ethyl dibenzoylacetoacetate, $COMe\cdot CBz_2\cdot COOEt$.

Ethyl dihydrodiamidopyromellitate, $C_6H_2(NH_2)_2(COOEt)_4$,

$$[(COOEt)_4 : (NH_2)_2 : H_2 = 1:3:4:6:2:5:1:4, = \Delta_{2,5}, \text{ or}$$

$1:3:4:6:2:5:3:6, = \Delta_{1,4}]$, is made by treating an alcoholic solution of ethyl diamidopyromellitate with zinc-dust and dilute sulphuric acid; it may also be obtained, though only in small quantity, by fusing together ammonium acetate and ethyl paradiketohexamethylenetetracarboxylate, into which latter substance it is itself converted when dissolved in concentrated sulphuric acid and treated with a little water. It dissolves in chloroform, and with difficulty in alcohol, from which it crystallises in colourless needles melting at 212°. When treated with 1 mol. of bromine, it loses its two hydrogen-atoms, and forms ethyl diamidopyromellitate. It also yields an acetyl-derivative melting at 132°.

Pyrazolone-derivative of dihydroxypyromellitic (quinoltetracarboxylic) acid, $C_6\left(\genfrac{}{}{0pt}{}{NH}{CO}>NPh\right)_2(COOH)_2$, is best prepared by treating a hot aqueous solution of the acid with twice the theoretical amount of phenylhydrazine hydrochloride, and heating the mixture for three to five hours on the water-bath to complete the reaction. A hydrazide of the acid is probably first formed, and then loses two molecules of water, yielding the pyrazolone-derivative. This forms yellow crystals, which exhibit all the properties of a pyrazolone-derivative. When it is oxidised with fuming nitric acid, or when an alkaline solution of it (which is purple in colour) is oxidised with potassium ferrocyanide, or by simple exposure to the air, a very stable compound,

$$C_6\left(\genfrac{}{}{0pt}{}{N-}{CO}>NPh\right)_2(COOH)_2,$$

is formed, which gives with alkalis a yellow solution exhibiting a green fluorescence. Two of the hydrogen-atoms in the pyrazolone-derivative are replaceable by metals. When it is heated with excess of benzoic chloride, the dibenzoyl-dipyrazolone anhydride,

$$O<\genfrac{}{}{0pt}{}{CO}{CO}>C_6\left(\genfrac{}{}{0pt}{}{NBz}{CO-}>NPh\right)_2,$$

is formed. This forms yellow crystals soluble in alcohol, melting at 140°, and volatilising without decomposition at a very high temperature. Both it and its solutions show a green fluorescence. After boiling with alcoholic soda, acids precipitate the free acid in yellow flakes, the benzoyl-groups not being eliminated.

Dihydroxypyromellitic acid, when heated with large excess of hydroxylamine hydrochloride, yields a hydroxamic acid, which is reconverted into the original acid when boiled with acids. When heated for 10 to 15 minutes at 300—350°, it forms *quinoltetracarboxylic anhydride*, $C_6(OH)_2\left(\genfrac{}{}{0pt}{}{CO}{CO}>O\right)_2$, which is soluble in acetone and ethyl acetate, and crystallises from the latter in yellow prisms with red fluorescence. It volatilises without decomposition at 350°, and dissolves in water giving a red solution, which when left to itself, or heated, is transformed into the acid. Its alkaline salts are very deep red in colour.

Dihydroxypyromellitic acid yields bromanil, $C_6H_4Br_2$, when allowed to remain for 12 hours with excess of bromine and some water; quinone-tetracarboxylic acid, $C_6O_2(COOH)_4$, is probably first formed, and then its carboxyl-groups are replaced by bromine. It also yields chloranil when treated with potassium chlorate and hydrochloric acid, but with iodine and hydriodic acid, it yields, not iodanil, but iodoform, and with nitric acid, nitranilic acid, $C_6O_2(NO_2)_2(OH)_2$, which is, however, doubtless derived from unstable nitranil first formed. Dihydrodihydroxypyromellitic acid could not be prepared either by saponification of its ethyl salt or by reduction of dihydroxypyromellitic acid, carboxyl-groups being always eliminated. These facts, together with those known regarding succinosuccinic acid, show how unstable hydroxybenzenecarboxylic acids are. But dihydroxyterephthalic acid, and still more so dihydroxypyromellitic acid are stable, and so one is led " to the inevitable conclusion that these are coloured benzene-derivatives, and that they can never exist as quinolcarboxylic acids."

The author now proceeds to prove that the substituted groups in derivatives of ethyl dihydroxypyromellitate and dihydrodihydroxypyromellitate (paradiketohexamethylenetetracarboxylate) are joined to oxygen, and not directly to carbon. This he does by converting ethyl dimethoxypyromellitate by heating with alcoholic soda into the sodium salt, this into the silver salt, and this finally into a substance melting at 134°, which is identified as methyl dimethoxypyromellitate. The intermediate product, $OMe{\cdot}C_6(ONa)(COOEt)_4$, obtained by the action of methyl iodide on ethyl disodoxypyromellitate, was also examined; it forms yellow plates with green fluorescence, soluble in alcohol. The best way of preparing sodium salts such as that mentioned above is to dissolve the substance (an ethyl salt, &c.) in chloroform, and add a solution in alcohol of the theoretical amount of sodium, diluted with chloroform; the sodium salt is precipitated in the gelatinous state, and is dried on a porous plate in the air, or at 100°.

Methyl dimethoxypyromellitate, $C_6(OMe)_2(COOMe)_4$ is formed by heating methyl disodoxypyromellitate, $C_6(ONa)_2(COOMe)_4$, with excess of methyl iodide in a sealed tube. It melts at 134°, and volatilises without decomposition. Its reactions show that it is a methoxy- and not a ketonic compound.

Methyl diacetoxypyromellitate, $C_6(OAc)_2(COOMe)_4$, is formed by the action of acetic chloride on the above-mentioned sodium salt. It melts at 147°, and volatilises without decomposition. Its reactions are those of an acetyl-derivative of a phenol.

Methyl dihydrodiacetoxypyromellitate, $C_6H_2(OAc_2)_2(COOMe)_4$, is formed by the action of zinc and hydrochloric acid on the preceding compound. It melts at 173°, and volatilises without decomposition. It is dimorphous. With bromine, it yields methyl dihydroxypyromellitate, $C_6(OH)_2(COOMe)_4$, melting at 207°; with nitric acid, it behaves exactly like methyl paradiketohexamethylenetetracarboxylate, yielding first ethyl dihydroxypyromellitate, and then ethyl quinonepyromellitate, melting at 208°. It may also be obtained from methyl disodioparadiketohexamethylenedicarboxylate and acetic chloride; hence methyl paradiketohexamethylenetetracarboxylate is not a ketonic but a methoxy-derivative.

Ethyl dibenzoyloxypyromellitate, $C_6(OBz)_2(COOEt)_4$, is formed by treating the corresponding disodium compound with benzoic chloride. It melts at 157°, and when reduced with zinc and hydrochloric acid, yields *ethyl dihydrodibenzoyloxypyromellitate*, $C_6H_2(OBz)_2(COOEt)_4$, melting at 135°, and volatilising without decomposition. This substance is also formed when ethyl paradiketohexamethylenetetracarboxylate is treated with benzoic chloride. By bromine, it is reconverted into the pyromellitate, $C_6(OBz)_2(COOEt)_4$, melting at 157°; sulphuric acid decomposes it into benzoic acid and ethyl paradiketohexamethylenetetracarboxylate, melting at 143°.

The author now proceeds to prove that also in derivatives of ethyl dihydroxyterephthalate and succinosuccinate the substituted groups are united to oxygen.

Ethyl dimethoxyterephthalate, $C_6H_2(OMe)_2(COOEt)_2$ $[(OMe)_2 = 1:4]$, was prepared from the corresponding sodium salt and methyl iodide. It forms colourless plates with a marked blue-violet fluorescence, melting at 101·5°, and volatilising without decomposition. Its entire behaviour shows that the methyl-groups are united to oxygen. When heated with dilute alcoholic soda, it yields *dimethoxyterephthalic acid*, $C_6H_2(OMe)_2(COOH)_2$, melting at 265°. It is not itself fluorescent, but in aqueous solution exhibits blue-violet fluorescence.

Ethyl dibenzyloxyterephthalate, $C_6H_2(O{\cdot}CH_2Ph)_2(COOEt)_2$, is formed by treating the corresponding disodium salt with benzyl chloride. It forms colourless needles exhibiting blue-violet fluorescence, melting at 96·5°, and volatilising without decomposition. It does not give the ordinary ketonic reactions. In the presence of alkalis, the benzyl groups are stable, but with acids, *ethyl dihydroxyterephthalate*, $C_6H_2(OH)_2(COOEt)_2$, melting at 133°, is formed, and bromine appears to replace some of the hydrogen of the benzyl-groups. When reduced with zinc and hydrochloric acid, it yields *ethyl α-dihydrodibenzyloxyterephthalate*, $C_6H_4(OCH_2Ph)_2(COOEt)_2$, which forms colourless crystals, with faint blue-violet fluorescence, melting at 169°, and volatilising without decomposition. It was impossible to remove any of the hydrogen-atoms. Three isomerides of this substance (six isomeric dihydrobenzene-derivatives are possible) are obtained by treating ethyl disodiosuccinosuccinate with benzyl chloride, namely, a β-variety melting at 148·5°, which is transformed by sulphuric acid into a polymeric second, ϖ-variety melting at 272°, and volatilising without decomposition, and a third, γ-variety melting at 140·5°, also volatile without decomposition. None of these compounds gives the ketonic reactions.

Ethyl diacetoxyterephthalate, $C_6H_2(OAc)_2(COOEt)_2$, prepared from ethyl disodoxyterephthalate and acetic chloride, melts at 154°, and is not acted on by bromine.

Ethyl diacetoxysuccinosuccinate, $C_6H_4(OAc)_2(COOEt)_2$, prepared from ethyl disodoxysuccinosuccinate, melts at 169°, and is converted by bromine into ethyl dihydroxyterephthalate. But these two substances are crystallographically absolutely identical. A similar isomorphism also occurs between *ethyl dibenzoyloxyterephthalate*, $C_6H_2(OBz)_2(COOEt)_2$, melting at 174°, and *ethyl α-dibenzoyloxysuccinosuccinate*, $C_6H_4(OBz)_2(COOEt)_2$, melting at 165°. The latter substance is formed by acting on ethyl disodoxysuccinosuccinate with benzoic chloride, and when treated with bromine yields ethyl dibenzoyloxyterephthalate. Ethyl dibenzoyloxyterephthalate is formed from the disodoxyterephthalate and benzoic chloride; when reduced with zinc and aqueous hydrochloric acid, it yields three varieties of ethyl dihydrodibenzoyloxyterephthalate, $C_6H_4(OBz)_2(COOEt)_2$, an α-variety melting at 165°, identical with that obtained from the ethyl disodoxysuccinosuccinate, a β-variety melting at 138°, and a γ-variety melting at 102·5°; all three varieties volatilise without decomposition. If, however, alcoholic hydrochloric acid be used, the α-variety is obtained, together with two, possibly three, new isomerides.

Finally a few compounds are described to complete the work on durene (Abstr., 1887, 255). *Methyl dinitropyromellitate*, prepared from the silver salt and methyl iodide, forms long, flat, transparent needles, melting at 180·6°; when reduced, it yields *methyl diamidopyromellitate*, forming long, flat needles melting at 149·6°, and this on further reduction yields *methyl dihydrodihydroxypyromellitate* (*paradiketohexamethylenetetracarboxylate*) in heavy cubes with faint blue fluorescence, melting at 175°. This again, when treated with bromine, yields *methyl dihydroxypyromellitate*, which is a granular, yellow powder melting at 207°. *Methyl quinonepyromellitate*, $C_6O_2(COOMe)_4 + 2CH_3{\cdot}OH$, obtained by oxidation of the diamidopyromellitate with nitric acid, is colourless. At 150° it loses alcohol, becoming yellow; it then melts at 208°, and volatilises unchanged. C. F. B.

Hydrazobenzenedisulphonic Acid. By H. LIMPRICHT (*Ber.*, 23, 1052—1057).—The compound obtained by the reduction of metanitrobenzenesulphonic acid, and described as hydrazobenzenesulphonic acid (Abstr., 1880, 805, 807, 808, 809), is, in reality, benzidinedisulphonic acid, as was suggested by Schultz. The true hydrazobenzenedisulphonic acid cannot be isolated, but it can be obtained in an impure condition as follows:—A solution of potassium metazobenzenedisulphonate is treated with a solution of basic lead acetate, the red, crystalline precipitate of the basic lead salt washed well with boiling water, then suspended in hot water, and treated with hydrogen sulphide; the colourless filtrate, on evaporation, yields a mixture of metamidobenzenesulphonic acid, benzidinesulphonic acid, and hydrazobenzenedisulphonic acid, from which the last-named compound can be obtained, mixed, however, with benzidinedisulphonic acid, by extracting with cold water. It forms colourless crystals, is readily soluble in water, and has powerful reducing properties; when treated with mineral acids, it is converted into benzidinedisulphonic acid, and when its alkaline solution is evaporated, it is converted into azobenzenedisulphonic acid. The *barium* salt, $C_{12}H_{10}S_2N_2O_6Ba$, is a colourless, or yellowish, crystalline compound, only sparingly soluble in hot water, and insoluble in alcohol; it seems to crystallise with 2 mols. of water. The *potassium* salt, $C_{12}H_{10}S_2N_2O_6K_2$, is crystalline.

F. S. K.

Decomposition of Sulphones. By E. STUFFER (*Ber.*, 23, 1408—1414).—It is well known that certain sulphones are quite stable towards alkalis, whilst others are readily hydrolysed. The author has studied the action of alkalis on a number of different sulphones, for the purpose of discovering the connection between their constitution and decomposibility. Compounds of the formulæ

$CH_2(SO_2R)_2$ and $R'\cdot CH(SO_2R)_2$ are unacted on by alkalis; an increase in the length of the carbon chain (R) linked to the SO_2-group, does not influence this result. Trimethylenediethylsulphone and trimethylenediphenylsulphone are also unaffected by alkalis. On the other hand, the isomeric *propylenediphenylsulphone*,

$$SO_2Ph\cdot CHMe\cdot CH_2\cdot SO_2Ph,$$

which forms colourless crystals, and melts at 113—114°, reacts with alkalis with elimination of one phenylsulphone-group, in this respect resembling ethylenediphenylsulphone.

The author has also prepared *diphenylsulphonebromopropane*, $C_3H_5Br(SO_2Ph)_2$, and *triphenylsulphonepropane*, $C_3H_5(SO_2Ph)_3$. The former compound is obtained by warming a mixture of allyl bromide and sodium phenylmercaptide: on pouring into water, an oily liquid separates, which is purified by treating with potassium permanganate and dilute sulphuric acid; it crystallises from alcohol in colourless needles melting at 160°, and is easily hydrolysed. Triphenylsulphonepropane is prepared by boiling allyl tribromide with an alcoholic solution of sodium benzenesulphonate. The compound crystallises from dilute alcohol in colourless needles melting at 226°, and is readily hydrolysed on warming with alkalis. J. B. T.

Oxidation of Phenyl Trithioformate. By E. LAVES (*Ber.*, 23, 1414—1417).—Phenyl trithioformate is dissolved in benzene and treated with slight excess of potassium permanganate solution and dilute sulphuric acid. The filtrate from the manganese precipitate contains benzenesulphonic acid. The manganese precipitate is dried and extracted with boiling alcohol; on cooling, *methyldiphenylsulphone phenyl sulphide*, $SPh\cdot CH\cdot(SO_2Ph)_2$, separates in lustrous, silky needles melting at 174—175°. The compound is sparingly soluble in cold water; it has acid properties, and dissolves in sodium hydroxide solution in the cold, and in sodium carbonate solution on heating; from each of these it is reprecipitated unchanged by acids. On oxidation, the corresponding trisulphone is formed melting at 215°.

Ethenyldiphenylsulphone phenyl sulphide, $SPh\cdot CMe(SO_2Ph)_2$, is obtained by dissolving the above compound in dilute alcoholic sodium hydroxide, and heating the solution, together with methyl iodide, in a sealed tube; it crystallises from chloroform, and melts at 194° with previous softening. Benzenesulphonic acid is obtained as sole product by the oxidation of phenyl trithioformate with alkaline potassium permanganate solution.

The above results are in apparent contradiction to the observations of Gabriel (compare Abstr., 1877, 311), who obtained phenyl disulphide by the oxidation of phenyl trithioformate. J. B. T.

Acetyl-derivatives of Indole. By C. ZATTI and A. FERRATINI (*Ber.*, 23, 1359—1361).—1'-*Acetylindole*, C_8NH_6Ac, corresponding with 1-acetylpyrroline, may be readily prepared by acting on indole with acetic anhydride in the usual manner, evaporating the excess of the latter in a vacuum, and then distilling the residue with steam. The yellowish, oily liquid obtained is purified by redistillation in a current of steam, and then fractionated under reduced pressure. It boils at 152—153° under 14 mm. pressure, with slight decomposition, and has an odour resembling that of the known acetyl-derivatives of pyrroline and indole. It is readily decomposed by alkalis into indole and acetic acid.

The acetyl compounds remaining after the first treatment with steam consist of the two known acetyl-derivatives of indole in almost equal proportions. The original product, on treatment with anhydrous reagents, yields almost solely the 1′ : 3′-diacetylindole, and it would therefore appear that the latter has been partially converted into 3′-acetylindole by the action of the water. Experiment has shown that 1′ : 3′-diacetylindole is in reality thus decomposed on long-continued boiling with water.

3′-Acetylindole undergoes condensation on treatment with benzaldehyde forming *3′-cinnamylindole*. $C_{17}H_{13}NO$, which crystallises from alcohol in small, yellow, lustrous plates melting at 229—231°, and corresponding exactly with the compound obtained in a similar manner from 1′-acetylpyrroline. Unsuccessful attempts were made to convert this by oxidation into an acid corresponding with pyrrylglyoxylic acid. H. G. C.

Benzilorthocarboxylic Acid. By C. Graebe (*Ber.*, 23, 1344—1349).—It was observed by Juillard and Graebe (Abstr., 1888, 1095) that benzilorthocarboxylic acid exists in two modifications, one of which is yellow and the other white. Further investigation has confirmed this result, and has shown that the two compounds differ not only in their colour, but also in melting point and in solubility in concentrated alcohol, 50 per cent. alcohol, and chloroform. In their chemical relationships, however, no difference has yet been found.

In the preparation of benzilorthocarboxylic acid by the oxidation of desoxybenzoïncarboxylic acid, a mixture of both modifications is formed, and, on recrystallisation from water or dilute alcohol, a mixture of white and yellow crystals is also usually obtained. By very slow crystallisation from chloroform, and at a low temperature, both the mixture and the yellow modification are completely converted into the white compound. The yellow modification is best prepared by heating the mixture by itself to 140—150°, or with benzene to 160—180°, in a sealed tube.

The molecular weight, as found by Raoult's method, was the same for both acids. Both dissolve in solutions of alkalis and alkaline carbonates, forming a yellow solution from which acids precipitate the unaltered substances. By the action of concentrated alkalis, both yield the same benzhydroldicarboxylic acid. They also yield the same ethyl salt, melting at 71°, and the same monoxime,

$$COPh{\cdot}C(NOH){\cdot}C_6H_4{\cdot}COOH,$$

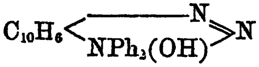
which is colourless, melts at 166°, does not lose water at 100°. and may be converted into the dioxime, which at once loses water, forming the anhydride. The carboxyl-group is not altered in the formation of the anhydride. The monoxime also readily yields a hydrazone, and phenylhydrazine also acts readily on the yellow and white modifications forming the same hydrazone.

The difference in colour of the two compounds is most readily explained by assuming a structure of the two compounds similar to that given by Victor Meyer for benzile and isobenzile, namely, Ph·CO·CO·Ph and  $O<\begin{matrix}CPh\\|\\CPh\end{matrix}>O$. The extreme readiness with which one modification passes into the other is against this view, and the author thinks that the isomerism is best explained in a similar manner to that of the benziledioximes, as given by V. Meyer and Auwers. According to this hypothesis, the carboxyl exercises such an influence on the benzile molecule that two configurations are possible, the one of which is formed chiefly at a low and the other at a high temperature. If the carboxyl-group be converted into the group COOEt, its influence is lessened, and only that modification corresponding with benzile is formed, and the addition of an oximido-group appears to produce a like effect. If two carboxyl-groups are introduced into benzile, as in diphthalic acid, their influence becomes so strong that only the colourless modification exists, whereas if the acid be converted into an ethereal salt, their influence is so much weakened that a white and yellow modification are again obtained, as has been shown experimentally for the methyl salts.

If this hypothesis is correct, it then becomes necessary to ascertain to which of the possible configurations of benzile, namely,  $\begin{matrix}Ph\cdot C:O\\|\\O:C\cdot Ph\end{matrix}$ and $\begin{matrix}O:C\cdot Ph\\|\\O:C\cdot Ph\end{matrix}$, these modifications correspond. On this question the formation of anhydrides may throw some light. Thus the two oximes of desoxybenzoïncarboxylic acid both yield anhydrides of the formulæ  $\begin{matrix}Ph\cdot C\cdot CH_2\cdot C_6H_4\\ \| \qquad | \\ N-O-CO\end{matrix}$ and $\begin{matrix}Ph\cdot CH_2\cdot C-C_6H_4\\ \| \qquad | \\ N\cdot O\cdot CO\end{matrix}$, whilst the monoxime of benzilemonocarboxylic acid does not yield an anhydride. In the first case, therefore, either free rotation is possible or the carboxyl-group is originally in such a position that separation of water can readily take place, whilst in the case of benzilemonocarboxylic acid monoxime free rotation cannot take place, and the carboxyl-group is not in a position which allows of the elimination of water. Diphthalic acid dioxime also readily yields an anhydride, which, according to Juillard and Graebe (*loc. cit.*), is a dilactone, the formation of which must be rendered possible by the relative position of the carboxyl- and carbonyl-groups.

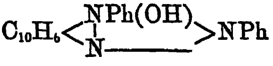
The formation of anhydrides, which should always be possible if free rotation can take place, appears to be most readily understood on Victor Meyer's hypothesis. A large amount of experimental work is, however, necessary before the question can be regarded as settled, and the author is therefore continuing his investigation with a view to this end.
H. G. C.

Azo-derivatives of Phenyl-β-naphthylamine. By T. ZINCKE (*Ber.*, 23, 1315—1325).—According to Zincke and Campbell (this vol., p. 787), the azimido-compounds contain the group —N:N·N·R, and not, as usually supposed, the group $\genfrac{}{}{0pt}{}{N}{N}\!\!>\!N{\cdot}R$. The formula given by Zincke and Lawson for the ammonium base obtained by the oxidation of benzeneazophenyl-β-naphthylamine (Abstr., 1887, 731) therefore requires alteration. If this compound is an azammonium compound corresponding with those obtained by the action of alkyl iodides on azimido-compounds, its constitution would be represented by the formula I, in favour of which is the fact that the oxidation compound resembles the latter substances in having a bitter taste, and in the fact that the free base readily undergoes decomposition.



$$C_{10}H_6<\begin{array}{l}\overline{\qquad\quad}N\\ NPh_2(OH)\end{array}\!\!\gg N$$

I.



$$C_{10}H_6<\begin{array}{l}NPh(OH)\\ N\overline{\qquad\quad}\end{array}\!\!>NPh$$

II.

$$C_{10}H_6<\begin{array}{l}N\!\!-\!\!-\\ NPh\end{array}\!\!\gg NPh{\cdot}OH.$$

III.

Experiments made to obtain evidence of a direct connection between these compounds have, however, only given negative results. Thus it was not found possible to convert the azimido-compound

$$C_{10}H_6<\begin{array}{l}\overline{\quad}N\\ NPh\end{array}\!\!\gg N$$

into the chloride $C_{10}H_6<\begin{array}{l}\overline{\qquad}N\\ NPh_2Cl\end{array}\!\!\gg N$, and compare this with the chloride obtained from the oxidation compound. An unsuccessful attempt was also made to convert the azammonium compound $C_{10}H_6<\begin{array}{l}\overline{\qquad\quad}N\\ NMePhCl\end{array}\!\!\gg N$, by oxidation, into the compound

$$NHMe{\cdot}C_{10}H_6{\cdot}N_2Ph.$$

It was therefore necessary to consider the other possible formulæ, which are given above in II and III, and whose formation from the azo-compound may be readily understood. They explain also the fact that the ammonium base is readily reconverted into the azo-compound, either by heating its aqueous solution or by the action of reducing agents. In the first case, the oxygen set free acts on a portion of the original substance, forming a new base, which has the formula $C_{22}H_{15}N_3O$. More energetic reduction converts the azo-compound into phenyl-β-naphthylamine and aniline. This reaction, although readily explained by formulæ II and III, is not in favour of formula I, as, if that were correct, the phenyl must change its position in the reaction. On the other hand, it is not easy to understand why the linkage of the nitrogen-atoms assumed in II and III does not remain unaltered when the hydrogen takes the place of the hydroxyl-group.

Experiments made to ascertain whether this oxidation-product and the azammonium compounds were acted on in the same way were without success, but the investigations of Matthes (see next abstract), on the oxidation of isomeric azo-compounds, have given more favourable results. If the formula I be correct, the isomeric azo-compounds $C_7H_7 \cdot NH \cdot C_{10}H_6 \cdot N_2Ph$ and $NHPh \cdot C_{10}H_6 \cdot N_2 \cdot C_7H_7$ would yield, on oxidation, one and the same base; whereas, if the second or third formula is correct, different bases would be obtained. The results given below show that two different bases are formed. This is, therefore, in favour of formula II or III, but cannot be regarded as a proof, as geometrical isomerides of the first formula might possibly exist. Further experiments are therefore necessary for the full explanation of these reactions.

The above ammonium base is poisonous, acting chiefly on the brain.

H. G. C.

Azo-derivatives of Secondary β-Naphthylamines. By P. MATTHES (*Ber.*, **23**, 1325—1334).—The compounds described below were prepared according to the method given by Zincke and Lawson (Abstr., 1887, 730); in consequence, however, of the tendency of many of the compounds to form azines, an excess of acid and too high a temperature must be avoided. The oxidation was carried out sometimes with chromic acid, sometimes with potassium dichromate, and the chromates formed converted into the hydrochlorides by the action of alcohol and hydrochloric acid.

Paratolueneazo-β-naphthylphenylamine, $NHPh \cdot C_{10}H_6 \cdot N_2 \cdot C_7H_7$, is obtained from β-naphthylphenylamine, and paradiazotoluene chloride, and crystallises from hot alcohol or acetic acid in deep-red needles having a fine metallic lustre, and melting at 120°. On oxidation, it forms an ammonium base, $C_{23}H_{17}N_3$, which is best isolated as the nitrate, the hydrochloride and sulphate being very soluble. The *nitrate* is sparingly soluble in water and cold alcohol, more readily in hot alcohol, and forms slender, slightly-yellow needles melting at 284—285°, and reddening at 140°. The *picrate*,

$$C_{23}H_{17}N_3,C_6H_2(NO_2)_3 \cdot OH,$$

forms slender, yellow needles melting at 238—239°; the *platinochloride*, $(C_{23}H_{17}N_3)_2,H_2PtCl_6$, a granular, yellow precipitate; the *mercurochloride*, $C_{23}H_{17}N_3,HHgCl_3$, a white, crystalline precipitate; and the *stannochloride*, $C_{23}H_{17}N_3,HSnCl_3$, small, yellow needles which become brown at 145° and melt at 175—176°.

Benzeneazo-β-naphthyltolylamine, $C_7H_7 \cdot NH \cdot C_{10}H_6 \cdot N_2Ph$, is prepared from β-naphthyltolylamine and diazobenzene chloride, and also forms deep-red needles with a metallic lustre; it is readily soluble in benzene and acetic acid, less so in alcohol and ether, and melts at 152°. On oxidation, it yields an ammonium base isomeric with the one obtained from the foregoing azo-compound, which is also best isolated as the *nitrate*. The latter forms short, slender, slightly-yellow needles which do not melt at 320°. The *picrate*,

$$C_{23}H_{17}N_3,C_6H_2(NO_2)_3 \cdot OH,$$

has a slightly darker colour than the isomeric salt, and melts at 206—207°. The *platinochloride*, $(C_{23}H_{17}N_3)_2,H_2PtCl_6$, also melts at a very high temperature, and forms a yellowish precipitate; and the *stannochloride*, $C_{23}H_{17}N_3,HSnCl_3$, crystallises in yellowish needles melting at 205—206.

Benzeneazo-αβ-dinaphthylamine, $C_{10}H_7{}^{\alpha}\cdot NH\cdot C_{10}H_6\cdot N_2Ph$, formed by acting on αβ-dinaphthylamine with diazobenzene chloride, always contains a violet-coloured impurity which is the hydrochloride of the isomeric diazo-compound. The latter may be decomposed by ammonia, and the product recrystallised from benzene, when the pure β-compound is obtained in woolly aggregates of deep-red needles melting at 167°. The oxidation requires great care, and then yields an ammonium base, whose *nitrate*, $C_{26}H_{17}N_3,HNO_3$, melts at 245—250° with decomposition. The *platinochloride*, $(C_{26}H_{17}N_3)_2,H_2PtCl_6$, forms a greyish-yellow precipitate, which is more soluble than the isomeric compound.

α-Naphthaleneazo-β-naphthylphenylamine, $NHPh\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_7{}^{\alpha}$, is formed from β-naphthylphenylamine and α-diazonaphthalene chloride without warming, and forms dark-red needles with metallic lustre which melt at 140°, and crystallise best from acetic acid. The ammonium base, obtained on oxidation, forms a *nitrate*, $C_{26}H_{17}N_3,HNO_3$, which crystallises in slightly-yellow needles, the melting point of which is above 320°. The *picrate*, $C_{26}H_{17}N_3,C_6H_2(NO_2)_3\cdot OH$, crystallises from acetic acid in short, hair-like needles melting at 270—271°, whilst the *platinochloride*, $(C_{26}H_{17}N_3)_2,H_2PtCl_6$, separates from acetic acid as a granular, crystalline precipitate.

β-Naphthaleneazo-β-naphthylphenylamine, $NHPh\cdot C_{10}H_6\cdot N_2\cdot C_{10}H_7{}^{\beta}$, obtained from β-diazonaphthalene chloride, forms brick-red needles melting at 154—155°. The ammonium base formed by its oxidation is separated as the *nitrate*, $C_{26}H_{17}N,HNO_3$, which crystallises from alcohol in slender, yellowish needles melting above 320°. The *picrate*, $C_{26}H_{17}N_3,C_6H_2(NO_2)_3\cdot OH$, also forms slender, yellow needles which melt at 214°.

Benzeneazo-ββ-dinaphthylamine, $C_{10}H_7{}^{\beta}\cdot NH\cdot C_{10}H_6\cdot N_2Ph$, can only be prepared in the cold and in absence of an excess of acid, as otherwise the azine described below is obtained. It forms red needles or plates, soluble in alcohol and benzene, and melts at 139°. On oxidation, it does not yield an ammonium base, but forms the azine.

Symmetrical-ββ-naphthazine, $C_{10}H_6<\overset{N}{\underset{N}{|}}>C_{10}H_6$, is formed most readily by adding a strongly acid solution of diazobenzene chloride to a warm solution of ββ-dinaphthylamine, the azo-compound first formed decomposing in presence of acids into the azine and an aniline salt. It crystallises from hot alcohol or acetic acid in long, woolly, aggregates of slender, yellow needles which melt at 242—243°. Its solution in alcohol and acetic acid shows a strong blue, and in acetic acid a green fluorescence. H. G. C.

β-Dinaphthylcarbamide Chloride and β-Tetranaphthylcarbamide. By O. KYM (*Ber.*, 23, 1540—1543).—Kühn and Landau (this vol., p. 634) contradicted the author's statement (*ibid*, p. 633) that β-dinaphthylcarbamide chloride cannot be conveniently prepared by the action of carbonyl chloride on β-dinaphthylamine at the ordinary temperature; but there is some mistake in their work, for they used a solution of 1 part of β dinaphthylamine in 30 parts of cold benzene, whilst the author finds that, at 14·5°, 92·3 parts of benzene are required to dissolve 1 part of pure β-dinaphthylamine, and 70·6 for 1 part of the crude substance. However, he finds that when a solution of carbonyl chloride in toluene is allowed to remain in a closed vessel with a nearly saturated benzene solution of β-dinaphthylamine, crystals of the hydrochloride of the latter substance are slowly deposited, but the method is not an advantageous one for the preparation of β-dinaphthylcarbamide chloride.

β-Tetranaphthylcarbamide, $CO[N(C_{10}H_7)_2]_2$, was prepared by heating 2 grams of pure β-dinaphthylamine with 2·5 grams of β-dinaphthylcarbamide chloride in a test-tube, the final temperature being 260°. The resulting crystalline mass was crystallised from toluene, and then recrystallised from benzene. Small, sandy, ill-defined crystals were thus obtained, yellowish-white in colour, melting at 294—295°, and dissolving readily in benzene and toluene, but little in alcohol and acetic acid.

The substance obtained by Kühn and Landau by heating β-dinaphthylamine and β-dinaphthylcarbamide chloride with zinc-dust could not have been β-tetranaphthylcarbamide, for it melted at 167—169°, that is below β-dinaphthylamine and β-dinaphthylcarbamide chloride, whereas all tetralkyl carbamides melt at much higher temperatures than the corresponding dialkyl-amines and carbamide chlorides. C. F. B.

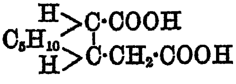
Action of Hydriodic Acid on 1 : 4′-Nitronaphthalenesulphonamide. By A. Eckbom (*Ber.*, 23, 1118—1124).—Two products are obtained in this reaction, 1 : 4′-amidonaphthalenesulphonamide and 1 : 4′-diamidodinaphthyl bisulphide, according to the strength of the hydriodic acid; when the acid is very strong, the latter substance only is formed.

Amidonaphthalenesulphonamide, $[NH_2\cdot C_{10}H_6\cdot SO_2NH_2 = 1 : 4']$, is obtained by gently boiling nitronaphthalenesulphonamide with red phosphorus and excess of hydriodic acid (sp. gr. = 1·5) for six hours. The hydriodide crystallises out when the mixture is cooled; it is dissolved in alcohol, treated with sulphurous anhydride and then with ammonia, and the precipitated amide recrystallised from alcohol. It forms small, glittering, colourless tables melting at 259—260° to a brown oil, insoluble in water and cold alcohol, dissolving with difficulty in benzene, but more readily in acetic acid or hot alcohol. The *hydrochloride* crystallises partly in colourless, glittering scales, partly in star-like groups of needles; it is anhydrous. The *hydriodide* forms needles which are soluble in alcohol. The *acetonaphthalide*, obtained by treating the amide with the theoretical quantity of acetic anhydride, melts at 231—232°, and dissolves with difficulty in alcohol and water. The *diacetonaphthalide*, obtained by treating the amide with excess of acetic anhydride, forms thin scales melting at 200°. Both these compounds are anhydrous.

Diamidodinaphthyl bisulphide, $NH_2\cdot C_{10}H_6\cdot S\cdot S\cdot C_{10}H_6\cdot NH_2$ $[NH_2 : S = 1 : 4']$, is found in the mother liquor after the amidonaphthalenesulphonamide has crystallised out. If nitronaphthalenesulphonamide is reduced with hydriodic acid of sp. gr. 1·96, diamidodinaphthyl bisulphide only is formed. It crystallises from alcohol in thin, lustrous, colourless scales melting at 193° to a brown oil. It is found to be identical with the substance obtained by reducing dinitrodinaphthyl bisulphide, and must, therefore, have the constitution given above. The *hydrochloride* (with 2HCl) forms minute, colourless needles decomposed by water and alcohol. The *hydriodide* and the *sulphate* crystallise in needles. The *diacetonaphthalide* compound forms anhydrous, colourless scales melting at 274°, sparingly soluble in alcohol and water, more readily in acetic acid. The *dipropionaphthalide* compound, obtained by treating the amido-compound with propionic anhydride, forms anhydrous, colourless scales melting at 242°, insoluble in water, but soluble in acetic acid.

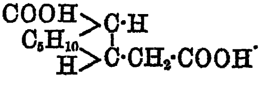
Amidonaphthalenesulphonamide, when heated at 140° for 2—3 hours in sealed tubes with red phosphorus and hydriodic acid (sp. gr. = 1·5), yields a substance crystallising in tables, which seems to be the hydriodide of *amidothionaphthol*. C. F. B.

Camphoric Acids. By J. E. MARSH (*Proc. Roy. Soc.*, **47**, 6—12). —When excess of phosphorus pentachloride is heated with camphoric acid on the sand-bath, *chlorocamphoryl chloride*, $C_{10}H_{13}Cl_3O_3$, is obtained. If, however, the temperature is not allowed to rise above that of boiling water, camphoryl chloride is the chief product of the reaction. This substance boils at 140° under 15 mm. pressure. When it is added gradually to 10 times its weight of hot water, about equal quantities of ordinary camphoric anhydride and a lævo-rotatory camphoric acid are formed, together with a small proportion of a more soluble substance, which appears to be a mixture of dextrogyrate camphoric acid and the new lævo-acid. The acid may be separated from the anhydride by treatment with sodium carbonate, in which the latter is insoluble. It dissolves, however, in hot caustic soda, and from the solution thus obtained the ordinary dextrorotatory acid is precipitated. On distillation, the lævo-acid gives the anhydride of the dextro-acid. Although the two acids have specific rotatory powers of +48·25° and −48·09° for the D-line, they are not merely optical isomerides; for the lævo-acid differs markedly in its ordinary properties from the dextro-acid, the melting points, for example, being 170° and 185° respectively. The mixture of the two isomerides, also, does not yield any definitely characterised compound. The camphoryl chloride from which both the acids are prepared is lævo-gyrate. To interpret his results, the author proposes the following geometrical formulæ for the two acids:—



$$C_6H_{10}\begin{matrix}\overset{H}{>}C\cdot COOH\\ |\\ \underset{H}{>}C\cdot CH_2\cdot COOH\end{matrix}$$

and



$$C_6H_{10}\begin{matrix}\overset{COOH}{>}C\cdot H\\ |\\ \underset{H}{>}C\cdot CH_2\cdot COOH\end{matrix}.$$

The first formula appertains to the dextro-acid and its optically opposite isomeride—dextro- and lævo-ciscamphoric acids; the second formula represents the new lævo-acid and the corresponding dextro-isomeride—dextro- and lævo-transcamphoric acids. The two pairs are thus related to each other as maleic acid is to fumaric acid. Lævo-transcamphoric acid would appear to be identical with the lævo-acid obtained by Friedel from the so-called mesocamphoric acid. J. W.

Composition of Digitonin. By H. KILIANI (*Ber.*, 23, 1555—1560).—According to Schmiedeberg, commercial digitalin contains, in addition to digitoxin, its most important pharmacological constituent, three glucosides, namely, digitonin, digitalin, and digitaleïn, the first in greater amount, and when heated with dilute acid, it yields a substance which reduces Fehling's solution, and also a crystalline compound insoluble in water, which he named digitogenin. The author dissolved 1 part of commercial digitalin in 10 parts of water, added 1 part of concentrated hydrochloric acid (sp. gr. 1·19), and heated the mixture for six hours on the water-bath. By this means, a solution and a light-grey precipitate were obtained. The solution contained about equal quantities of two glucoses, which were identified by means of the melting points of their osazones, and their behaviour when oxidised, as galactose and dextrose respectively. The precipitate of digitogenin was crystallised from alcohol, and found to be rather more than equal in amount to either of the two glucoses. It has the constitution $(C_5H_8O)_x$, probably $C_{15}H_{24}O_3$. Digitonin has, therefore, very probably the composition $C_{27}H_{44}O_{13}$, and its hydrolysis is expressed by the equation—

$$\underset{\text{Digitonin.}}{C_{27}H_{44}O_{13}} + 2H_2O = \underset{\text{Digitogenin.}}{C_{15}H_{24}O_3} + \underset{\text{Galactose.}}{C_6H_{12}O_6} + \underset{\text{Dextrose.}}{C_6H_{12}O_6}.$$

This would require a ratio of 1·4 : 1 : 1 between the weights of digitogenin, galactose, and dextrose formed; that actually found is more nearly 1 : 1 : 1, but it must be remembered that at the moment of hydrolysis digitogenin is much more easily attacked than galactose and dextrose, and very readily yields resinous products. An analysis of the raw material agreed well with the formula $C_{27}H_{44}O_{13}$; not so, however, did Schmiedeberg's analysis.

Digitogenin.—The following details may be added to Schmiedeberg's data regarding this substance. One part requires for solution 35 parts of boiling or 100 parts of cold 93 per cent. alcohol, and 20 parts of boiling or 30 parts of cold chloroform, and 30 parts of cold glacial acetic acid; it is insoluble in water and aqueous alkalis. It seems to form a compound containing chloroform of crystallisation, which loses its chloroform only very slowly at 110°. With alcoholic potash, it forms a crystalline potassium compound, strongly alkaline, and little soluble in alcohol. It forms no stable compounds with barium hydroxide or phenylhydrazine, but is attacked by mineral acids and oxidising agents. C. F. B.

Brazilin. By C. SCHALL and C. DRALLE (*Ber.*, 23, 1428—1437; compare Abstr., 1889, 55, 1004).—On treating the dibromobrazileïn bromides with zinc-dust and acetic acid, part of the halogen is eliminated; with acetic anhydride, instead of acetic acid, acetyl-derivatives are obtained. The following compounds have been prepared in this manner; they are amorphous or slightly crystalline powders, ranging in colour from dark brown to yellowish-brown;

they contain about 1 mol. H_2O, which is driven off by heating at 140°. *Dibromoacetylbrazilein*, $C_{16}H_9Br_2O_3Ac$, from octobromobrazilein; *dibromodiacetylbrazilein*, $C_{16}H_8Br_2O_5Ac_2$, from hexabromobrazileïn; *dibromotriacetylbrazilein*, $C_{16}H_7Br_2O_5Ac_3$, from monobromobrazileïn; *dibromotetracetylbrazilein*, $C_{16}H_6Br_2O_5Ac_4$, from tetrabromobrazileïn; *tribromobrazilein*, $C_{16}H_9Br_3O_5$, from octobromobrazileïn; *tribromotetracetylbrazilein*, $C_{16}H_5Br_3O_5Ac_4$, from hexa- and octobromobrazilein.

An amorphous modification of brazilin tetramethyl ether is obtained by cooling the molten crystalline modification, or by precipitating from acetic acid solution with water; it melts at 82—86°, and is at once converted into the crystalline modification by heating at 89°, or more slowly at ordinary temperatures. The refraction equivalent of this compound indicates the existence of six double bonds. *Dibromobrazilin tetramethyl ether*, $C_{16}H_8Br_2(OMe)_4$, is obtained by treating an alcoholic solution of the ether with a glacial acetic acid solution of bromine at ordinary temperatures; it melts at 215°, and is insoluble in alkalis. A 20 per cent. solution of brazilin tetramethyl ether in glacial acetic acid is mixed with a 10 per cent. solution of bromine in the same menstruum, the mixture is first cooled, then heated nearly to boiling; in this way two compounds are formed, the one speedily separates in brilliant, red crystals, the other is deposited more slowly. The red substance appears to be a *dibromobrazilin tetramethyl ether dibromide*, $C_{16}H_6Br_2O(OMe)_4Br_2$, isomeric with the reddish-brown compound described in a previous paper. The second compound formed in the above experiment is *bromobrazilin tetramethyl dibromide*, $C_{16}H_7BrO(OMe)_4Br_2$.

It has been found that brazileïn may easily be prepared by treating a 30 per cent. solution of brazilin in glacial acetic acid, with an equal molecular proportion of potassium nitrite; after remaining for several hours, crystals of pure brazileïn are deposited; the yield is 70 per cent. of the brazilin employed. Hæmatein is obtained in a similar manner from hæmatoxylin.

Brazileïndihydroxime, $C_{16}H_{10}O(OH)_2(NOH)_2$, is obtained by heating an alcoholic solution of brazileïn with excess of hydroxylamine in a sealed tube. The substance is very insoluble, and could not be recrystallised. *Brazileinphenylhydrazone*, $C_{16}H_{12}O_4{:}N_2HPh$, is obtained by boiling brazilein with phenylhydrazine; after purification, the compound is obtained as a dark brown powder which does not melt; it is soluble in alkalis. During the preparation of this compound, a considerable evolution of ammonia occurs, which probably indicates the presence of an alcoholic group in brazileïn.

A comparison of specimens of brazileïn, prepared by each of the four known methods, shows that the compounds are identical: (*a*) in the silvery lustre and form of the crystals; (*b*) in the melting point and crystalline form of the acetyl compound, $C_{16}H_9O_5Ac_3 + 2C_2H_4O_2$; (*c*) in the identity of the substances obtained by three different methylation processes; these facts prove, therefore, that there is only one brazileïn.

J. B. T.

Diastase considered as a Mixture of Maltase and Dextrinase. By H. P. Wijsman, Jun (*Rec. Trav. Chim.*, 9, 1—13; compare also Lintner and Eckhardt, this vol., 519, and Brown and Morris, Trans., 1890. 507).—The author starts with the assumption that the diastase of malt is composed of a mixture of two enzymes—*maltase* and *dextrinase.* The former converts starch into a mixture of maltose and a dextrin coloured violet by iodine, and corresponding with the erythrogranulose of various workers; the latter enzyme converts starch into a dextrin which reduces Fehling's solution, is not coloured by iodine, and corresponds with the maltodextrin of Herzfeld and of Brown and Morris. Maltodextrin is converted into maltose by maltase, and when dextrinase acts on erythro-granulose, a dextrin is formed which does not reduce Fehling's solution, and is not coloured by iodine—this dextrin the author terms *leucodextrin.*

The following experiments are quoted in proof of the above theory. A diastase was prepared by fractionally precipitating with alcohol of 97 per cent., a malt-extract, made with 20 per cent. alcohol, and purifying the precipitate by repeated solution and precipitation. The method employed to show the presence of two enzymes in this preparation consisted of partial separation by diffusion into a gelatinous mass, made by adding gelatin to a solution of Lintner's soluble-starch. When a small quantity of diastase solution was placed on a layer of the solidified starch solution, the progress of the hydrolysing action of the former could be traced by means of iodine solution, it being found that after 1—2 days' action the diffusion-field of the diastase formed a colourless zone bordered by a violet ring, whilst the gelatin with unaltered starch was coloured deep blue. From this the author assumes that the two enzymes diffuse into the gelatin mixture at different rates depending on their relative concentrations, and the violet-coloured ring denotes the space in which the maltase has penetrated beyond the dextrinase, whilst in the non-coloured inner zone both enzymes are present. When a portion of the violet-coloured ring was removed, and placed on a fresh portion of starch-gelatin, and the enzyme allowed to diffuse, no non-coloured zone was observed, the whole of the product of the action being coloured violet by iodine. The author also mentions, as a proof of his theory, the known fact that alcohol, heat, acids, &c., have a differential action on diastase: maltase and dextrinase being influenced to a greater or lesser extent by these reagents.

The formation of maltose was proved by means of *Photobacterium phosphorescens*, Beijerinck, which develops phosphorescence by the oxidation and assimilation of certain foods, of which maltose is one. Starch and the dextrins are not able to bring about the phosphorescence. By means of the starch-gelatin method, used in conjunction with this bacterium, the author considers that he proves the formation of maltodextrin by the action of dextrinase, and the subsequent conversion of this into maltose by the action of maltase. G. H. M.

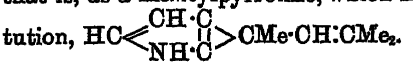
Nature of Gum-ferments. By F. Reinitzer (*Zeit. physiol. Chem.*, 14, 453—470).—The gum-ferment described by Wiesner (*Sitz. Wiener Akad.*, 92 (1885), 40) in various species of gum is not the cause of the formation either of gum or plant mucilage. It cannot change cellulose into gum or mucilage, but it converts starch paste to a considerable extent (40 per cent. of the dried starch) into a reducing sugar, with the probable simultaneous formation of a dextrin. The small quantity of sugar almost always found in gum-arabic is probably the result of this action. Wiesner further considers that Reischl's gum test (*Ber. österr. Ges. Ford. Chem. Ind.*, 1 (1879), 74), which consists in boiling with orcinol and hydrochloric acid, depends for its occurrence on the presence of gum-ferment. This is also erroneous. Its occurrence is really due to the carbohydrate itself, and is probably explained by the fact that boiling it with the acid gives rise to furfuraldehyde, which yields the blue colour with orcinol.

Pepsin which is completely free from carbohydrate material does not give a coloured precipitate with these reagents. Diastase purified by precipitation with alcohol gives only a small quantity of the precipitate, and this is probably due to adherent traces of dextrin.

The ferment itself has hitherto only been obtained with certainty from gum-acacia, cherry gum, from a few rarer gums, and from certain tissues of various kinds of stone-fruit, being absent in all the other tissues. Its occurrence in mucilage-yielding tissues, and in wood is very doubtful; tragacanth, however, appears often to contain it; but it is absent in plant mucilage. The darker kinds of gum-acacia appear to contain it more abundantly than the lighter varieties.

W. D. H.

Action of Acetone on Pyrroline. By M. Dennstedt (*Ber.*, 23, 1370—1374).—The condensation-product of acetone and pyrroline first observed by Baeyer, and further examined by the author and Zimmerman (Abstr., 1887, 598, 1052), has a molecular weight, as determined by Raoult's method, twice as great as has been hitherto supposed. Its formula is therefore $C_{28}H_{36}N_4$, instead of $C_{14}H_{18}N_2$ It has previously been shown that the compound splits up on dry distillation into pyrroline, isopropylpyrroline, and a pyrroline of the composition $C_{10}H_{13}N$, boiling at about 275°. The constitutional formula previously assigned to this compound is not in agreement with the results described in this paper, and the author now regards it as a condensation-product of 2 mols. acetone and 1 mol. pyrroline, that is, as a mesitylpyrroline, which has possibly the following constitution,



$HC{<}\begin{matrix}CH\cdot C\\ \| \\ NH\cdot C\end{matrix}{>}CMe\cdot CH{:}CMe_2$.

Besides these products, a quantity of higher boiling oil has been obtained from the decomposition-products. It readily becomes brown in the air, is not readily volatile with steam, but otherwise shows all the characteristic properties of the pyrroline-derivatives. On account of its high boiling point it could not be purified, but the analysis showed it to be very rich in carbon, and it was also found to yield a 1′-acetyl compound boiling above 360°. On reduction with tin and hydrochloric acid, it yields a *stannochloride* of the composition $C_{13}H_{19}N,HSnCl_3$, which forms well-developed, slightly-yellow crystals, becomes dark at 150°, and melts to a brown liquid at 170°. The base is set free by alkali, and may be distilled off in a current of steam. It is a yellowish liquid, lighter than water, which has a characteristic odour and boils at 274°. Its *hydrochloride*, $C_{13}H_{19}N,HCl$, forms compact crystals or thick needles melting at 227—228°. The *platinochloride* and *aurochloride* are precipitated by adding platinic or gold chloride to the solution of the hydrochloride, but the first named decomposes in a short time and the latter immediately with deposition of platinum and gold respectively.

The composition of this reduction-product renders it probable that the formula of the original substance is $C_{13}H_{17}N$, which is probably a *phoronpyrroline*, and may have the constitution

$$HC<\begin{matrix}CH\cdot C\\ NH\cdot C\end{matrix}>CMe\cdot CH{:}CMe\cdot CH{:}CMe_2.$$

Mesitylpyrroline, $C_{10}H_{13}N$, may also be reduced in a similar manner, but the hydrochloride is hygroscopic, and the stannochloride does not crystallise, so that the compounds have not yet been obtained in a pure condition. H. G. C.

Condensation-products of α-Acetylpyrroline with Benzile. By A. ANGELI (*Ber.*, 23, 1355—1357).—Like the fatty and aromatic ketones, α-acetylpyrroline readily forms condensation-products with benzile. When the two substances mixed in equal molecular proportions are heated with concentrated aqueous potash on the water-bath, two products are obtained, one of which may be collected on cooling, and recrystallised from benzene, the solution being previously heated with animal charcoal. It forms small, yellow, lustrous plates which melt at 184°, and have the formula $C_{20}H_{15}NO_2$. The second compound is obtained by acidifying the alkaline solution, and recrystallising the precipitate first from alcohol, then from benzene, and finally from alcohol again. It then forms hard, colourless crystals which have the composition $C_{20}H_{17}NO_3$, and melt at 216°.

The constitution of these compounds is readily explained by analogy with the compounds obtained by Japp and Miller (Trans., 1885, 11) from benzile and acetophenone. The first compound corresponds with triphenylcrotolactone, and may be termed *diphenylpyrroylcrotolactone*,  $\begin{matrix}CPh\cdot CH\\ CO\text{——}O\end{matrix}>C\cdot C_4NH_4$. By the action of alkalis this then takes up water and passes into the second compound, which is *α-diphenyl-β-pyrroylpropionic acid*, $C_4NH_4\cdot CO\cdot CH_2\cdot CPh_2\cdot COOH$.

Pyrryl methyl ketone also combines with ethyl salts. Ethyl oxalate in this manner yields *ethyl pyrroylpyruvate*,

$$C_4NH_4\cdot CO\cdot CH_2\cdot CO\cdot COOEt.$$

H. G. C.

Dimethylpyrrolidine and Diamidohexane. By J. TAFEL and A. NEUGEBAUER (*Ber.*, 23, 1544—1550).—A further examination of these compounds, which were obtained by the reduction of the diphenylhydrazone of acetonylacetone (Abstr., 1888, 1015), has shown that the formulæ assumed for them,  $\begin{matrix}CH_2\cdot CHMe\\ CH_2\cdot CHMe\end{matrix}>NH$ and $NH_2\cdot CHMe\cdot CH_2\cdot CH_2\cdot CHMe\cdot NH_2$ respectively, are correct.

Diamidohexane, $NH_2\cdot CHMe\cdot CH_2\cdot CH_2\cdot CHMe\cdot NH_2$, may be prepared by warming an alcoholic solution of acetonylacetone, reducing it directly with sodium amalgam and acetic acid, and separating the two basic products as before described. The following salts were prepared:—*Hydrochloride*, $C_6H_{16}N_2,2HCl$, colourless needles, sparingly soluble in alcohol. *Platinochloride*, $C_6H_{16}N_2,H_2PtCl_6$, aggregates of small plates, sparingly soluble in alcohol, and decomposing at 238° without melting. *Aurochloride*, $C_6H_{16}N_2,2HAuCl_4$, golden prisms easily soluble in alcohol. *Carbonate*,  $\begin{array}{l} CH_2\cdot CHMe\cdot NH\cdot CO \\ | \qquad\qquad\qquad\qquad\quad | \\ CH_2\cdot CHMe\cdot NH_3\cdot O \end{array}$, a white, crystalline substance soluble in water and alcohol, but not in ether, and decomposing at about 100°; prepared by passing carbonic anhydride into an ethereal solution of diamidohexane.

When diamidohexane hydrochloride is rapidly distilled, ammonium chloride, dimethylpyrrolidine hydrochloride, and unchanged diamidohexane hydrochloride distil over. The mixture is distilled with potash, when ammonia is first evolved; the bases then distil over, and are dried over baryta and separated by fractionation.

2 : 5-*Dimethylpyrrolidine*,  $\begin{array}{l} CH_2\cdot CHMe \\ | \\ CH_2\cdot CHMe \end{array}\!\!>NH$. The oxalate and platinochloride have already been described. The *hydrochloride* forms colourless needles melting at 188—190°. *Nitrosodimethylpyrrolidine* was obtained by the action of sodium nitrite on a solution of dimethyl pyrrolidine in excess of sulphuric acid. It is a yellow oil boiling at 135° at 60 mm. pressure, slightly soluble in water, and separated from the solution by alkalis, alkaline carbonates, and sodium chloride. Easily soluble in ether, alcohol, chloroform, benzene, and 50 per cent. acetic acid; also in light petroleum and cold sulphuric acid, but decomposing when this last solution is warmed. When reduced with zinc-dust and dilute acetic acid, it yields dimethylpyrrolidine, and also the *hydrazine compound* of this substance. This was oxidised by means of mercuric oxide to the *tetrazone*, $(C_6H_{12})_2N_4$, which melts at 43°, and distils without decomposing. It dissolves easily in alcohol, ether, benzene, light petroleum, and chloroform, also in dilute acids; but those solutions decompose it when warmed.

1 : 2 : 5-*Trimethylpyrrolidine*,  $\begin{array}{l} CH_2\cdot CHMe \\ | \\ CH_2\cdot CHMe \end{array}\!\!>NMe$, is formed, together with its methyl iodide additive compound, when dimethylpyrrolidine in cooled ethereal solution is treated with methyl iodide and allowed to remain for several hours, the product being finally treated with potash. It is separated from unchanged dimethylpyrrolidine, and purified; it then boils at 115—116° under 750 mm. pressure. Its *hydrochloride*, $C_7H_{16}NCl$, forms brilliant, white prisms; the *platinochloride* a yellow, uncrystallisable oil, little soluble in alcohol. The *methiodide*, $C_8H_{18}NI$, is formed with much evolution of heat by adding methyl iodide to the base. It dissolves in water, and less easily in alcohol, from which it crystallises out in well-formed, colourless prisms melting at 255—256°. When heated with solid potash, it yields dimethylamidohexylene.

Dimethylamidohexylene, $CHMe{:}CH\cdot CH_2\cdot CHMe\cdot NMe_2$, is a strongly alkaline liquid, boiling at about 130°, smelling like the pyrrolidine-derivatives, and little soluble in water. It yields by direct addition a *methiodide*, $C_9H_{20}NI$, melting at 187°. C. F. B.

Pyridine-derivatives from Propaldehyde and Propaldehyde-ammonia. By E. DÜRKOPF and H. GOTTSCH (*Ber.*, **23**, 1110—1112).—An addition to a previous paper (this vol., p. 794). Waage's parvoline is shown to have the formula [Et : Me_2 = 2 : 3 : 5] in the following manner :—(1) when oxidised, it yields carboxydinicotinic acid, and must therefore have its alkyl-groups in the positions 2 : 3 : 5; (2) the dimethylpyridinecarboxylic acid obtained by oxidation of Waage's parvoline yields, when distilled with lime, a lutidine which has been shown (see next abstract) to have the methyl-groups in the positions 3 : 5.

The methylpyridinedicarboxylic acid, [$(COOH)_2$: Me = 2 : 3 : 5 or 2 : 5 : 3], obtained by further oxidation of Waage's parvoline, gives off carbonic anhydride at 225° when heated with acetic acid and anhydride, and forms a white mass of β-methylnicotinic acid, [COOH : Me = 3 : 5], melting at 214—216°, and soluble in water.

The parvoline boiling at 216—217°, when oxidised, yields a dimethylpyridinedicarboxylic acid, which, when carefully purified, formed yellowish, sparingly soluble needles melting at 258°, giving no coloration with ferrous sulphate, but forming a precipitate with mercurous nitrate, and with concentrated solutions of copper salts. In these properties it agrees with the αγ-dimethyldinicotinic acid described by Weber (Abstr., 1887, 1117), but it is anhydrous, whereas Weber's acid crystallised with 2 mols. H_2O. If, however, these two compounds are identical, then the parvoline boiling at 216—217° is a tetramethylpyridine of the constitution [Me_4 = 1 : 2 : 3 : 4]. C. F. B.

A New Lutidine. By E. DÜRKOPF and H. GÖTTSCH (*Ber.*, **23**, 1113—1114).—The base obtained from dimethylpyridinecarboxylic acid (preceding abstract) boils at 169—170°, and is shown to be a *lutidine* of the constitution $C_5NH_3Me_2$ [Me_2 = 3 : 5], for when oxidised with a cold dilute solution of permanganate, it yields dinicotinic acid, $C_5NH_3(COOH)_2$ [$(COOH)_2$ = 3 : 5], crystallising in small, anhydrous needles, soluble in water, and melting at 314—315° (uncorr.). This lutidine is a clear, strongly refracting liquid, moderately soluble in cold water, less so in warm; its sp. gr. at 0° is 0·9614, water at 4° being 1. The *platinochloride*, $(C_5NH_3Me)_2,H_2PtCl_6$, forms dark-red needles and plates melting with decomposition at 255—256°. The *aurochloride*, $C_5NH_3Me_2,HAuCl_4$, forms yellow needles melting at 149°, and little soluble in water. The *mercurochloride* forms long needles melting at 170°, and sparingly soluble in water. A small quantity of this lutidine is also formed by the action of propaldehyde-ammonia on propaldehyde. C. F. B.

Piperidine Bases. By E. LELLMANN and M. BÜTTNER (*Ber.*, **23**, 1383—1388).—It has been shown by Lellmann (Abstr., 1887, 604) that bromobenzene readily acts on piperidine at 250°, with elimination of hydrogen bromide and formation of tertiary phenylpiperidine.

The authors have extended the investigation to the action of piperidine on other halogen-derivatives of aromatic hydrocarbons, and find that a similar action takes place in all cases. The reaction was carried out in a sealed tube, heated in most cases to 250—260°.

Tertiary-α-naphthylpiperidine, $C_{10}H_7{\cdot}C_5NH_{10}$, is obtained as a thick, yellow oil boiling at 185—190° under 5—10 mm. pressure, and having a slightly fæcal odour. It dissolves readily in alcohol, ether, and benzene, and yields a *hydrochloride* which is readily soluble in water, and crystallises in fascicular aggregates of needles. Its *platinochloride*, $C_{15}H_{17}N,H_2PtCl_6 + 2H_2O$, is a sparingly soluble precipitate.

Tertiary β-naphthylpiperidine, $C_{10}H_7{\cdot}C_5NH_{10}$, crystallises from light petroleum in nodular aggregates of small prisms melting at 57—58°, which become grey on standing. The *platinochloride* is a pale-yellow precipitate which has the composition $C_{15}H_{17}N,H_2PtCl_6 + 6H_2O$.

Tertiary anthracylpiperidine, $C_{14}H_9{\cdot}C_5NH_{10}$, is obtained as a yellow precipitate which is very quickly oxidised in the air Its *platinochloride*, $C_{19}H_{19}N,H_2PtCl_6 + 2H_2O$, is a yellow precipitate which also becomes red in the air.

Tertiary phenanthrylpiperidine, $C_{14}H_9{\cdot}C_5NH_{10}$, crystallises from ether in nodular aggregates melting at 113°. Its *platinochloride*, $C_{19}H_{19}N,H_2PtCl_6 + 6H_2O$, is soluble with difficulty in water.

Paranitro-α-naphthylpiperidine, $NO_2{\cdot}C_{10}N_6{\cdot}C_5NH_{10}$, obtained by the action of 1 : 4-bromonitronaphthalene on piperidine, crystallises from alcohol in long, yellow needles melting at 77°. It is a very feeble base, the salts of which are at once decomposed by water.

Piperydylrhodamine,  $CO{<}{\genfrac{}{}{0pt}{}{C_6H_4}{O—}}{>}C{<}{\genfrac{}{}{0pt}{}{C_6H_3(C_5NH_{10})}{C_6H_3(C_5NH_{10})}}{>}O$, is obtained in almost the theoretical quantity, by heating fluoresceïn chloride with piperidine at 220°. If forms a violet, flocculent precipitate which is soluble in alcohol, and very stable towards alkalis. The *hydrochloride*, $C_{30}H_{30}O_3N_2,2HCl$, is very readily soluble in water, the dilute solution having a bluish-red tinge, whilst concentrated hydrochloric acid colours it yellow. The *platinochloride* and *aurochloride* are amorphous, violet precipitates. H. G. C.

β-Methylpiperidine Bases. By E. LELLMANN and M. BÜTTNER (*Ber.*, 23, 1388—1390).—Whereas piperidine acts very readily with halogen-derivatives of hydrocarbons (compare preceding abstract), it has been found in the course of an investigation which will shortly be published, that α-methylpiperidine and coniïne have very little tendency to undergo this reaction, owing seemingly to the proximity of the alkyl-group to the nitrogen-atom. The authors find that β-methylpiperidine undergoes this reaction much more readily than the α-compound, but, as might be expected, less readily than piperidine.

Paranitrophenyl-β-methylpiperidine,

$$NO_2{\cdot}C_6H_4{\cdot}C_5NH_9Me\ [NO_2{:}C_6H_4 : Me = 1 : 3],$$

is prepared by heating parachloronitrobenzene with β-methylpiperidine for five hours. It crystallises from alcohol in small, golden plates, and from light petroleum in yellow prisms which have a pale-blue surface colour, and melt at 61°. The *hydrochloride* forms colourless needles which are partially decomposed by water; the *platinochloride* forms lustrous, brownish-red crystals, fairly soluble in water; and the *aurochloride*, $C_{12}H_{16}N_2O_2,HAuCl_4 + 2H_2O$, small, pale-yellow needles which melt with decomposition above 55°.

Orthoparadinitrophenyl-β-methylpiperidine, $C_6H_3(NO_2)_2 \cdot C_5NH_9Me$, is obtained in a similar manner from ordinary dichloronitrobenzene. It forms beautiful, yellow needles melting at 67°, and readily soluble in alcohol, ether, and benzene.

β-Methylpiperidine also acts on bromobenzene and α-bromonaphthalene, but less readily than piperidine. H. G. C.

Quinoline-ring Formation: Constitution of Benzene. By W. MARCKWALD (*Ber.*, 23, 1015—1025).—The synthesis of quinoline-derivatives by Skraup's reaction affords a means of deciding between Dewar's, Kekulé's, and Baeyer's formulæ for benzene. If Dewar's formula expresses the constitution of benzene, meta- and para-phenylenediamine should yield quinoline-derivatives of a constitution analogous to that of anthracene-derivatives; if Kekulé's formula is the true one, the quinoline-derivatives obtained should have a phenanthrene-like structure; if Baeyer's centrical formula is the true one, two isomerides might be formed from each of the diamines.

As a matter of fact, they both yield quinoline-derivatives having the phenanthrene-like structure, and no isomerides are formed in the reaction, so that Dewar's benzene formula is inadmissible.

A quinoline-derivative having a phenanthrene-like structure is also obtained from β-naphthylamine, and all β-naphthaquinolines have an analogous constitution.

The formation of a quinoline-derivative from α-bromo-β-amidonaphthalene with elimination of hydrogen bromide, and from α-nitro-β-amidonaphthalene with elimination of nitrous acid, are reactions which tend to show the inadmissibility, not only of Dewar's, but also of Baeyer's benzene formula, whereas they are in complete accordance with that of Kekulé.

These considerations have led the author to investigate the behaviour of paraxylylenediamine with glycerol, nitrobenzene, and concentrated sulphuric acid; the constitution of this diamine is such that if Baeyer's or Dewar's benzene formula is correct, two quinoline-rings must be formed in the reaction, whereas if benzene has the constitution expressed by Kekulé's formula, the formation of two quinoline-rings would be impossible.

The experiments, which were carried out under varied conditions, have shown that amidodimethylquinoline is the only product of the reaction.

Amidodimethylquinoline, [$Me_2 : NH_2 = 1 : 4 : 3$], crystallises from hot dilute alcohol in yellow needles, melts at 175°, with previous softening, and is almost insoluble in hot water and light petroleum, and only sparingly soluble in cold alcohol, but readily in ether, benzene, chloroform, acetone, and hot alcohol. It has a slight aromatic odour, and is only very slightly volatile with steam, but it sublimes in beautiful, yellow crystals. The salts are yellow or red, crystalline compounds, generally readily soluble in water, but only sparingly soluble in alcohol; very dilute solutions of the salts impart to a pine-chip an intense, reddish-yellow coloration, and give a reddish-brown, semi-crystalline precipitate with mercuric salts. The *hydrochloride*, $C_{11}H_{12}N_2,2HCl$, decomposes at 100°; the *platinochloride*,

$$C_{11}H_{12}N_2,H_2PtCl_6,$$

crystallises in needles, and is partially decomposed by water. The *sulphate*, *nitrate*, and *dichromate* crystallise in needles; the *picrate*, $C_{11}H_{12}N_2,2C_6H_3N_3O_7$, decomposes slowly at 182°. The *acetyl*-derivative, $C_{11}H_{11}N_2Ac$, crystallises in microscopic needles, melts at 212°, and sublimes without decomposition; it is readily soluble in alcohol, but only sparingly in ether, light petroleum, and benzene, and insoluble in water; it yields a crystalline *platinochloride*, a crystalline *aurochloride*, and a crystalline *picrate*, $C_{11}H_{11}N_2Ac,C_6H_3N_3O_7$, which melts at 223—224°.

Phenyldimethylquinolylthiocarbamide, $NHPh\cdot CS\cdot NH\cdot C_{11}NH_{10}$, prepared by treating amidodimethylquinoline with phenylthiocarbimide, separates from hot alcohol as a yellowish, crystalline powder, melts at 157—159° with previous softening, and is readily soluble in hot alcohol and benzene, but only moderately easily in ether, and insoluble in water and light petroleum. It dissolves freely in mineral acids, but is partially reprecipitated on the addition of water; the *platinochloride*, $(C_{18}H_7N_3S)_2,H_2PtCl_6$, and the *aurochloride* are crystalline. F. S. K.

Colouring Matters from Tetradihydroquinoline. By E. LELLMANN and H. BOYE (*Ber.*, 23, 1374—1383).—It has previously been shown (Abstr., 1888, 1108) that paramidophenylpiperidine gives all the colour reactions of paramidodimethylaniline and its homologues. The former may be regarded as having been derived from amidoethylpropylaniline by the loss of two atoms of hydrogen with formation of a closed chain or ring.

Researches which will shortly be published have shown that paradiamidodiphenylpiperazine, which may be regarded as having been derived in a similar manner from two molecules of amidodimethylaniline, also yields indamine colours when treated in the same manner.

Tetrahydroquinoline may also be regarded as derived from ethylorthotoluidine by elimination of two atoms of hydrogen and formation of a closed chain, and the authors have therefore examined the behaviour of this compound with regard to the formation of colouring matters, and have found that it can in fact be readily converted into indamine and azo-derivatives.

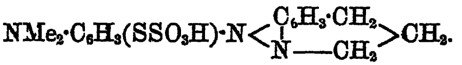
By the action of the theoretical quantity of potassium dichromate on a mixture of the hydrochlorides of amidodimethylaniline and tetrahydroquinoline in equal molecular proportions, or allowing the hydrochlorides of the latter compound and of paranitrosodimethylaniline to remain together in aqueous solution, an indamine is obtained which has doubtless the constitution  $NMe_2{\cdot}C_6H_4{\cdot}N{<}\begin{array}{l}C_6H_3{\cdot}CH_2\\ |\\ N\text{——}CH_2\end{array}{>}CH_2$. This compound readily passes without change of composition into a leuco-base.

It is probable that this property is due to the fact that two atoms of hydrogen in the piperidine-ring are given off, and that they then act on the colouring matter forming the leuco-base, which would on this supposition have the constitution

$$NMe_2{\cdot}C_6H_4{\cdot}NH{\cdot}C_6H_3{<}\begin{array}{l}CH_2{\cdot}CH\\ \qquad\quad \|\\ NH\ {\cdot}CH\end{array}{\cdot}$$

On oxidation, the leuco-base is converted into a new indamine containing two atoms of hydrogen less than the first compound, and this in the same manner passes after a time into an isomeric leuco-base,  $NMe_2{\cdot}C_6H_4{\cdot}NH{\cdot}C_6H_3{<}\begin{array}{l}CH{\cdot}CH\\ |\qquad \|\\ N\text{—}CH\end{array}$, which must be a derivative of quinoline.

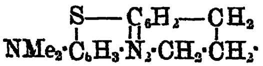
These reactions have been followed, not on the above compound, but on the corresponding *tetrahydroquinolinedimethylanilinethiosulphonic indamine*, obtained, according to Bernthsen's method (Abstr., 1889, 776), by the oxidation of tetrahydroquinoline and amidodimethylanilinethiosulphonic acid. It has the constitution



$$NMe_2{\cdot}C_6H_3(SSO_3H){\cdot}N{<}\begin{array}{l}C_6H_3{\cdot}CH_2\\ |\\ N\text{——}CH_2\end{array}{>}CH_2.$$

The leuco-compound into which it passes on standing is not colourless, but has a brown colour.

The colouring matter, which may be shortly termed "tetrahydroindamine," is readily acted on by zinc-dust and hydrochloric acid, with evolution of hydrogen sulphide and formation of a leuco-base, which on oxidation with ferric chloride yields a colouring matter of the methylene-blue series; this has the constitution



$$\begin{array}{l}\quad S\text{——}C_6H_2\text{—}CH_2\\ \quad |\qquad\ \ \|\qquad\ \ |\\ NMe_2{\cdot}C_6H_3{\cdot}N_2{\cdot}CH_2{\cdot}CH_2{\cdot}\end{array}$$

The tetrahydro-blue, which in its colour closely resembles methylene-blue, is faster than tetrahydro-indamine; thus, after several months, no external change was noticeable in the substance itself, although the fibres dyed with it gradually became paler.

The leuco-base of the dihydroindamine obtained from tetrahydroindamine is decomposed by continued boiling with water, with formation of a new leuco-base, which on oxidation yields a "dihydro-blue," probably having the constitution  $\begin{array}{l}\quad S\text{——}C_6H_2\text{—}CH_2\\ \quad |\qquad\ \ \|\qquad\ \ |\\ NMe_2{\cdot}C_6H_3{\cdot}N_2{\cdot}CH{:}CH\end{array}{\cdot}$ Its leuco-base, unlike that of the tetrahydro-blue, is scarcely oxidised by the air, and on reduction with zinc-dust and hydrochloric acid, appears to be converted into the latter compound.

Methyltetrahydroquinoline (kairoline) is also oxidised in presence of amidodimethylanilinethiosulphonic acid to an indamine resembling in most respects those already described, but which may be recrystallised from water without alteration. H. G. C.

Ethanediquinolyline. By A. M. Comey (*Ber.*, 23, 1115—1117).—Dibenzyl was prepared by heating benzyl chloride with sodium for 3—4 hours in a reflux apparatus over the bare flame, and then distilling off the dibenzyl. It was then converted into paradinitrobenzyl, and this was reduced with tin and hydrochloric acid. The paradiamidodibenzyl obtained was cautiously heated with nitrophenol, sulphuric acid, and glycerol in a reflux apparatus; the mixture solidified on cooling, and was then treated with much hot water, deprived of excess of phenol by means of a current of steam, and treated with aqueous soda. A brown, tarry mass separated; it was boiled with toluene, and the toluene evaporated from the solution, the base being thus obtained as a brown, crystalline mass. This was dissolved in dilute sulphuric acid, and alcohol was added; ethanediquinolyline was thus precipitated as the normal sulphate, which was dissolved in very dilute sulphuric acid, boiled two or three times with animal charcoal, and then decomposed with aqueous soda. *Ethanediquinolyline*, $C_2H_4(C_9NH_6)_2$ [$C_2H_4 = 3$], thus obtained forms colourless, hexagonal plates melting at 124°, soluble in ether, alcohol, benzene, and toluene, but insoluble in water. The *dihydrochloride*, $C_{20}H_{16}N_2,2HCl + 4H_2O$, forms silky needles, very soluble in water, which readily lose their water of crystallisation, but not their hydrogen chloride, when dried over sulphuric acid. The *sulphate* forms stout prisms, dissolving easily in hot water, slightly in cold, and insoluble in alcohol. The *platinochloride*, $C_{20}H_{16}N_2,H_2PtCl_6$, forms a mass of minute crystals, insoluble in cold water. The *aurochloride*, $C_{20}H_{16}N_2,2HAuCl_4$, forms a yellow precipitate, also insoluble in cold water. C. F. B.

Formation of α- and β-Phenylenepyridineketonecarboxylic Acids by the Oxidation of Naphthaquinoline-derivatives. By O. Doebner and J. Peters (*Ber.*, 23, 1228—1242).—α-Phenylenepyridineketone and some of its derivatives have already been obtained by Skraup and Cobenzl (Abstr., 1883, 1010) and by Doebner and Kuntze (Abstr., 1889, 411) by the oxidation of α-naphthaquinoline and of α-naphthacinchonic acids. The authors find that they may be very readily prepared by the oxidation of α-cinnamenylnaphthacinchonic acids, which may be obtained in a similar way to the α-cinnamenylcinchonic acids (Doebner and Peters, this vol., p. 176).

α-Cinnamenyl-α-naphthacinchonic acid, 
$$CHPh{:}CH{\cdot}C\!\!\begin{array}{l}\diagup N—C_{10}H_6 \\ \diagdown CH{:}C{\cdot}COOH\end{array},$$

may be prepared by dissolving cinnamaldehyde (1 mol.) and pyruvic acid (1 mol.) in ether, and adding an ethereal solution of α-naphthylamine (1 mol.), cooling well during the addition. The reaction may be also carried out in warm alcoholic solution. The acid separates in a few hours in slender, yellow crystals, which are collected, washed with ether, and recrystallised from acetic acid. It then forms slender, citron-yellow needles which melt with decomposition at 256°, are insoluble in water, sparingly soluble in ether, chloroform, and benzene, more readily in alcohol and acetic acid. The alkaline salts form fascicular aggregates of silky needles, readily soluble in water, whilst the salts of the alkaline earths form flocculent precipitates, the *barium* salt, $(C_{22}H_{14}NO_2)_2Ba$, containing 2 mols. of water. The *copper* salt, $(C_{22}H_{14}NO_2)_2Cu + H_2O$, is a greenish-yellow, flocculent precipitate; and the *silver* salt, $C_{22}H_{14}NO_2Ag$, a voluminous, yellow powder.

α-Cinnamenyl-α-naphthaquinoline, $\mathrm{CHPh{:}CH{\cdot}C}\Big<\begin{array}{l}\mathrm{N{-}C_{10}H_6}\\ \qquad\ \,|\\ \mathrm{CH{:}CH}\end{array}$, is obtained from the foregoing compound by heating it alone or with soda-lime; a reddish oil distils over which solidifies on allowing its ethereal solution to evaporate. It crystallises from a mixture of alcohol and ether in pale-yellow, concentrically-grouped needles melting at 104° It is insoluble in water, but dissolves readily in ether and benzene, sparingly in alcohol, the solutions showing a blue fluorescence, whereas the solutions in sulphuric and acetic acids have a green fluorescence. Its *picrate*, $C_{21}H_{15}N,C_6H_3N_3O_7$, crystallises in slender, golden-yellow needles which melt at 230°; and the *dichromate*, $(C_{21}H_{15}N)_2,H_2Cr_2O_7$, forms slender, orange-red prisms, insoluble in water. The *platinochloride*, $(C_{21}H_{15}N)_2,H_2PtCl_6$, is a microcrystalline, orange-yellow precipitate, sparingly soluble in water and alcohol.

When α-cinnamenyl-α-naphthacinchonic acid is oxidised in the cold with dilute potassium permanganate solution, the cinnamenyl-group is converted into carboxyl, *α-naphthaquinoline-αγ-dicarboxylic acid*, $\mathrm{COOH{\cdot}C}\Big<\begin{array}{l}\mathrm{N{-}C_{10}H_6}\\ \qquad\ \,|\\ \mathrm{CH{:}C{\cdot}COOH}\end{array}$, being formed. This crystallises from alcohol in greenish-yellow, concentrically-grouped needles which melt at 278° with decomposition, and are soluble in hot alcohol and acetic acid, and in hot concentrated mineral acids. The *silver* salt, $C_{15}H_7NO_4Ag_2$, and the *copper* salt, $C_{15}H_7NO_4Cu + 2H_2O$, are obtained as white and dirty-green precipitates by adding silver nitrate or copper acetate to a solution of the ammonium salt. On distillation, the acid splits up into carbonic anhydride and α-naphthaquinoline, the latter being identical with the compound obtained by Skraup and Cobenzl (Abstr., 1881, 920; 1883, 1010).

When either of the foregoing acids is treated with potassium permanganate at 80—90°, *α-phenylenepyridineketonedicarboxylic acid*, $\begin{array}{l}\mathrm{CO{-}}\\ \ |\\ \mathrm{C_6H_4}\end{array}\!\!>\mathrm{C_5NH(COOH)_2}$, is formed, and may be isolated by filtering off the manganese dioxide, concentrating, adding hydrochloric acid, and recrystallising the precipitate from hot water. It forms long, lustrous, yellow needles which melt at 264°, and are sparingly soluble in cold water, ether, and alcohol, readily in hot water and acetic acid; it also dissolves in alkalis with a red colour. The *silver* salt, $C_{14}H_5NO_5Ag_2$, is a voluminous, yellow precipitate.

On distillation, the acid splits up into carbonic anhydride and α-phenylenepyridineketone, the properties of which agree exactly with those given by Skraup and Cobenzl (*loc. cit.*)

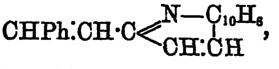
α-Cinnamenyl-β-naphthacinchonic acid, $\mathrm{CHPh{:}CH{\cdot}C}\Big<\begin{array}{l}\mathrm{N{-}C_{10}H_6}\\ \qquad\ \,|\\ \mathrm{CH{:}C{\cdot}COOH}\end{array}$,

is prepared in exactly the same manner as the corresponding α-compound, β-naphthylamine being substituted for α-naphthylamine. It forms lustrous, citron-yellow needles melting at 305°, and is insoluble or sparingly soluble in the ordinary solvents, crystallising best from alcohol containing a little hydrochloric acid. The salts of the alkalis and alkaline earths are crystalline compounds, sparingly soluble in cold, more readily in hot water. The *silver* salt, $C_{22}H_{14}NO_2Ag$, is a white, flocculent precipitate.

The acid, like the α-compound, splits up on heating by itself or with soda-lime into *α-cinnamenyl-β-naphthaquinoline*,



$$CHPh{:}CH{\cdot}C\!\left<\begin{matrix}N{-}C_{10}H_6\\ |\\ CH{:}CH\end{matrix}\right.,$$

and carbonic anhydride. The former crystallises from a mixture of alcohol and ether in white, silky needles melting at 175°, and readily soluble in acetic acid, sparingly in alcohol and acetone, and insoluble in water. The *platinochloride*, $(C_{12}H_{15}N)_2,H_2PtCl_6 + 2H_2O$, forms orange-yellow plates which lose their water of crystallisation at 110°. The *dichromate*, $(C_{21}H_{15}N)_2,H_2Cr_2O_7$, crystallises in yellow needles; and the *picrate*, $C_{21}H_{15}N,C_6H_3N_3O_7$, in golden-yellow needles melting at 254°.

On oxidation with potassium permanganate in the cold, α-cinnamenyl-β-naphthacinchonic acid yields *β-naphthaquinoline-αγ-dicarboxylic acid*, which crystallises in pale-yellow, slender needles melting at 288°, and soluble in acetic acid and hot alcohol. The *barium* salt, $C_{15}H_7NO_4Ba + H_2O$, is a white, flocculent precipitate; and the *silver* salt, $C_{15}H_7NO_4Ag_2$, a white precipitate. On distillation, the acid yields β-naphthaquinoline, which crystallises in white plates, and is identical with Skraup and Cobenzl's compound.

It follows from this that α-cinnamenyl-β-naphthacinchonic acid has the formula analogous to that of phenanthrene previously assigned to it, and has not a formula corresponding with that of anthracene.

By the oxidation of both the foregoing acids with potassium permanganate at 80—90°, *β-phenylenepyridineketonedicarboxylic acid*,  $\left.\begin{matrix}CO{-}\\ |\\ C_6H_4\end{matrix}\right>C_5NH(COOH)_2$, is formed. It crystallises from hot water in citron-yellow needles melting at 284°, sparingly soluble in water, alcohol, and ether, readily in acetone and acetic acid. It is very hygroscopic, and is only completely dried at 140°. Its *silver* salt, $C_{14}H_5NO_5Ag_2$, is a white, almost insoluble precipitate. When heated above its melting point, β-phenylenepyridineketonedicarboxylic acid loses carbonic anhydride, and forms a yellowish-brown oil which solidifies on cooling, and crystallises from hot water in colourless needles melting at 128—129°, readily soluble in alcohol. It is a base, and is therefore readily dissolved by acids and reprecipitated by alkalis. The platinochloride, $(C_{12}H_7NO)_2,H_2PtCl_6 + 2H_2O$, forms beautiful, orange-yellow needles which lose their water of crystallisation at 110°.

H. G. C.

Synthesis of Pyrazole. By L. BALBIANO (*Ber.*, 23, 1103—1108).—Epichlorhydrin, dissolved in absolute alcohol, was treated with hydrazine hydrate and boiled for five hours in a reflux apparatus. On cooling, hydrazine hydrochloride was deposited, and the alcoholic solution left, on evaporation, a yellow syrup easily soluble in water. No definite compound could be isolated from this, but it reduces platinum chloride, and doubtless contains the compound

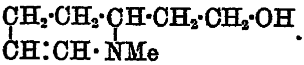
$$O<\begin{array}{l}CH\cdot CH_2\cdot N_2H_3\\ |\\ CH_2\end{array}.$$

Hydrazine hydrate was then treated with epichlorhydrin in a reflux apparatus, and when the reaction was over, the mixture was heated for 30 minutes on a water-bath, treated with powdered zinc chloride (to act as a dehydrating agent), and heated for an hour longer. The resinous mass thus obtained was treated with water and distilled in a current of steam, the distillate, which contained pyrazole and ammonia, being collected until it ceased to give a precipitate with mercury chloride. The whole distillate was then treated with mercury chloride, and the mercury compound of pyrazole and ammonia suspended in water and decomposed with hydrogen sulphide. The solution was concentrated, treated with aqueous potash, and extracted with ether. The ether extract left, on evaporation, colourless needles of pyrazole, $C_3N_2H_4$, soluble in water, alcohol, and ether, having a faint odour of pyridine, melting at 69·5—70° and boiling at 186—188° under 757·9 mm. pressure. In all these properties it resembles the substance obtained by Buchner (Abstr., 1888, 1274, and 1889, 694), by heating methyl acetylenedicarboxydiazoacetate. The platinochloride and picrate of these two substances are also identical.

Pyrazole platinochloride, $(C_3N_2H_4)_2,H_2PtCl_6 + 2H_2O$, forms yellowish-red needles soluble in water and alcohol. When heated at 100°, it loses $2H_2O$, and at 200—210°, loses 4HCl besides, forming the compound $(C_3N_2H_3)_2PtCl_2$, which, at a little above 250°, decomposes without melting.

Pyrazole picrate, $C_3N_2H_4,C_6H_2(NO_2)_3\cdot OH$, forms small, yellow needles soluble in alcohol, and slightly in cold water, and melting at 159—160°. C. F. B.

The Relation between Cocaïne and Atropine. By A. EINHORN (*Ber.*, 23, 1338—1344).—It has already been shown by Ladenburg (Abstr., 1883, 670; 1887, 740; and this vol, p. 67) that the tropine obtained from atropine is a 1-methyl-α-hydroxyethyltetrahydropyridine, the position of the double linkage not having been ascertained. Buchka gives, as the most probable formula,



$$\begin{array}{l}CH_2\cdot CH_2\cdot CH\cdot CH_2\cdot CH_2\cdot OH\\ |\qquad\qquad\quad |\\ CH:CH\cdot NMe\end{array}.$$

The tropidine obtained from this by elimination of water would then have the formula

$$\begin{array}{l}CH_2\cdot CH_2\cdot CH\cdot CH:CH_2\\ |\qquad\qquad\quad |\\ CH:CH\cdot NMe\end{array},$$

which is closely connected with the formula proposed by the author for anhydroecgonine,

$$\begin{array}{l}CH_2\cdot CH_2\cdot CH\cdot CH:CH\cdot COOH\\ |\qquad\qquad\quad |\\ CH:CH\cdot NMe\end{array}.$$

By the action of concentrated hydrochloric acid at 280° on anhydroecgonine, the author obtained a mixture of pyridine bases, one of which gave an aurochloride melting at 212°, the base of which appeared to have the formula $C_7H_{13}N$ (Abstr., 1889, 909). A microcrystallographic examination of this salt by Lehmann showed that it contained an impurity. The base was therefore isolated as the *picrate*, which is readily obtained pure by crystallisation from water. From this pure compound, the *aurochloride* and *platinochloride* may be obtained in the pure condition. The numbers found on analysis agree with the formula $C_8H_{13}N$, instead of $C_7H_{13}N$, and the crystallographic examination by Arzruni and Lehmann of the three salts, and the corresponding salts of tropidine, has shown their complete identity. The picrate from both sources forms long crystals with a distinct longitudinal cleavage; the aurochloride exists in two enantiotropic modifications which are converted into one another at a temperature below the boiling point of water. The platinochloride also exists in two modifications, the one of which is rhombic, and the other monoclinic, the former having an orange and the latter a cinnabar-red colour.

These facts show, therefore, the genetic relationships which exist between anhydroecognine and tropidine, and also support the formula given by Buchka for the latter compound. The only step now wanting for the conversion of cocaïne into atropine is the formation of tropine from tropidine by the addition of the elements of water.

H. G. C.

Methylcocaïne. By F. Giesel (*Chem. Centr.*, 1890, i, 718—719; from *Pharm. Zeit.*, **35**, 137—138).—The author has isolated a well characterised base from the mother liquors obtained in the preparation of cocaïne from ecgonine. It is very readily soluble in ether, and separates from this solvent as an oil, which becomes solid and crystalline at a low temperature. It melts at 40°. Its salts are generally somewhat less soluble than those of cocaïne. The nitrate especially, and also the sulphate and hydrobromide, may be used to separate the new base from cocaïne. With potassium permanganate, chromic acid, and gold chloride, it behaves as cocaïne does. When heated with hydrochloric acid, benzoic acid and methylecgonine were obtained in quantities corresponding with the formula of *methylcocaïne*, $C_{18}H_{23}NO_4$. In the hydrolysis by hydrochloric acid, benzoylmethylecgonine hydrochloride is obtained as a middle product. Benzoylmethylecgonine differs from ecgonine and anhydroecgonine in being almost insoluble in absolute ethyl and methyl alcohols.

J. W. L.

Berberine and Hydroberberine. By R. Gaze (*Chem. Centr.*, 1890, i, 590—591; from *Zeit. Naturwiss. Halle*, **62**, 399—457).—The author prepares pure berberine from *acetoneberberine*,

$$C_{20}H_{17}NO_4,C_3H_6O,$$

which is prepared from berberine sulphate. 50 grams of berberine sulphate is treated with 1000 grams of water and 500 grams of acetone, with addition of sodium hydroxide. The acetoneberberine is decomposed by heating with chloroform and alcohol for 12 hours. The pure berberine salts may be prepared from acetoneberberine by heating it with the acid until completely dissolved. Berberine, as prepared by the author, contains 5½ or 6 mols. H_2O. The compound with 6 mols. is stable in the air, but if heated or if placed over concentrated sulphuric acid for some time, 4 mols. of water are liberated, and the alkaloïd now absorbs water and carbonic anhydride with avidity.

Tetrabromoberberine hydrobromide, $C_{20}H_{17}NO_4Br_4,HBr$, prepared by the action of excess of bromine on the aqueous solution of berberine sulphate. forms dark red crystals. Cold alcohol causes a loss of 2 atoms of bromine, and by warming with alcohol the 4 atoms are abstracted, the hydrobromide remaining.

Bromoform unites with freshly precipitated berberine forming *bromoformberberine*, a somewhat unstable compound, being resolved into the hydrobromide by solution in acetone or benzene, and converted into *chloroformberberine* by solution in chloroform; the latter melts at 178—179°.

A sulphide, probably the pentasulphide, is formed by the action of yellow ammonium sulphide.

Hydroberberine, $C_{20}H_{21}NO_4$, first prepared by Hlasiwitz and Gilm by the action of sulphuric acid (15 c.c.), glacial acetic acid (20 c.c.), and water (200 c.c.) on berberine sulphate (8 grams), has been examined by the author regarding the following reactions: (*a*) with methyl iodide, the methiodide, $C_{20}H_{21}NO_4,MeI + H_2O$, which forms white crystals melting at 228—235°, is formed. (*b*) The chloride, $C_{20}H_{21}NO_4,MeCl + 3H_2O$, is obtained from the last named by the action of silver chloride. (*c*) the hydroxide, $C_{20}H_{21}NO_4,MeOH + 3\frac{1}{2}H_2O$ (?), which melts at 162—164°, and is unstable and crystalline, is prepared from the iodide by means of moist silver oxide. When heated in a current of hydrogen, the methyl-group becomes combined in the berberine molecule, forming *methylhydroberberine*, $C_{21}H_{23}NO_4 + 2H_2O$, which forms colourless needles melting at 224—226°. (*d*) *Hydroberberine ethiodide*, $C_{20}H_{21}NO_4EtI + H_2O$, melts at 223—225°. (*e*) *Hydroberberine ethochloride* contains 2½ mols. of water, and melts at 138—140° in its water of crystallisation, and at 225° when anhydrous. (*f*) *Ethylammonium base*, $C_{20}H_{21}NO_4,EtOH + 4H_2O$, melts at 158—161°, and forms colourless crystals, which are exceedingly bitter; from this, *ethylhydroberberine*, $C_{22}H_{25}NO_4 + 4\frac{1}{2}H_2O$, is obtained, which melts at 233—235°, forms colourless crystals, and does not behave as a tertiary base. Bromine forms an unstable perbromide with hydroberberine.

J. W. L.

Stability of Oxyhæmoglobin. By G. YEO (*Proc. Physiol. Soc.*, 1890, 7).—Tubes were filled with much diluted blood and sealed, the whole of the operations being performed with antiseptic precautions. Six years later, the bands characteristic of oxyhæmoglobin were still visible in most of the tubes (compare this vol., p. 651).

W. D. H.

Methæmoglobin and Sulphur-methæmoglobin. By T. ARAKI (*Zeit. physiol. Chem.*, **14**, 405—415).—The typical absorption band of methæmoglobin is between the C and D lines of the solar spectrum; two other bands are also described, situated approximately in the positions of the α- and β-bands of oxyhæmoglobin. Many writers regard these bands as due to methæmoglobin itself; the author, however, considers that they are due to admixture with oxyhæmoglobin, because their intensity does not necessarily vary with the concentration of the solution, as the typical band in the red does. On treating solutions of carbonic oxide-hæmoglobin with potassium ferricyanide, methæmoglobin is formed slowly.

Experiments were performed in order to see what happens when a solution of methæmoglobin is allowed to undergo putrefaction in a sealed tube; the following were the results obtained:—At first, methæmoglobin disappears, and the bands of oxyhæmoglobin, then that of hæmoglobin appears; by shaking the latter with the air, oxyhæmoglobin is again formed.

Sulphur-methæmoglobin is the substance which gives the greenish hue to dead bodies during putrefactive processes; it was originally described by Hoppe-Seyler (*Med. Centr.*, 1863, No. 28). It can be obtained from blood by passing oxygen and hydrogen sulphide through it. The lines of the solar spectrum coincided with the following numbers on the scale used; C = 46; D = 80; E = 125; *b* = 134; F = 165. The absorption-bands of an aqueous solution of sulphur-methæmoglobin were as follows: I*a* = 45—55, ill-defined; I*b* = 60—68, dark and well marked; the space 55—60 was shaded. On shaking this solution with the air, oxyhæmoglobin was formed; by the action of sodium hydroxide, hæmochromogen makes its appearance; the group of atoms which is present as hæmochromogen in hæmoglobin is thus also present as such in sulphur-methæmoglobin. All attempts to obtain sulphur-methæmoglobin in a crystalline form, or to obtain hæmin crystals from it, or to obtain a sulphur containing hæmatin from it, failed. W. D. H.

Physiological Chemistry.

Decomposition of Ethereal Salts in the Alimentary Canal. By H. K. L. Baas (*Zeit. physiol. Chem.*, **14**, 416—436).—Researches on the digestion of fats have shown that these substances undergo only a small amount of decomposition in the intestine, and theories have been formulated to explain how this assists the absorption of the emulsified fats. It was thought that some light might be thrown on the subject by investigating simpler substances having a similar constitution to the fats. The drugs were taken by the experimenter himself, or administered to dogs, and the urine and fæces subsequently examined, in order to see how much of the material taken had undergone decomposition. The following example of an experiment will serve as an illustration of the methods adopted and results obtained.

This experiment (on a dog) lasted seven days; on the fourth day, 5 grams of methyl salicylate was given; the following table gives analytical details regarding the urine:—

Day.	Total excretion of sulphates.		B : A.
	A. Normal sulphates.	B. Ethereal hydrogen sulphates.	
1...........	0·4052	0·0628	1 : 6·48
2...........	0·4548	0·0802	1 : 5·67
3...........	0·2264	0·0394	1 : 5·75
4...........	0·1204	0·0245	1 : 4·92
5...........	0·8202	0·4195	1 : 1·95
6...........	0·3468	0·1017	1 : 3·43
7...........	0·1804	0·0290	1 : 6·22

From the first to the fourth day, the daily average of ethereal hydrogen sulphates was 0·0513. The increase of these on the fifth and sixth days corresponds with 12·98 per cent. of the drug given. The amount of salicyluric acid in the urine of the fifth, sixth, and seventh days was 1·517 gram; adding this to the increase of ethereal hydrogen sulphates, it is calculated that 23·68 per cent. of the drug is accounted for, and, therefore, that amount probably underwent decomposition in the body. Another drug investigated was salol (phenyl salicylate); it was much more fully decomposed (from 43 to 69 per cent.), and this produced much greater toxic effects than the first mentioned.

The following table gives the mean results obtained in this, and previous researches of the same nature:—

Drug.	Amount of decomposition in the body.	
Glyceryl benzoate ..	54, 61·6, and 97 per cent.	Schmiedeberg (*Arch. exp. Path. u. Pharmak.*, 16, 367).
Phenyl succinate....	84 per cent.............	
Phenyl benzoate	Complete..............	
Phenyl carbonate ...	68·33 per cent. (Lesnik, *ibid.*, 24, 167).	
Phenyl salicylate (salol)	43·95 and 69·06 per cent.	Present research.
Ethyl salicylate.....	21·21 per cent.	
Methyl salicylate ...	23·66 and 24·75 per cent.	
Neutral fats........	Very slight (Cl. Bernard, Maly, Munk)	

The present research shows that only a comparatively small amount of the drug given undergoes decomposition. W. D. H.

Proteïds of Liver and Kidney Cells. By W. D. HALLIBURTON (*Proc. Physiol. Soc.*, 1890, 7).—The proteïds obtainable from liver and kidney cells belong almost exclusively to the class of globulins. The nucleo-albumin, which was previously described in lymph cells (Abstr., 1888, 974), is absent from liver cells, but present in kidney cells. No evidence of true myosin or myosinogen is found in either. Although portions of the fresh tissues are found to hasten the coagulation of salted blood-plasma, and of hydrocele and pericardial fluids very considerably, this power is destroyed at a fairly low temperature, and all attempts to prepare fibrin-ferment from the cells by Schmidt's alcohol method failed. W. D. H.

The Proportion of Blood to Body Weight. By S. M. COPEMAN and C. S. SHERRINGTON (*Proc. Physiol. Soc.*, 1890, 8—9).—The method employed for determining the proportion of the weight of the blood to that of the whole body is one which can be readily performed on the living animal, and may be best described by an example:—A rabbit was anæsthetised with chloral and chloroform, and the right cervical sympathetic was divided; a drop of arterial blood taken from the right ear was then ascertained, by the method of Roy (Abstr., 1887, 608), to be of a certain specific gravity (in this experiment 1·0520); 30 c.c. of 0·75 sodium chloride solution having a specific gravity of 1·0046 at a temperature of 38° was then injected into the external jugular vein in 15 seconds. 30 seconds later, a drop of arterial blood was again taken from the right ear, and the sp. gr. of it estimated as before (found in this experiment to be 1·0470). The weight of the animal before the injection was 3572 grams; no solid food had been given for 30 hours before the experiment. On two assumptions, (i) that the blood and injected fluid were thoroughly mixed together in the 30 to 45 seconds; and (ii) that only a negligible quantity had escaped from the circulation in that time, the calculation ran as follows:—

$$30.\ 1{\cdot}0046 + 1{\cdot}0520 = (30 + x)\,1{\cdot}0470,$$

$$x = 254{\cdot}4 \text{ c.c. weighing } 267{\cdot}6 \text{ grams.}$$

$$\frac{267{\cdot}6}{3572} = 7{\cdot}49 \text{ p. c. of body weight.}$$

It is urged that the method gives results which are, at least, trustworthy for comparison one with another. Working with it, it was found that young animals possess relatively to body weight a larger quantity of blood than adult animals, and that in a period of abstention from food, water being allowed, the amount of blood relatively to the body weight increases very largely.

Experiments on dilution of the circulating blood were also performed. 30 c.c. of saline solution injected quickly, namely, in 20 seconds *per venam*, appears to become thoroughly mixed with the circulating blood in 30 to 45 seconds. Physiological saline solution thrown into the circulation is removed from it with very great rapidity, for instance, 30 c.c. injected into the circulation of the rabbit may almost completely disappear from it in 10 minutes' time. This immediate disappearance does not take place to any great extent by the kidneys—the rate of removal not being appreciably less rapid after taking the kidneys out of the circulation. The rate of removal is hardly appreciably altered by cutting the limbs out of the circulation, nor by section of the spinal cord behind the bulb. By continuous injection of "normal" saline solution, the sp. gr. of the blood may be kept for an hour at 1·030, the normal being 1·055, without production of any obvious signs of distress: naturally, the urinary and other secretions become greatly increased, and of a watery character. Hæmorrhage causes a fall in the sp. gr. of the blood, reaching its lowest 20—30 minutes after the hæmorrhage. Division of the spinal cord behind the bulb also causes a fall in the sp. gr. of the blood; this fall is slight and reaches its full extent almost immediately. By injection of a strong solution of sugar or sodium chloride the sp. gr. of the circulating blood may in a few minutes be lowered by 20 degrees. 100 c.c. of water placed in the peritoneal cavity of a rabbit may disappear from it completely in eight hours without a lowering of sp. gr. of the circulating blood, except to the extent of half a degree for a varying number of minutes immediately after the placing of the fluid in the peritoneal cavity; the water is, however, during the eight hours largely, if not entirely, got rid of in the urinary and intestinal secretions. The sp. gr. of blood from the jugular had on many occasions been compared with that from the carotid, but had never been observed to differ from it by more than so slight an extent as to leave the matter dubious. On the other hand, the blood of the splenic vein had on several occasions been found to be of a higher sp. gr. than the arterial blood; also on several, but fewer, occasions, the blood of the renal vein had been found to be of lower sp. gr. than the arterial blood (compare this vol., p. 808). In an area in which there is obstruction to the circulation from the venous side, the blood rapidly becomes of high sp. gr., and may be found 20 degrees higher than before the obstruction. A very constant effect of operative interference with the peritoneal cavity is a heightening of the sp. gr. of the circulating blood; the mere opening of the peritoneal cavity through the linea alba may be followed by an increase of the sp. gr. of the blood to the extent of six or seven degrees, this increase reaching its maximum a variable number of hours after the operation (compare this vol., p. 393). Abstention from food, except water, at first causes a diminution in the sp. gr. of the blood; later, the sp. gr. of the blood increases, and becomes in time considerably above its normal as observed before the commencement of the period of abstention. W. D. H.

Is Free Hæmoglobin present in the Blood-plasma of the Splenic Vein? By E. A. Schäfer (*Proc. Physiol. Soc.*, 1890, 9—10). —The observations were made for the purpose of testing the statement which occurs in many text-books of physiology (the origin of which appears to be obscure) that the blood-plasma of the splenic vein normally contains free hæmoglobin. The method adopted was to allow the blood to flow directly from the vein into a carefully cleaned and previously superheated glass tube, within which it was allowed to coagulate, and, after the shrinking and subsidence of the clot, the serum was then examined with the spectroscope. In every case a control tube of arterial blood of the same animal was taken at the same time. The blood of a large number of animals of different kinds (rabbit, cat, dog, monkey), killed at various stages of digestion, has been in this way examined in the course of the last two years, with the result of proving that free hæmoglobin is normally absent both in the blood-plasma of the splenic vein and in that of arterial blood. In some of the experiments, the serum from both sources was found to be slightly coloured with free hæmoglobin, but not more so in the case of that derived from the blood of the splenic vein than in that derived from the general arterial blood; indeed, there was sometimes a preponderance in favour of the arterial serum. The opinion is held that such coloration is not normal, but is due to the setting free of some of the hæmoglobin by a destruction of red corpuscles resulting from an accidental cause, which in these experiments was probably to be lookod for in the chloroform or ether which had been administered as an anæsthetic. W. D. H.

Lecithin and Cholesterin in Red Blood Corpuscles. By P. MANASSE (*Zeit. physiol. Chem.*, **14**, 437—452).—The cholesterin in the red corpuscles of the blood is identical with that obtained from gall-stones, in melting point, specific rotatory power, and reactions. The rotatory power in chloroform solutions sinks with a rise of temperature. The corpuscles contain as a mean 0·151 per cent. of cholesterin. The lecithin of the red corpuscles is similarly identical with that obtained from egg-yolk, brain, &c. The decomposition-products are in all cases the same. The corpuscles contain as a mean 1·867 per cent. of lecithin. W. D. H.

Pernicious Anæmia. By W. HUNTER (*Brit. Med. Journ.*, 1890, ii, 1—4, 81—85).—A case of this disease is described with clinical details. The urine was normal in quantity, of low specific gravity, and contained as its principal pigment "pathological urobilin" (compare this vol., p. 400). Occasionally cells of renal origin containing blood-pigment were present. The urine contained excess of iron; the average secretion of iron in the urine in health is from 3 to 5 milligrams daily; in three cases of chlorosis it averaged 1·76 milligrams; in the present case it varied from 6·5 to 32·3 milligrams. The liver was found to be richer in iron than normal.

The opinion was formerly expressed (Abstr., 1888, 1324) that the destruction of the blood corpuscles, characteristic of the disease, which occurs in the portal circulation, and which is similar in essential characteristics to that produced by poisoning with toluylenediamine, is probably brought about by certain poisonous agents of a cadaveric nature absorbed from the intestinal tract. Special attention was therefore directed to the products of putrefaction in the urine. Estimation of the ethereal hydrogen sulphates and their ratio to the normal sulphates showed that the absolute amount of putrefaction as measured by that of the aromatic sulphates was not increased; the normal ratio of the two classes of sulphates was, however, considerably altered, being 1 : 3 instead of the normal 1 : 10. Improvements in the patients' condition were coincident with returns to the normal ratio.

It was further found that the urine contained a ptomaïne, putrescine (tetramethylenediamine), a substance absent in the urine of health, and that of most diseased conditions, but present in that of cystinuria, and probably also in that of cases of cholera (see Baumann and Udránszky, Abstr., 1889, 1024). In one specimen another diamine which was not fully identified was also discovered. These diamines are not, however, markedly toxic, and they can hardly be considered the poisons that produce the blood-destruction, but their presence indicates the existence of certain special micro-organisms in the alimentary tract, and, therefore, a condition more than any other favourable to the production of other and more poisonous alkaloïds not yet discovered.

A further support to the supposition that the alimentary tract is the seat of the formation of the poison was found in the fact that the gastro-intestinal mucous membrane was distinctly unhealthy in appearance, showing well-defined patches of inflammation resembling those frequently seen in the kidney when that organ is the seat of localised infection with pathogenic microbes. The neighbouring lymphatic glands were similarly affected. W. D. H.

Cystin in the Urine. By S. Delépine (*Proc. Roy. Soc.*, **47**, 198).—The examination of several specimens of urine from which cystin was deposited led to the following conclusions:—

1. That the simple addition of an acid in which cystin is not soluble is not sufficient to separate cystin from the urine, and therefore that the theory generally held as to the state of combination of cystin in the urine is probably inaccurate.

2. That a compound exists in certain urines which under the influence of a fermentation yields cystin.

3. That the fermentation is due to the growth of an organism which can seemingly be separated from the urine by ordinary filtration, and must therefore be a large organism, possibly a torula.

4. That the cases recorded in which cystin has been found deposited in the kidneys and liver indicate that the fermentation may begin in the organism. W. D. H.

Action of Related Chemical Compounds on Animals. By W. Gibbs and H. A. Hare (*Amer. Chem. J.*, **12**, 365—379; compare this vol., pp. 280 and 813).—*The Toluidines.*—Orthotoluidine, both in the frog and in the dog, produces decreased reflex activity and power, followed by an increase in both these functions, and finally by another decrease, deepening into paralysis, coma, and death. It has but little effect on the heart, except by direct contact when in large amount, but it causes a breaking down of the blood with formation of methæmoglobin, and a depression of the spinal cord. In the warm-blooded animal it produces a marked fall of temperature equal to 4° or 5°. Death is produced by respiratory failure, and eventually the heart stops in diastole. The pulse is slowed through depression of the heart-muscle, not through stimulation of the pneumogastric nerves. The vaso-motor system is also depressed. Metatoluidine changes the blood into methæmoglobin, and produces a loss of reflex activity due to depression of the spinal cord. It lowers the body temperature very remarkably, but only affects the circulation when administered in large doses. It kills chiefly by respiratory failure, except when sent *en masse* into the heart, when it kills by simultaneous respiratory and cardiac failure. Paratoluidine, like the ortho-compound, produces depression, followed by temporary increase and final loss of reflex activity. Its dominant action is also destruction of the blood corpuscles and formation of methæmoglobin. It depresses the spinal cord, and kills by respiratory failure, the heart beating for some moments afterwards. Under its influence, it is found that in the case of the frog's heart the auricle beats twice to a single beat of the ventricle. When brought, in large amount, into direct contact with the heart, it arrests this viscus in diastole. In small doses of 0·031 gram per kilo., it causes an increase of pulse-rate, which is not due to vagal depression. The lethal dose when injected into the jugular vein is 0·208 gram of ortho-, 0·125 gram of meta-, and 0·10 gram of para-toluidine per kilo. of body weight, but it varies greatly with the rapidity of injection.

The Dihydric Phenols.—Catechol causes epileptic convulsions, accompanied by a slowing of the pulse, due to vagal stimulation, and a fall of blood-pressure; death ensues from respiratory failure, the heart continuing to beat for a few moments later. The blood is also changed in appearance. Resorcinol causes epileptic convulsions with a fall of blood-pressure, due to its action on the vaso-motor system, and a slowing of the pulse, due, at least in part, to peripheral vagal stimulation. The heart is not depressed, and death ensues from respiratory failure, probably from the action of the blood. Quinol causes convulsions accompanied by a fall of blood pressure, due to a slowing of the pulse, or in the case of a larger dose by a rise of blood-pressure, due to increased force of the heart beat. The pulse is at first slowed by stimulation of the vagus, and then becomes very rapid, owing to peripheral pneumogastric palsy. The appearance of the blood is also much changed. The lethal dose is of catechol 0·04 to 0·05 gram, of resorcinol 0·7 to 1·0 gram of quinol 0·08 to 0·1 gram per kilo. of body weight, injected into the jugular vein.

Trihydric Phenols.—Phloroglucinol and Pyrogallol.—Both these substances slow the pulse by vagal stimulation, both change the appearance of the blood, and both kill by vagal stimulation, direct or indirect. The lethal dose is of phloroglucinol 1·0 to 1·2 gram, of pyrogallol 0·08 to 0·1 gram per kilo. of body weight, injected into the jugular vein. C. F. B.

Physiological Action of Hyoscine Hydrochloride. By PAVLOFF (*St. Petersburg Med.-chi. Acad. Dissertations*, No. 9, 1889—90).—From observations on warm-blooded animals with doses varying from 0·00005 gram to 0·02 gram. per kilo. of body weight, it was found that the beat is first slowed from stimulation of the inhibitory apparatus. It is then quickened from a paralysing action on the peripheral inhibitory apparatus. The blood pressure is increased by stimulation of the vaso-motor apparatus, especially the centres in the brain and spinal cord. The respiratory centre is stimulated to a slight extent by large doses. The salivary secretion is diminished. The temperature is not altered. The acidification of the blood is not hastened. The irritability of the brain is diminished. The sense of touch is not affected, although the perception of pain is somewhat diminished. The pupils are quickly, markedly, and persistently dilated from stimulation of the sympathetic nerves. The pharmacological action is very similar to that of atropine, but the latter does not lower the irritability of the brain cortex. T. M.

Chemistry of Vegetable Physiology and Agriculture.

The Fungus-symbiosis of the Leguminosæ. By B. FRANK (*Tagebl. Versamml. deut. Naturforsch. Aertzte*, 1889, 257—259).—In the first part of the paper, the conditions and mode of formation of nodules on the roots of peas, lupins, and beans are discussed. In the infected plants not only the root nodules, but the above-ground organs (stems, leaf-stalks, &c.) of the plants are found to contain bacteroids. The roots of *Phaseolus vulgaris* always have nodules containing bacteroïds, even in a sterilised soil. With regard to the physiological meaning of the symbiosis, the author considers that Hellriegel was premature in maintaining that the bacteria of the root nodules bring free nitrogen into combination, and so make it available to the plant, and gives the following reasons :—When peas and lupins are grown in ignited sand containing mineral but no nitrogenous nutriment, an extraordinary difference is shown, according to whether a small amount of a fertile soil is added or not. It is true that the sand contains no nitrogen, but, at the same time, all the organic constituents of an ordinary soil are also wanting. The difference brought about by the infection consists in a whole series of phenomena, resulting in the strengthening of the whole plant. If the non-infected sand is manured with nitrate, there is practically no result with lupins, and very little with peas, indicating that it is not the want of nitrogen which is overcome by the symbiosis. The fertilising action of the rhizoplasmidium is further seen in (1) the increase of total produce, (2) the increased chlorophyll-production, (3) the more energetic carbon-assimilation, (4) the formation of nodules rich in albuminoïds, (5) the increased production of flower, fruit, and seed, and of carbonaceous and nitrogenous vegetable substance. In the case of peas and lupins, this increased production will also take place in soil containing humus but free from organisms, and therefore without nodule-formation; the plants develop even better in a sterilised than in a non-sterilised soil.

With regard to *Phaseolus vulgaris*, the plants will not thrive in a soil free from nitrogen, whether infected or not, but develop well in soil containing humus. N. H. M.

The Rôle of Sugar and its Development during the Growth of the Beetroot. By E. DURIN (*Bied. Centr.*, **19**, 337—338).—The disappearance of sugar from the beetroot during the second period of its growth is not due to seed formation alone; a considerable portion is used up in developing other organs. A bed of beetroot at the period of ripeness was divided into two equal parts, the one part being left exposed to light and the other kept dark. The plants kept in the dark lost their green leaves and formed a crown of yellow leaves. At the commencement of the experiments the sap of the roots contained 6·95 per cent. of sugar. After eight weeks, the sap of those plants which were kept in the dark contained 3·15 per cent. of sugar, so that half the sugar had been used up in forming new leaves. The rest of the plants were then kept covered, and remained healthy until the percentage of sugar sank to about 0·5—0·6, when they showed a mark which spread quickly until the whole root was rotten. Other experiments were made, the results of which also show that sugar is taken up from the roots to form stalks and leaves, and that the root dies when all the sugar is used up. N. H. M.

Assimilation of Carbon by Green Plants from certain Organic Compounds. By E. H. ACTON (*Proc. Roy. Soc.*, **47**, 150—175).—A. Meyer (*Botan. Zeitung* for 1886, pp. 81, 105, 129, 145) found that starch was formed by leaves placed in solutions of various organic substances. The author has extended this investigation, both by using a greater variety of solutions and by supplying them not only directly to the leaves, but also through the medium of the roots. He operated in all on 15 different species, some of which were water plants. His principal experimental results are as follows:—

Starch is formed when the following substances are supplied either to the leaves or to the roots: glucose, cane-sugar, inulin, glycerol.

Starch is formed when soluble starch is supplied to the leaves, but not when it is supplied to the roots.

Humus extract, obtained by digesting leaf-mould with dilute alcohol and filtering, forms starch when supplied to the roots, but not when given directly to the leaves.

Starch is not formed under any circumstances with acraldehyde (and compounds), allyl alcohol, dextrin, glycogen, acetaldehyde (and compounds), levulinic acid, artificial humus from cane-sugar.

Glucose is more readily taken up by roots than cane-sugar, and may all be withdrawn from a 1 per cent. solution.

Many green plants (? all) behave in the same manner to the above substances. J. W.

Presence and Behaviour of Nitric Acid in Plants. By SERNO (*Chem. Centr.*, 1890, i, 592—593; from *Landw. Jahrb.*, **18**, 877—905). —The author has examined a large number of plants for nitric acid, and has found it present in nearly all. In some it is present in much larger quantity than in others. Among those in which it exists in almost all the organs are the *Malvaceæ*, *Cruciferæ*, *Papaveraceæ*, *Convolvulaceæ*, *Labiatæ*, *Compositæ*, and the *Urticaceæ*. In others, nitrates were not present in those parts above ground, but were present in the youngest rootlets. It appears to pass from the roots, which absorb it from the earth, upwards, and becomes used for the formation of the nitrogenous constituents.

In wood-forming plants, the author has found an accumulation of nitrates in the first year until the formation of wood has ceased, and in later periods it is present in the roots, also in the young shoots of early spring. It disappears during the winter. In the case of perennial herbs also, nitric acid was found in the newly-formed fibrous roots; during the winter they store it up for transformation in spring, when the new growth commences. In the case of cultures in distilled water, asparagine disappeared during the later stages of growth, but was formed again as soon as nitrates were added. The author considers this a proof that nitric acid is transformed into amido-compounds, especially asparagine. J. W. L.

Carbohydrates in Peach Gum. By W. E. Stone (*Amer. Chem. J.*, **12**, 435—440).—The gum which exudes from the bark of the wild peach-tree when it is injured, or from the fruit when punctured by insects, was heated with dilute sulphuric acid for 10 hours, the solution then neutralised with barium carbonate, filtered, and evaporated. The syrup thus obtained was boiled with alcohol, and the clear alcoholic solution decanted and evaporated. A white, crystalline substance was then obtained, which, by fractional crystallisation, followed by repeated recrystallisation of the fractions, was resolved into two compounds having specific rotatory powers equivalent respectively to those of arabinose and galactose. That one of these is arabinose was shown by the melting point of its phenylhydrazine compound, and by its yielding furfuramide when it is distilled with sulphuric acid, and the distillate treated with ammonia. The other, from the melting point of its phenylhydrazine compounds, and from its yielding mucic acid when oxidised with nitric acid, was identified as galactose. Peach gum, therefore, contains both arabinose and galactose, that is, a true glucose associated with a pentaglucose. C. F. B.

Carbohydrates of the Sweet Potato (Batatas edulis). By W. E. Stone (*Ber.*, **23**, 1406—1408).—Finely-divided sweet potatoes were boiled for some time with strong alcohol; after filtering and concentrating the solution, cane-sugar crystallised out. It was identified by its specific rotatory power, its fermentability with yeast, and its behaviour towards Fehling's solution both before and after hydrolysis. The quantity of sugar in the potatoes was found to be 1½—2 per cent. Baking the potatoes converted part of the starch into the soluble form, and caused the cane-sugar to be hydrolysed to glucose. J. B. T.

Experiments with Beetroot. By O. Kohlrausch and F. Strohmer (*Bied. Centr.*, **19**, 322—333).—The results of previous experiments indicated that no increase in the amount of sugar in beetroot is obtained by increased manuring with potassium nitrate, and that the physiological actions of the potash and the nitric acid partly cancel each other in the production of sugar. The authors have repeated the experiments in the same place and under the same conditions, manuring with sodium nitrate and potassium phosphate in order to determine whether the low amount of sugar was due to the potassium nitrate or to local conditions. The experiments were conducted in vessels containing 25 kilos. of sand, and seeds of a uniform size were employed.

The following conclusions are drawn from the results of the experiments extending over five years:—(1) The application of increasing amounts of potash gives rise to a corresponding increased production of sugar. (2) An increased manuring with nitric acid has the effect of increasing the amount of leaf of the plants, and is unfavourable to sugar-formation, so that the production of sugar is diminished. (3) The increased nitric acid manuring has also the effect of raising the amount of nitric acid, and also the proteïn in the roots. (4) The increased sugar production brought about by the application of potash is at once cancelled by the physiological action of the corresponding amount of nitric acid. (5) Phosphoric acid influences leaf growth in a manner favourable to sugar production, and expedites the ripening of the plants; phosphoric acid, therefore, assists the favourable action of potash in the formation of sugar.

N. H. M.

Source of Nitrogen of Plants. By A. G. Schmitter (*Bied. Centr.*, 1890, 393—395).—The growth of lupins on poor moorland soils was compared with the growth on the same soils improved by the addition of fertile soil. No perceptible difference was noticed in the growths of the two sets of plants; at any rate the difference was so slight, as to render useless the extra expense, &c., occasioned by the addition of fertile earth.

E. W. P.

Loss and Gain of Nitrogen by Soil. By A. Pagnoul (*Compt. rend.*, **110**, 910—912).—The experiments were carried out in pots which contained 22 kilos. of earth each, the surface exposed being 7·54 square decimetres, and the pots being so constructed that the water could readily drain away. The 22 kilos. contained 22·44 grams of nitrogen, and to this was added 0·540 gram in the form of dried blood, and 1·0 gram in the form of ammonium sulphate, giving a total of 23·980 grams of nitrogen in the 22 kilos. of soil. Two lots, A and *a*, were left without any crop, two, B and *b*, were sown with grass, and two, C and *c*, with clover. After a year (March, 1888 to March 1889), the following results were obtained:—

	A.	*a.*	B.	*b.*	C.	*c.*
Nitrogen remaining in the soil.	24·640	23·760	26·180	27·720	29·260	32·340
Nitrogen removed in the crops.	—	—	1·490	1·456	4·266	4·144
Nitrogen in the drainage water	0·967	0·779	0·071	0·088	0·212	0·184
Total	25·607	24·539	27·741	29·264	33·738	36·668
Nitrogen gained from the air ..	1·607	0·559	3·761	5·284	9·758	12·688

The gain of nitrogen per hectare *by the soil* is as follows:—(1) no crop, 29 kilos.; (2) grass, 394 kilos.; (3) clover, 904 kilos.

The proportion of ammoniacal and nitric nitrogen removed by the drainage water in each case was as follows:—

	No crop.		Grass.		Clover.	
Ammoniacal nitrogen	0·025	0·017	0·024	0·020	0·021	0·016
Nitric nitrogen	0·942	0·762	0·047	0·068	0·191	0·168

C. H. B.

Analytical Chemistry.

Ruffle's Method of Estimating Ammonia. By A. BUCHAN (*Chem. News*, **61**, 231).—To prevent fusion of the contents of the tube in estimating ammonia, the author prepares his soda-lime by heating a mixture of equal proportions of ground quick-lime and sodium carbonate until all aqueous vapour is eliminated.

D. A. L.

Estimation of Ammonia in Sand and Sewage. By A. HAZEN (*Amer. Chem. J.*, **12**. 427—428).—The sand (from filters) is placed in a small flask fitted with two tubes, one of which passes to the bottom of the flask, whilst the other is connected to a condenser. Through the first, steam, obtained by boiling water previously freed from ammonia, is blown in until 50 c.c. of distillate has been collected; this. it is found, contains all the free ammonia in the sand. Alkaline permanganate of full strength is then placed in the flask, and the distillation continued; the first 50 c.c. of distillate contains eight- or nine-tenths of the albuminoïd ammonia, and the rest comes over with the next 50 c.c. The flask may, if necessary, be heated with a small flame. The process is also well adapted to the examination of sewage, and anything that contains enough ammonia. It takes less time than the ordinary method, and gives the same results for free ammonia, but somewhat higher for albuminoid ammonia; but in the latter case the results are sharper, and different experiments agree better. The author prefers the use of indiarubber, freed from ammonia by long boiling, for stoppers and connections. C. F. B.

Effect of Temperature on the Nessler Test. By A. HAZEN and H. W. CLARK (*Amer. Chem. J.*, **12**, 425—426).—The authors find that the low results obtained by them and by Smart were due, not to imperfect condensation of the ammonia, but to the low temperature of the distillates, which had been condensed in a block-tin condenser. It is found that the colour produced in the Nessler test varies with the temperature, and is deeper according as the solution is warmer; it is thus necessary to bring the distillate and the standard ammonia solution to the same temperature before comparing the tints which they give with the Nessler solution. C. F. B.

Estimation of Nitric Acid by Reduction to Ammonia. By E. Boyer (*Compt. rend.*, **110**, 954—956).—The reduction of nitric acid to ammonia by the action of zinc and hydrochloric acid is generally incomplete, oxides of nitrogen, and even free nitrogen, being evolved. By careful attention to the conditions, however, the reduction can be made complete, and can be utilised for the estimation of nitric acid.

5 grams of zinc, in granules the size of peas, is introduced into a test-tube 300 mm. long and 22 mm. in diameter; 10 c.c. of the solution containing not more than 0·5 gram of the nitrate is then added, and 5 c.c. of hydrochloric acid of sp. gr. not lower than 1·19. When the evolution of hydrogen ceases, a further quantity of 5 c.c. of acid is added, and the reduction is complete in 10 minutes. Success depends on careful attention to the concentration and proportions of the solutions.

The ammonia is estimated in the usual way, but must be expelled by means of magnesia, since sodium or potassium hydroxide forms an insoluble ammonia-derivative in presence of zinc. The liquid is mixed with potash or soda until just alkaline and about 2 grams of magnesia is added.

C. H. B.

Estimation of Nitric Acid by Schulze and Tiemann's Method. By L. Spiegel (*Ber.*, **23**, 1361—1363).—The author has previously shown (*Zeitsch. für Hygiene*, 1887, 163) that in Schulze and Tiemann's method of estimating nitric acid in drinking water, an error of at least 3 per cent. occurs, unless the gases in the decomposition flask are driven out at the end of the operation by carbonic anhydride. In reply to the objection of Tiemann that carbonic anhydride is difficult to obtain free from air, the author states that if the pieces of marble are allowed to remain in warm water before being placed in Kipp's apparatus, the gas evolved is practically free from air in half an hour.

The following apparatus, in which the necessity of creating a vacuum is avoided, is described by the author as the most suitable. An ordinary bolt-head of about 150 c.c. capacity is fitted with a doubly-bored caoutchouc stopper, through which are passed entrance and exit tubes. The latter reaches to within 2 c.c. of the bottom, and has blown on it, above the cork, a bulb of about 50 c.c. capacity. Into the tube at the lower end of the bulb a second tube is ground, which is connected with the apparatus evolving carbonic anhydride.

After the water has been placed in the flask, carbonic anhydride is passed through the apparatus until all the air has been driven out, and about 20 c.c. of freshly prepared and well-boiled solution of ferrous chloride placed in the bulb, and allowed to pass into the flask by slightly raising the second tube. Afterwards 40 c.c. of concentrated boiled hydrochloric acid is added in a similar manner. As soon as the liquid boils, the current of carbonic anhydride is cut off, and only renewed towards the end of the operation, when the contents of the flask become thick. With this apparatus, it is necessary to employ reagents from which the air has been previously expelled by boiling.

H. G. C.

Estimation of Arsenic. By F. W. Boam (*Chem. News*, **61**, 219).—The following method is recommended as rapid and accurate, and is applicable to all arsenical ores which are attacked by nitric acid :—

1 to 1·5 gram of dry pulverised ore is boiled to dryness with 20 to 25 c.c. of nitric acid, and when cool is boiled with 30 c.c. of a 30 per cent. solution of sodium hydroxide, filtered, and diluted to 250 c.c. 25 c.c. of this solution is acidified with 50 per cent. acetic acid containing 10 per cent. of sodium acetate, boiled, and titrated with $\frac{1}{4}$ normal uranium acetate, using potassium ferrocyanide as an indicator.

D. A. L.

Estimating Silica in Silicates by Fusion with Alkaline Carbonates. By J. P. Gilbert (*Chem. News*, **61**, 270—272; 281—282).—The author, investigating the fusion method of estimating silica, determined under varying conditions the insoluble silica obtained, the silica passing into solution, and the residue left after treating the former with hydrofluoric acid. In the first set of experiments, a blast furnace slag, containing 46 per cent. of calcium oxide, 10 per cent. of alumina, and less than 1 per cent. of magnesium oxide, was employed, and the silica was dehydrated either on the water-bath, or at 125°, or on an iron plate over a Bunsen, or at 280°. The results show that, practically, all the silica is rendered insoluble on the water-bath, the soluble never exceeding a few tenths of a milligram, and therefore there is no gain in this respect by the use of higher temperatures, the effect of which seemingly is to render some of the alumina insoluble, as indicated by the residue left after treatment with hydrofluoric acid, but there is no evidence of re-combination of silica with lime and alumina even at 280°.

Calcium chloride appears to aid the dehydration, but magnesium chloride does not. In a second series of experiments with a slag containing 35 per cent. of calcium oxide, 15 per cent. of magnesium oxide, and 15 per cent. of alumina, it was observed that the best results were obtained at 120°, the residue after hydrofluoric acid and the soluble silica were, especially at 280°, moderately large—a few milligrams; owing, the former to magnesium oxide, the latter to recombination of silica and magnesium oxide.

A sample of orthoclase, practically free from lime and magnesia, yielded a moderate amount (2 or 3 milligrams) of soluble silica, not increased by the higher temperatures, which the author regards as the result of the absence of the beneficial factor, calcium chloride. It therefore appears that some silica always fails to be rendered insoluble by the heating alone, and to test this, some silica from the lime slag was repeatedly treated by fusion with alkaline carbonates in the usual way, with the result that a diminished amount of insoluble silica was obtained each time.

With regard to the purity of the silica obtained, the author applied Lindo's plan of copious dilution, which, permitting as it does of abundant washing, yields a pure silica when the silica is associated with alkalis or alkaline earths, as in glass; but when much alumina is present it is not so easy to obtain such pure silica by this means.

The results, as a whole, confirm the statement that the ordinary fusion process for the estimation of silica does not always render all the silica insoluble. Evaporation with sulphuric acid is, however, far more potent than the use of hydrochloric acid for the dehydration, and should be employed when admissible.

D. A. L.

Caustic Soda or Potash and Carbon in Analysis. By C. A. Burghardt (*Chem. News*, **61**, 260—262).—The author suggests a method for the decomposition of refractory silicates, several refractory oxides and compounds of oxides, and some other insoluble minerals. The finely pulverised mineral, mixed without about a tenth of its weight of finely divided charcoal, is added to about six times its weight of molten caustic soda or potash, and heated over a Bunsen flame until combustible gases cease to be evolved. The mass is extracted with water, and the insoluble residue again treated in like manner. With a sample of "black tin" (dressed tin ore of Cornwall) sodium silicate, aluminate, and stannate were obtained in solution, whilst the insoluble residue contained silica, bismuth oxide, cupric oxide, ferric oxide, calcium carbonate, and manganese dioxide. Wolframite yields sodium tungstate, manganate, silicate, and niobate, if present, in solution, and iron oxides and manganese dioxide insoluble. With chrome iron ore, three times its weight of ammonium nitrate was placed, along with the caustic soda, on the mineral and charcoal mixture in the crucible and heated. The aqueous extract of the fused mass was evaporated to dryness with ammonium nitrate, and, after separating the alumina and silica, the filtrate when acidified with hydrochloric acid yielded chromic chloride without further reduction. The insoluble portion was ferric oxide, magnesium carbonate, carbon, &c. Rutile and ilmenite yield sodium titanite; barium sulphate gives barium carbonate and sodium sulphate. Simple silicates, such as kaolin, talc, cyanite, &c., and double silicates, such as tourmaline, hornblende, garnet, &c., are also decomposed and rendered soluble. D. A. L.

New Method for the Estimation of Free and Combined Carbon in Iron and Steel. By O. Pettersson and A. Smitt (*Ber.*, **23**, 1401—1402).—A weighed quantity of iron, which should consist of one piece hammered or rolled into a thin sheet, is plunged into molten hydrogen potassium sulphate; the iron becomes converted into ferric sulphate, and the combined carbon is oxidised to carbonic anhydride, which, together with the evolved sulphurous anhydride, is absorbed by a known quantity of a solution of sodium and barium hydroxides.

The barium sulphite is oxidised to sulphate by the addition of a little potassium permanganate solution, the carbonate is then decomposed with nitric acid, and the carbonic anhydride determined in an apparatus described in another paper. The fused mixture of potassium hydrogen sulphate and ferric chloride is dissolved in hydrochloric acid, the graphite collected on a platinum funnel, filtered through asbestos, and the whole dried and weighed. A mixture of air and nitrous fumes is now passed through the funnel, which is heated to redness; so soon as all the graphite is burned, the funnel is again weighed and is then ready for another determination. The accuracy of this method is from 0·06—0·02 per cent. From 0·2—0·8 gram of iron should be taken for analysis, the quantity depending of course on the amount of carbon contained in the sample. J. B. T.

Electrolysis of Metallic Phosphates. By E. F. Smith (*Amer. Chem. J.*, 12, 329—336; compare Moore, Abstr., 1886, 921; Brand, this vol., p. 294).—This paper relates to the deposition of metals by the electrolysis of solutions of their phosphates in phosphoric acid, whereon is based a convenient method of separating them.

Copper from Iron.—A solution, containing 0·0996 gram of copper and 0·1700 gram of iron, was treated with 30 c.c. of disodium phosphate solution (sp. gr. 1·0358) and 4½ c.c. of phosphoric acid (sp. gr. 1·347), and made up to 125 c.c. A current generating 0·6 c.c. of oxyhydrogen gas per minute gave a deposit of copper weighing 0·0996 gram.

Copper from Aluminium.—Weight of copper, 0·0996 gram; of aluminium 0·1000 gram. Disodium phosphate, 20 c.c.; phosphoric acid, 3 c.c.; total dilution, 100 c.c. Current, 3 c.c. of oxyhydrogen gas per minute. Copper deposited, 0·0995 gram.

Copper from Chromium.—Copper, 0·0996 gram; chromium slightly more than 0·0996 gram. Disodium phosphate, 20 c.c.; phosphoric acid, 3 c.c. Dilution and current as in previous case. Weight of copper deposited, 0·0994 gram.

Copper from Zinc.—Zinc, 0·1500 gram; copper, disodium phosphate, and phosphoric acid as in previous experiment; dilution 100 c.c.; current, 0·15 c.c. oxyhydrogen gas per minute. Weight of copper deposited, 0·0993 gram.

Copper from Cobalt.—Cobalt, 0·0968 gram; copper, 0·0996. Conditions similar to those of preceding experiment, except the current 0·22 c.c. of oxyhydrogen gas per minute. Copper deposited, 0·0995 gram.

Copper from Nickel.—Copper, 0·0996 gram; nickel, 0·1105 gram. Conditions as in preceding experiment. Copper deposited, 0·0996 gram.

Copper from Cadmium.—The separation may be effected by using a fairly large excess of phosphoric acid and a current generating not more than 0·10 to 0·20 c.c. of oxyhydrogen gas per minute, when the copper is deposited.

The preceding experiments show that copper may be readily separated from other metals, under the conditions given, by using feeble currents. In all cases, before interrupting the current, the acid liquid was syphoned off and replaced by water, the deposits were washed with cold and hot water, but no alcohol or ether was used. The poles of the electrolysing battery were about ¾ inch apart.

Cadmium from Zinc, Nickel, Iron, Chromium, and Aluminium.—Cadmium may be separated from these metals, in a properly diluted solution containing free phosphoric acid, by currents giving 0·35 c.c. of oxyhydrogen gas per minute. The deposit is not so satisfactory as in the case of copper, but accurate results are obtained if concentration of the solution is avoided, and the poles of the electrolysing cell are about 1¼ inches apart. It is also desirable to slightly increase the current before disconnecting.

Silver cannot be satisfactorily deposited in solutions containing free phosphoric acid, but from an ammoniacal solution of the phosphate its liberation is rapid and satisfactory.

Manganese is deposited as dioxide from solutions containing nitric or sulphuric acids; but, in presence of an excess of phosphoric acid, this behaviour is not observed, a weak current separating only copper from a solution containing the two metals. G. T. M.

Electrolytic Separations. By E. F. SMITH and L. K. FRANKEL (*Amer. Chem. J.*, **12**, 428—435; compare also this vol., pp. 664 and 831).—The metals were held in solution in excess of potassium cyanide, and deposited by means of a current from Daniell cells running for 16 hours. The deposited metal was washed with boiling water, or in the case of bismuth with cold water and absolute alcohol, and dried on a warm iron plate. In the following, the metal which is deposited on electrolysis is mentioned first:—

Mercury from Palladium.—Results good; a large excess of potassium cyanide should be present.

Silver and cadmium could not be separated in this way from palladium; some of the latter metal was always deposited.

Mercury from Arsenic.—Results satisfactory; the arsenic may be present either as arsenite or as arsenate.

Cadmium from Arsenic.—Results good; the arsenic must be in the form of an arsenate.

Silver from Arsenic.—Results satisfactory; the arsenic must be present as arsenate, not as arsenite.

Copper from Arsenic.—Results good, but a stronger current (giving 1·5 to 10 c.c. of mixed gases per minute in a water-voltameter) is required, and a large excess of potassium cyanide is not advisable. The separation was also attempted in solutions containing excess of ammonia, and with fairly good results, but considerable skill and attention are necessary.

Mercury from Tungsten.—Results good, but the current should not exceed 0·8 c.c. per minute, otherwise the deposit of mercury is contaminated with oxide of tungsten.

Silver from Tungsten.—Results good; the current must not be too strong.

Cadmium from Tungsten.—Results good, but too high if the current exceeds 0·6 c.c. per minute, when the deposit is spongy.

Mercury from Molybdenum.—Results good.

Silver from Molybdenum.—Results good.

Cadmium from Molybdenum.—Results good.

Bismuth from Copper.—The bismuth was taken as the citrate, dissolved in excess of alkali, and copper sulphate and excess of potassium cyanide added; satisfactory results were obtained.

C. F. B.

Quantitative Separation of Titanium and Tin. By H. HAAS (*Chem. Centr.*, 1890, i, 732—733; from *Inaug. Diss. Erlangen*).—The method described by the author is recommended as being applicable for the separation and determination of minute quantities of titanium, and is as follows:—5 to 10 grams of the finely-divided mineral is mixed with a little water in a platinum crucible, dilute (1 : 10) sulphuric acid added until the mass is of a thin consistence, it is then warmed on the water-bath until, with additions of hydrofluoric and sulphuric acids, the mineral is dissolved. 10 to 20 c.c. of sulphuric acid is then added, the solution concentrated, and finally the last traces of hydrogen fluoride expelled by careful heating over a bare flame. Water is now added, the solution digested on the water-bath, and then transferred to a sufficiently capacious porcelain dish. It is neutralised with sodium hydroxide solution, 2 c.c. of concentrated sulphuric acid added, the volume made up to 400 c.c., and boiled for six hours, water being added to replace that which evaporates. The precipitate is collected, washed with hot water, and after diluting so that the sulphuric acid is not more than 0·5 per cent., the filtrate is boiled again to test whether the precipitation is complete.

The precipitate is ignited in a porcelain crucible, then washed on to a filter and washed with water, dried, and ignited again in a porcelain crucible, and finally reduced in a current of hydrogen. The metals are boiled with 20 per cent. hydrochloric acid for half-an-hour, filtered, and the insoluble portion again reduced in hydrogen and boiled with hydrochloric acid. The filtrates, containing all the tin, are neutralised with sodium carbonate, slightly acidified with hydrochloric acid, precipitated with hydrogen sulphide, filtered, washed with dilute ammonium acetate solution, and the filtrate again treated with hydrogen sulphide. The stannous sulphide is reduced in hydrogen, converted into metastannic acid, and finally weighed as stannic oxide.

That portion of the metals which remains insoluble in hydrochloric acid, the titanium dioxide, is ignited in a platinum crucible, fused with 6 to 10 times its weight of potassium carbonate, digested in water, diluted to 200 c.c., and acidified with sulphuric acid until the solution is clear or slightly opalescent. Sodium carbonate is now added until the precipitate commences to be permanent, 2 c.c. of concentrated sulphuric acid added, the liquid diluted to 400 c.c., and boiled for six hours in a capacious porcelain dish, the precipitate filtered off, washed with hot water, the filtrate boiled again to ensure that the precipitation is complete, and the precipitate heated in hydrogen. Traces of iron are removed by boiling for half-an-hour with 20—30 c.c. of hydrochloric acid. The insoluble titanium dioxide is washed and weighed as such. J. W. L.

New Method of Titrating Alcohol with Chromic Acid. By R. BOURCART (*Chem. Centr.*, 1890, i, 547; from *Bull. Soc. Ind. Mulhouse*, 59, 558—562).—The author adds potassium dichromate and sulphuric acid to the alcohol in tubes, which are closed by stoppers tightly fastened down, and heats the same for 2 to 3 hours on the water-bath. After the oxidation is completed, potassium iodide is added and the liberated iodine titrated with sodium thiosulphate. The strength of the potassium dichromate solution used is 0·5 per cent.; the sulphuric acid is 25 per cent., and the alcohol should be about 0·5 per cent.

Aldehyde may also be determined in the same way. The method gives results which agree within about 1·5 per cent. J. W. L.

Raisin Wines and their Richness in Nitrogen. By P. Cazeneuve and L. Ducher (*Bull. Soc. Chim.* [3], 3, 514—518).—The authors review the methods suggested for distinguishing between raisin and grape wines, and conclude that no satisfactory process exists. They have determined the total nitrogen in both classes of wines, and find that in dry white wines the total nitrogen is almost identical, but that in sweet white wines a difference of about 0·5 gram per litre of total nitrogen exists. T. G. N.

Estimation of Sugars with Copper Potassium Carbonate Solution. By H. Ost (*Ber.*, 23, 1035—1039).—Copper carbonate dissolves freely in a cold concentrated solution of potassium carbonate, yielding a deep-blue solution of a readily soluble double salt, which crystallises in slender, blue needles; if the solution is heated, a basic copper carbonate or the black oxide is deposited, but in presence of a sufficient quantity of potassium hydrogen carbonate, the solution is quite stable, even at its boiling point, and can be advantageously employed for the volumetric or gravimetric estimation of sugars.

The standard solution is prepared by dissolving potassium carbonate (250 grams) and potassium hydrogen carbonate (100 grams) in water, gradually adding a solution of crystalline copper sulphate (23·5 grams), and making up to 1 litre. 50 c.c. of this solution is exactly decolorised by 9 to 10 minutes' boiling with 25 c.c. of a 0·4 per cent. solution (= 100 milligrams) of pure inverted sugar. The end of the reaction can be easily and accurately observed by the disappearance of the blue colour, and the liquid is then quite clear, not yellow, as is the case with Fehling's solution. In presence of cane-sugar, slightly smaller quantities of the inverted sugar solution are required. In the case of cane-sugar solutions very poor in inverted sugar, a copper solution containing one-fifth of the above quantity of copper sulphate is employed; this dilute solution has hardly any action on pure cane-sugar. The weight of the cuprous oxide precipitated by various quantities of inverted sugar, in presence and in absence of cane-sugar, is given in tables. F. S. K.

Detection of Benzoic Acid in Foods. By E. Mohler (*Bull. Soc. Chim.* [3], 3, 414—416).—The author employs the reaction of hydrogen sulphide on an ammoniacal solution of dinitrobenzoic acid (1 : 3 : 5), which determines the formation of reddish-brown ammonium diamidobenzoate [1 : 3 : 5]. In the case of beer, 100 c.c. is rendered alkaline by sodium hydroxide, and evaporated to a paste, which, after acidifying with hydrochloric acid, is mixed with sand and extracted with ether (20 c.c.). After evaporation of the ether, the residual extractive is sprinkled with sulphuric acid (2 c.c.), heated at 210°, and a few decigrams of sodium nitrate are added, the clear liquid formed is poured into ammonia-water, and a drop of ammonium hydrosulphide added, when a reddish-brown coloration will indicate benzoic acid if present. A few tenths of a milligram of benzoic acid may be thus detected. T. G. N.

Occurrence and Detection of Indigo-red in Urine. By O. ROSENBACH (*Zeit. anal. Chem.*, **29**, 240; from *Berlin klin. Wochensch.*, 1889, 13, 17, 22, 23).—Certain pathological urines, when oxidised by nitric acid, yield a deep burgundy-red to blue-red colour, which, by further action of nitric acid, passes into yellow. To the fresh urine, decolorised by lead acetate, filtered, and heated to boiling, nitric acid is added drop by drop until the purple colour is produced; the heating is then stopped, and ammonia added to alkaline reaction, whereon the red colouring matter is precipitated in an impure state. It is collected, washed with ammonia, dilute hydrochloric acid, and water, then dissolved in boiling alcohol. The solution deposits indigo-blue on cooling. The filtrate is purified from a brownish substance by alcoholic lead acetate, and most of the alcohol distilled off. The residue is mixed with much water, when a dark-brown powder separates, which, after crystallisation from ether or chloroform, shows the reactions of indirubin. A small specimen of the urine may be tested by adding nitric acid while boiling, then cooling, supersaturating with ammonia, and shaking with ether. A purple coloration of the ether shows the presence of indirubin. Urines which contain the chromogen of indigo-red give a more or less pronounced violet colour with Jaffé's indican test. M. J. S.

Analysis of Resins and Balsams. By M. BAMBERGER (*Monatsh.*, **11**, 84—86).—The author has examined a number of resins and balsams in order to determine their methyl-number, and has made use of the method and apparatus described by Benedikt and Grüssner (this vol., p. 299). The results are given in tabular form; and it appears that a large proportion of the substances investigated contain no methoxyl. Of those which do, the most important are given with their methyl-numbers in the following list:—Gum ammoniacum, 11; asafœtida, 18; gum benzoin, 13·3—30; dragons' blood, 33·8; guaiacum resin, 84; myrrh, 13·2; olibanum, 5·3; balsam of Peru, 14·4; tolu balsam, 46·8; acaroid resin, 26·4—32·7. G. T. M.

A Cyanogen Reaction of Proteïds. By J. GNEZDA (*Proc. Roy. Soc.*, **47**, 202—210).—The author modifies the "biuret reaction" (rose-red colour produced by biuret, peptones, and albumoses, on treatment with a solution of copper sulphate and a caustic alkali) in so far as he employs a solution of ammonia instead of the usual solution of caustic alkali, which may, however, afterwards be added. He finds that copper sulphate and ammonia added to albumin give a blue solution which becomes violet on addition of potash; peptones or albumoses treated with the first reagents give a violet solution which is turned red by potash. An ammoniacal solution of a nickel salt gives somewhat similar colour reactions. Various organic substances ultimately produced from proteids were tested in the same way, and from the results of his experiments, the author concludes that the colour reaction with copper sulphate and an alkali is a cyanogen reaction, the difference in the colours obtained being attributable to different modes of combination of the cyanogen-group. J. W.

General and Physical Chemistry.

Concentration of the Sun's Rays for Chemical Reactions. By J. W. Brühl (*Ber.*, 23, 1462).—The author has found a concave mirror very useful in starting and carrying out chemical reactions by the aid of sunlight. F. S. K.

Refractive Powers of Salts in Solution. By E. Doumer (*Compt. rend.*, 110, 957—958).—The refractive powers of salts in solution are not constant, but in some cases increase with the concentration, in others decrease, the variations being especially marked in the case of dilute solutions. In comparing the refractive powers of different salts it is therefore essential that the conditions should be strictly comparable. The author finds that his laws of the molecular refractive powers (this vol., p. 433) hold good only when the state of dilution is such that the density of the salt in the solution, with respect to hydrogen, is equal to the molecular weight of the salt. By density of the salt is meant the weight of salt contained in a unit volume of the solution.

The different results obtained by Walter are due to the fact that this condition of concentration of the solution was not fulfilled, and also that Walter's refractive powers are given by the expression $\frac{n - n_0}{p}$, n being the index of refraction of the solution n_0, that of water, and p the weight of the anhydrous salt contained in 100 grams of the solution, whilst the author's refractive powers are calculated from the expression $\frac{n^2 - n_0^2}{d}$, where n and n_0 have the same significance as before, but d is the weight of the salt contained in a unit volume of the solution. For the same salt, d and p may be regarded as proportional, but this does not by any means hold between different salts. C. H. B.

Determination of the Molecular Refraction of Solid Chemical Compounds in their Solutions. By F. Schütt (*Zeit. physikal. Chem.*, 5, 349—373).—The present paper deals with the examination of solutions of sodium chloride in water. The refractive indices for the potassium (red), sodium, lithium, thallium, and hydrogen, α, β, and γ lines, and the densities of solutions varying from 0·1 to 25 per cent. in concentration were determined with the greatest possible accuracy. From these the specific refraction was calculated by means of each of the three formulæ $(n - 1)d$ (Dale and Gladstone), $(n^2 - 1)/(n^2 + 2)d$ (Lorentz and Lorenz), and $(n^2 - 1)/(n^2 + x)d$ (Ketteler). The object was to ascertain with what accuracy the specific refraction of a concentrated salt solution might be determined from that of mixtures of the same with water, to determine the specific refraction of sodium chloride from that of its solution, and to compare the value thus obtained with that observed with the solid salt itself; and to decide with what degree of accuracy the refractive index of any given salt solution may be calculated from the percentage composition and density, if the refractive indices of water and of a more concentrated solution are already known.

In the above calculations it is assumed that if p be the percentage of salt in the solution, R′ the specific refraction of the solution, R that of sodium chloride, and R″ that of water,

$$100R' = pR + (100 - p)R''.$$

It is then found that of the formulæ used to express the specific refractions of sodium chloride and its solutions, that of Ketteler gives the best results. Using this formula, the specific refraction of a concentrated salt solution may be calculated from that of any other solution containing more than 1 per cent. salt to within $\frac{1}{4823}$. The specific refraction of sodium chloride calculated from that of any of its solutions containing more than 1 per cent. salt will be found to vary only $\frac{1}{515}$ in amount. The value thus obtained can therefore be used for the calculation of the molecular refraction; it is not, however, identical with that obtained for sodium chloride by direct determination. With the above value, the refractive indices of salt solutions of any concentration can also be calculated from those of a more concentrated solution and of water, the agreement between the numbers thus calculated and those observed being to within five units of the fifth decimal place.   H. C.

Dispersive Power of Carbon Compounds. Alcohols of the Fatty Series. By P. Barbier and L. Roux (*Compt. rend.*, **110**, 1071—1074, compare Abstr., 1889, 805).—The following results were obtained:—

	t°.	A.	B.
Methyl alcohol	10·0	1·3244	0·318
Ethyl alcohol	14·0	1·3522	0·358
Propyl alcohol	15·0	1·3733	0·381
Butyl alcohol	14·1	1·3892	0·398
Amyl alcohol*	—	—	0·415
Hexyl alcohol*	—	—	0·422
Heptyl alcohol	16·4	1·4105	0·430
Octyl alcohol	16·3	1·4179	0·437
Isopropyl alcohol	15·4	1·3661	0·380
Secondary butyl alcohol	15·4	1·3852	0·396
Diethyl carbinol	14·3	1·3976	0·407
β-hexyl alcohol	15·4	1·4053	0·4215
Secondary heptyl alcohol*	—	—	0·428
Secondary octyl alcohol	16·6	1·4158	0·4355
Isobutyl alcohol	21·8	1·3827	0·394
Isoamyl alcohol	22·1	1·3940	0·406

* These values of B were obtained by interpolation.

	$t°$.	A.	B.
Allyl alcohol	13·4	1·4061	0·5385
Diallyl carbinol	16·6	1·4281	0·614

In the alcohols of the ethyl series, the dispersive powers are continuous functions of the molecular weights, and increase with the molecular weight, a result the reverse of that obtained with compounds of the benzene series. Primary and secondary alcohols have practically the same dispersive powers, but in the case of the isoprimary alcohols the values are slightly lower than for the corresponding normal primary compounds. The elimination of hydrogen results in a considerable increase in the dispersive power.

C. H. B.

Seat of the Variation of Electromotive Force with Temperature. By A. GOCKEL (*Ann. Phys Chem.* [2], **40**, 450—463).—The author takes four cells and places them at the corners of a rectangle, and then joins them up as required along the sides of the rectangle by means of siphons. The cells at one pair of adjacent corners contain, *e.g.*, a solution of zinc sulphate with zinc electrodes, the other pair containing copper sulphate solution and copper electrodes. This arrangement thus gives two Daniell cells, one of which can be warmed in a water-bath whilst the other remains cold; the necessary connections are made with the siphons. By suitable combination, the temperature coefficients of the different contacts may be determined, and from these the author calculates by summation the temperature coefficient of the whole galvanic element. The agreement between direct experiment and calculation is fairly satisfactory. J. W.

New Method and Department of Chemical Research. By G. GORE (*Phil. Mag.* [5], **29**, 401—427).—The author in this paper gives the results of his investigation on the change of electromotive force of a zinc-platinum element brought about by changing the concentration of the solutions of different substances in which the metals are immersed. The method employed was that of the "voltaic balance" (compare Abstr., 1889, 665), which is much more delicate than the thermopile method he formerly used. Increased concentration is usually accompanied by increased electromotive force, and chemically analogous substances give curves which show a general similarity to each other, but which are still perfectly characteristic of the different compounds. The effect of change of temperature at one and at both metals was also studied. The experimental results are given in the form of numerous curves, and a theoretical discussion follows.

J. W.

Fall of Potential at the Cathode in Geissler's Tubes. By E. WARBURG (*Ann. Phys. Chem.* [2], **40**, 1—17).—This paper is a continuation of a former communication on the same subject (*Ann. Phys. Chem.* [2], **31**, 545).

The author had observed that whilst in a Geissler's tube filled with slightly moist nitrogen the difference of potential between the cathode and a point in the extreme visible limit of the negative glow remained constant, yet when the nitrogen was quite dry, a considerable increase of fall took place as the current passed. This he now attributes to the presence of minute quantities of oxygen in the nitrogen, and shows in the present communication how these traces may be removed. Sodium had previously been used for this purpose, but a difficulty was experienced in obtaining this metal in a state of sufficient purity. The author liberates his sodium within the closed tube in the "nascent" state by electrolysis through the glass, a portion of the tube being immersed in half per cent. sodium amalgam connected with the negative pole of a battery and heated to 300°, the cathode of the tube being connected with the positive pole. When the last trace of oxygen has been removed a deep-yellow light appears in the part of the tube in which the sodium is liberated. Nitrogen at 2·3 mm. pressure was freed from oxygen in 20 minutes, with a current from three Bunsen cells connected with an induction coil capable of giving a 25 mm. spark in air, and making 390 contacts a minute. The excess of sodium was afterwards distilled into a remote portion of the tube. From his experiments the author gets the following mean numbers for the fall at the cathode in volts:—Platinum cathode: in nitrogen, 232; in hydrogen, 300. Magnesium cathode: in nitrogen, 207; in hydrogen, 168.

Variations of a few per cent. still remain, but the author is of opinion that in perfectly pure gases the fall is independent of the current strength and of the pressure, being determined only by the chemical nature of the gas and of the cathode, and by the physical condition of the latter. J. W.

Surface-tension of Polarised Mercury. By F. PASCHEN (*Ann. Phys. Chem.* [2], 40, 36—52).—In continuation of a previous paper (this vol., p. 552), the author now investigates the effect of concentration of the electrolytic solution, and seeks to test Pellat's relation between the maximum of surface-tension and the point where electrolysis begins. For sulphuric and nitric acids, he finds that the maximum increases with increasing concentration, whilst the E.M.F. for incipient electrolysis diminishes. It thus happens that for a definite mean concentration the two values become equal, so that it is only for this concentration that Pellat's relation holds good. The fall beyond the maximum depends on the relative values of the E.M.F. for maximum surface-tension and for electrolysis. There is little or no fall for strong solutions of the above acids, when the E.M.F. for electrolysis is far below the maximum.

Other electrolytes investigated were solutions of nitric acid, ferrous sulphate, potassium hydroxide, potassium iodide, and mercuric cyanide. Nitric acid and ferrous sulphate behave very similarly to hydrochloric acid. The point for electrolysis is affected by the nature of the solvent (water, ethyl alcohol, amyl alcohol). A strong solution of potassium cyanide behaves abnormally, giving a deflection of the meniscus in a direction opposite to that when other electrolytes are employed. Experiments with electrometers containing Wood's metal instead of mercury led to identical results. J. W.

Passage of Electricity through Hot Gases. By J. J. THOMSON (*Phil. Mag.* [5], 29, 358—366, and 441—449).—The gases to be examined were contained in a platinum tube, into which the insulated terminals dipped. The tube was wrapped round with asbestos tape, placed in an outer iron tube, and the whole arrangement then put into a muffle furnace, heated by a gas-air blast. The electrodes were placed in circuit with a battery and a galvanometer of 4000 ohms resistance. When the gas had attained the temperature required, a reading of the galvanometer was made, the current reversed, and the opposite deflection observed.

Great differences were found in the behaviour of gases at a yellow heat. Air, nitrogen, sulphur, mercury, ammonia, steam, hydrogen sulphide, carbonic anhydride, nitric and sulphuric acids—all gave extremely small deflections; whereas bromine, iodine, hydrogen iodide, hydrogen chloride, and the vapour of several haloid salts, conducted well. To volatilise more refractory substances, such as silver and tin, the oxyhydrogen blowpipe was employed, the substances being contained in a hole made in a ganister brick. Mercury, thallium, and tin did not seem to conduct; but the vapours of the other metals, such as lead, aluminium, and magnesium, conducted much better than air, sodium and potassium being specially good conductors.

Whenever a gas became a good conductor on being heated, the author was able to detect dissociation by purely chemical means. All substances, however, which dissociate on heating do not necessarily conduct: ammonia and steam, for example. Conduction is only observed when the products of dissociation are atoms or unsaturated groups. The very slight conductivity in the case of air, &c., is probably due to convection of particles from the negative to the positive pole. Ohm's law seems to be approximately obeyed in the case of gases that conduct well. Cold metals are not capable of taking up electricity from hot gases, for no current is observed until both electrodes are red-hot. The nature of the electrodes seems to have no effect on the class of good conductors, neither does alteration of their relative size. No polarisation could be detected. Unsaturated gases, like NO and O_3, behaved exactly like air. J. W.

Electrical Conductivity of Fused and Solid Salts. By L. GRAETZ (*Ann. Phys. Chem.* [2], 40; 18—35).—The author placed a quantity of the salt to be investigated in a small porcelain crucible, the lid of which contained four openings for the reception of the wires leading to the electrodes, and those of the thermo-element used to measure the temperature. The crucible was placed in a large sand-bath, and precautions taken that the conducting wires should be kept hot, so as to prevent solidification of the fused salt on the electrodes and on the junction. The bath was heated to considerably above the temperature of fusion of the salt, and then allowed slowly to cool, simultaneous determination of the temperature and the conductivity being made from time to time. The melting point was determined by a separate experiment. Tables are given for the conductivity of the following substances: the chlorides, bromides, and iodides of cadmium and zinc, lead chloride, lead iodide, potassium nitrate, cuprous chloride, stannous chloride, and antimonious chloride. The results obtained serve to show that there is in no case a sudden change of conductivity at the melting point, as Foussereau (*Compt. rend.*, **98**, 1325) asserted. In conclusion, the author discusses at some length the theoretical aspect of the question, particularly in connection with dissociation.

J. W.

Conductivity of the substituted Succinic and Glutaric Acids. By C. A. Bischoff and P. Walden (*Ber.*, **23**, 1950—1958).—The authors have continued their investigation of the conductivity of the substituted succinic acids (this vol., p. 745; see also Bethmann, *Zeit. phys. Chem.*, **5**, 385), with the results given in the following table, in which K represents 100 times the dissociation constant:—

Substance.	Melting point.	K.
Trimethylsuccinic acid	105°	0·0054
h-Propyldimethylsuccinic acid	51—53	0·0054
h-Ethyldimethylsuccinic acid	62	0·0057
H-Ethyldimethylsuccinic acid	105	0·0059
H-Propyldimethylsuccinic acid	101—102	0·0059
Benzyldimethylsuccinic acid	128—130	0·0059
Succinic acid	180	0·00665 (Ostwald)
Asymmetrical dimethylsuccinic acid	140	0·0080
Ethylsuccinic acid	98	0·0083
Methylsuccinic acid	112	0·0086
Benzylsuccinic acid	161	0·00905
Antidimethylsuccinic acid	120	0·0122
Paradimethylsuccinic acid	194	0·0190
Mesoethylmethylsuccinic acid	88	0·0201
Paraethylmethylsuccinic acid	168·5	0·0206
Parabenzylmethylsuccinic acid	159—160	0·0219
Paradiethylsuccinic acid	192	0·0245
Mesobenzylmethylsuccinic acid	137—138	0·0247
Parabenzylethylsuccinic acid	154	0·0262
Tetramethylsuccinic acid	190—192	0·0314
Antidiethylsuccinic acid	128	0·0343
Mesobenzylethylsuccinic acid	123	0·0414

It will be seen that the trisubstituted succinic acids have the least conductivity, and also differ least among themselves.

Similar measurements have also been made with several of the substituted glutaric acids. As has been previously pointed out, the compounds described above as trisubstituted succinic acids may possibly be in reality disubstituted glutaric acids. They are therefore also included in the following table:—

Substance.	Melting point.	K.
Trimethylglutaric acid	97°	0·00352
Glutaric acid	97·5	0·00475
α-Symmetrical dimethylglutaric acid	126—127	0·0053
β- „ „ „	102—103	0·0055
Dimethylglutaric acid	99—101	0 0054
Trimethylsuccinic acid	105	0·0054
α-Methylglutaric acid	76	0·0054
h-Propyldimethylsuccinic acid = mesopropylmethylglutaric acid	51—53	0·0054
α-Symmetrical diethylglutaric acid	113—114	0·0055
h-Ethyldimethylsuccinic acid = mesoethylmethylglutaric acid	62	0·0057
H-*Ethyldimethylsuccinic acid* = paraethylmethylglutaric acid	105	0·0059
H-*Propyldimethylsuccinic acid* = parapropylmethylglutaric acid	101—102	0·0059
Benzyldimethylsuccinic acid = benzylmethylglutaric acid	128—130	0·0059

The differences in this case are too small to allow of the deduction of any conclusions concerning the constitution of the different acids.

H. G. C.

Conductivities of the Ammonium and Aniline Salts of the Hydroxybenzoic Acids. By D. BERTHELOT (*Compt. rend.*, **110**, 1066—1069).—The conductivity of mixtures of phenol and ammonia is considerably greater than the mean calculated conductivity, the difference being at a maximum with equal equivalents of phenol and the alkali. This also holds good for mixtures of benzoic acid with ammonia. The conductivity of ammonium benzoate when the base and acid are present in equivalent proportions, or where the benzoic acid is in excess, is greater than that of sodium benzoate.

In the case of orthohydroxybenzoic acid and ammonia in different proportions, the conductivities are always considerably less than the calculated values, but with the meta- and para-hydroxybenzoic acids the results are of the same kind and same order of magnitude as with benzoic acid. Notwithstanding the great differences between the conductivities of the three acids, the conductivities of mixtures of the acids with an equivalent quantity of ammonium are practically identical. A similar result was obtained previously with the sodium salts, the conductivity of which is somewhat lower. With orthohydroxybenzoic acid the maximum difference between the observed and calculated conductivities is given by a mixture of equal equivalents of the acid and the base; in the case of the meta- and para-acids the difference increases with the addition of a second equivalent of ammonia. A strictly analogous result was obtained with the sodium salts.

The observed conductivities of mixtures of aniline and benzoic acid are practically identical with the calculated values, and it follows that the aniline benzoate is completely dissociated in the solution. With orthohydroxybenzoic acid and aniline, the observed values are decidedly less than the calculated, and there is evidently considerable combination; with the meta- and para-acids, the results are almost the same as with benzoic acid, and there is very little combination. The observed values are slightly less than the calculated for the meta-acid, and slightly greater for the para-acid. C. H. B.

Electrolysis of Aluminium Fluoride in Igneous Fusion. By A. Minet (*Compt. rend.*, **110**, 1190—1193).—Aluminium sodium chloride, even when mixed with excess of sodium chloride, is too volatile to be used economically as an electrolyte. A mixture of 40 parts of aluminium sodium fluoride with 60 parts of sodium chloride is practically non-volatile below 1100°, and is sufficiently fluid at 800°. Electrolysis with carbon electrodes follows the ordinary laws of electrolyis of solutions. The composition of the electrolyte can be kept constant by repeatedly adding aluminium fluoride, but as this involves the loss of a quantity of fluorine equivalent to the aluminium deposited, a mixture of fluoride and oxide corresponding to the oxyfluoride, $Al_2O_3 \cdot Al_2F_6$, is used. The electrolytic cell is a cubical steel vessel, and in order to prevent corrosion, 5 per cent. of the current of the cathode is diverted by means of a resistance, and thus the internal surface of the cell is kept coated with a very thin layer of aluminium.

In one experiment with four cells, the temperature of the fused salt being 1100°, and the duration of the experiment 21 hours, the constants for a single cell were: difference of potential, 5·75 volts; intensity, 1500 amperes; E.M.F. of decomposition, 2 volts; resistance of electrolyte, 0·0025 ohm, and weight of metal deposited 5250 grams. C. H. B.

Determination of the Heat of Vaporisation by Means of the Steam Calorimeter. By K. Wirtz (*Ann. Phys. Chem.* [2], **40**, 438—449).—With the steam calorimeter of Bunsen and Joly, the author finds it is easy to determine with considerable accuracy the heat of vaporisation of liquids boiling below 100°. The vessel in which the liquid is contained is a test tube 23 mm. wide and 75 mm. long, surrounded by a loosely-fitting glass jacket 55 mm. long. This test tube is placed in the platinum basket, and the increase of weight noted on immersing it in steam. A second experiment is then made with the same apparatus, plus a weighed quantity of liquid. From the two weighings the quantity of steam condensed owing to the vaporisation of the liquid can easily be obtained. For precautions against spurting and overheating, the original paper must be consulted. The results of the author's experiments agree very well with those of Regnault, Andrews, and others. J. W.

Heat of Formation of Uric Acid and Alkaline Urates. By C. Matignon (*Compt. rend.*, **110**, 1267—1270).—Heat of combustion of 1 gram of uric acid in the calorimetric bomb, 2,754 Cal.; molecular heat of combustion at constant volume, 462·7 Cal., at constant pressure, 461·4 Cal.; heat of formation, +148·1 Cal.

Potassium Urates.—Heat of dissolution of the bibasic urate in dilute potassium hydroxide, −6·0 Cal., $C_3H_4N_4O_3$ sol + 2KOH sol. = $C_5H_2N_4O_3K_2$ solid $+2H_2O$ develops +37·5 Cal. Heat of formation of the bibasic urate, + 256·2 Cal.

Heat of dissolution of the monobasic urate, −8·4 Cal.; heat of neutralisation of solid uric acid by the first equivalent of solid potassium hydroxide, + 23·9 Cal.; heat of formation, + 207·0 Cal.

Heat of neutralisation of the solid monobasic urate by a second equivalent of solid potassium hydroxide, + 13·9 Cal.; heat of neutralisation of the dissolved salt by dissolved potash, +4·6 Cal. It follows from the thermochemical results that the second acid function of uric acid is of a phenolic rather than an acidic character.

Sodium Urates.—Heat of dissolution of the hydrated bibasic urate, $C_5H_2N_4O_3Na_2,H_2O$, in dilute sodium hydroxide solution, −1·4 Cal. Heat of neutralisation of uric acid by two equivalents of sodium hydroxide in solution, +6·2 Cal., in the solid state, +27·2 Cal. Heat of formation of the hydrated bibasic urate, +310·9 Cal.; of the anhydrous salt, +240·5 Cal.

Heat of dissolution of the monobasic urate dried at 100°

$$C_5H_3N_4O_3Na,\tfrac{1}{2}H_2O, \ -8·8 \text{ Cal.};$$

heat of neutralisation of solid uric acid by one equivalent of solid sodium hydroxide, with formation of the hydrated salt, +21·7 Cal.; heat of formation, 237·6 Cal.; heat of formation of the anhydrous salt, 198·5 Cal. It follows from these results that uric acid should decompose sodium and potassium phosphates with formation of the monobasic phosphates, and this is found to be the case. Heat of neutralisation of the dissolved monobasic urate with formation of the dissolved bibasic salt −5·7 Cal.; heat of neutralisation in the solid state, +10 Cal.

Ammonium Urate.—Molecular heat of combustion of the monobasic salt, +530 Cal.; heat of formation, +183 Cal.; heat of combination of gaseous ammonia with solid uric acid, +22·7 Cal. The bibasic salt could not be obtained.

Uric acid has only one truly acid function; the bibasic urates are analogous to the phenolates and the tribasic phosphates.

C. H. B.

Heat of Transformation of Isomeric Inosites. By BERTHELOT (*Compt. rend.*, **110**, 1244—1246).—The heat of solution of dextrogyrate inosite at 17·9° is −2·05 Cal., and that of lævogyrate inosite −2·03 Cal. The two numbers may therefore be taken as identical, and the mean is −2·04 Cal. No thermal disturbance is observed when the two solutions are mixed.

Heat of dissolution of racemic inosite, −3·87 Cal., or −7·74 Cal. for the double molecule; it follows that the heat of combination of the two optically active inosites is +3·66 Cal. Inactive nonracemic inosite from walnuts has a heat of dissolution −3·38 Cal. These numbers are of the same order of magnitude as in the case of the tartaric acids.

C. H. B.

the reduction of the pressure, an ordinary water pump may be employed.

The results obtained with sulphur do not show any grounds for assuming the existence of the molecule S_6, and are thus in agreement with Biltz's results (Abstr., 1888, 1028). On the other hand, the density in diphenylamine vapour agrees fairly well with the molecular formula S_8, previously deduced by Beckmann (this vol., p. 447) from the rise in the boiling point of its solutions.

H. G. C.

Laws of Molecular Volumes and of Boiling Points. By C. M. Guldberg (*Zeit. physikal. Chem.*, 5, 374—382).—The molecular volumes of liquids are ordinarily compared at their boiling points, that is, at temperatures corresponding with equal vapour-pressures. For obvious reasons this comparison should be made under strictly comparable conditions; and this would only be the case when pressure, volume, and temperature were expressed in terms of their critical values. That certain regularities in the molecular volumes at the boiling points have in spite of this been discovered, is explained on comparing the values of T (the absolute boiling point) with those of T_1, the absolute critical temperature, in those cases in which these two constants are known. The ratio T/T_1 is found to be not absolutely constant, but in all cases the value obtained approximates to 2/3. Hence it follows that qualities like the molecular volumes which only alter slowly with the temperature, are practically comparable at the boiling points.

Since the critical pressure of liquids is generally very much greater than that of the atmosphere, Gay-Lussac's and Boyle's laws may be looked on as applicable at the boiling point. If V is the volume of the saturated vapour, then $pV = BT/m$, or $mV = BT/p$. Here B/p would be a constant quantity which by a suitable choice of units might be made equal to unity, in which case the absolute boiling point would obviously be a measure for the molecular volume of a saturated vapour under a pressure of 1 atmosphere. H. C.

Improvements in the Apparatus for Crystallising at a Low Temperature and in absence of Moisture and Air. By J. W. Brühl (*Ber.*, 23, 1460—1461).—The improvements relate to the apparatus previously described (Abstr., 1889, 464). Instead of making an air-tight joint between the glass receiver (B) and the shallow bell-jar cover by means of an indiarubber ring, the edges of both are ground and greased, those of the receiver being turned slightly inwards at the top so that the greased surface forms a slight angle with the vertical. Instead of a platinum cone a marble is placed in the funnel-shaped portion of the receiver (B); it is then possible to apply greater pressure to the crystalline mass remaining in the receiver. The vessel containing the freezing mixture is wrapped round with flannel and covered with a felt plate.

The author finds that a marble placed in a funnel instead of a perforated plate, without either paper or cloth, forms a very good filter even for substances in a moderately fine state of division.

F. S. K.

Constitution of Solutions. By F. Rüdorff (*Ber.*, 23, 1846—1851; compare Abstr., 1888, 342, 889, and 1889, 98).—The previous researches of the author on the diffusion of double salts, have led him to divide them into two classes; the members of the first behave like a mixture of two simple salts, whilst those of the second act as definite chemical compounds. The object of the present research was to determine whether two salts, which do not react, behave towards each other when in solution in a manner at all comparable with a mixture of two indifferent gases. It is assumed that if the salts exert any mutual action, their combined effect on the solvent will be less than the sum of the influence of each separately. The method adopted consisted in determining the freezing point of various solutions. The following salts were investigated; the value t/g represents the constant depression of the freezing point caused by g parts of substance dissolved in 100 parts of water; the numbers are in all cases the mean of several experiments:—

	t/g.
Ammonium chloride	0·655
„ sulphate	0·277
Potassium chloride	0·462
Sodium „	0·604

The observed freezing point of mixtures of any two of these salts agreed very closely with the calculated numbers, showing that no interaction takes place. On the other hand, the freezing point of solutions of substances which form double salts, such as mixtures of mercuric cyanide and potassium cyanide; cupric chloride and ammonium chloride; aluminium sulphate and ammonium sulphate, &c., was always lower than that of the separate solutions. J. B. T.

Solid Solutions and Molecular-Weight Determinations of Solid Substances. By J. H. Van't Hoff (*Zeit. physikal. Chem.*, 5, 322—339).—The well-known laws of the reduction of the freezing points of solutions by dissolved substances have now been satisfactorily established for 18 different solvents. The investigation of this subject has, however, brought to light a number of exceptions to the general laws which as yet remain unexplained. Many of these the author assumes to be due to the fact that in certain cases the substance which separates out on freezing is not the pure solvent, but a solid solution of the dissolved substance in the solvent. The properties of solid solutions are, therefore, discussed in order to ascertain what the effect of this behaviour would be.

As instances of solid solutions, we have isomorphous mixtures and mixed crystals, amorphous solutions, as in the case of the glasses and certain minerals; and then such cases as the solution of hydrogen by palladium and other metals. In solid solutions, diffusion can apparently take place as in liquid solutions. Spring has shown that double decomposition takes place between solids under pressure, and this decomposition must be preceded by diffusion. Glass behaves as an electrolyte, in which case diffusion of ions takes place through the mass. It is also known that carbon has the power of diffusing through iron and porcelain. We may therefore assume that in solid solutions we have osmotic pressure, as in liquid solutions; and, if this is of kinetic origin, the laws applying to the latter will also apply to the former case. Hence the gaseous laws should be applicable to dilute solid solutions; and if this be the case the osmotic pressure will be proportional to the concentration. In the case of the absorption of hydrogen by palladium this seems to be so. Up to a certain point, hydrogen is absorbed under a constant pressure of 225 mm. until 600 parts by volume have been taken up, corresponding with the formation of Pd_2H; but above this point the hydrogen absorbed is proportional to the pressure, as is seen by the following numbers:—

Massive palladium.			Spongy palladium.		
v.	P.	$P/v - 600$.	v.	P.	$P/v - 600$.
809	1428	6·8	775	715	4·1
743	909	6·4	743	493	3·5
700	598	6·0	718	361	3·0
672	454	6·3	684	247	3·0
642	353	8·4	—	—	—

The analogy between liquid and solid solutions would, further, lead to the conclusion, that the vapour-pressure of a solid would be reduced on its taking any other substance into solution. This view is supported by the fact that many isomorphous mixtures are more stable, and do not so readily undergo efflorescence as either of their constituents. This reduction of the vapour-pressure of a solid by the introduction of foreign material is of importance in considering the effect which the separation of a solid solution in place of the pure solvent has on the lowering of the freezing point. For, since the freezing point of a solution is the point at which the vapour-pressure of the solution and of the separating solid is the same, the smaller the vapour-pressure of the solid the higher will be the melting or freezing point of the solution. Hence the separation of a solid solution from a solvent in place of the pure solvent would make the freezing point fall too high, or would cause too small a depression of the freezing point. This is, as a matter of fact, what so often comes under observation, particularly in those cases in which the formation of a solid solution by the union of solvent and dissolved substance might from the first be expected. This is the case with solutions of metacresol and parabromophenol in phenol, of aldoxime in acetoxime, and of thiophen and pyridine in benzene.

By the application of the Raoult methods to solid solutions, these, like liquid solutions, should be made available for molecular-weight determinations. Although nothing has as yet been done in this direction, it is of importance to note that, from the fact stated above, that there is proportionality between the amount of hydrogen absorbed by palladium and the pressure of the gas, we may conclude that free hydrogen and that held in solution by palladium have the same molecular composition. It is highly probable that the further study of solid solutions would throw much light on the question of the molecular structure of solids. H. C.

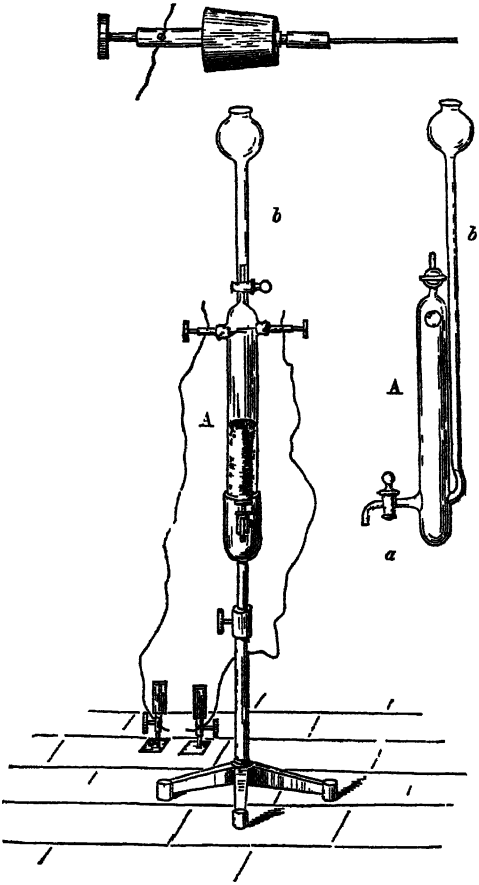
Possibility of Determining the Molecular Weights of Metals by two new Methods. By V. v. Türin (*Zeit. physikal. Chem.*, 5, 340—348).—The first method consists in measuring the E.M.F. of a simple galvanic cell, in which one electrode is formed of pure mercury, and the other of an amalgam of the metal, the molecular weight of which is being determined, the electrolyte being a mercury salt, either in solution in water or alcohol, or in the molten condition. The second method consists in measuring the E.M.F. of a simple galvanic cell, in which both electrodes are formed of amalgams of the metal, the molecular weight of which is being determined, of different concentrations, the electrolyte in this case being a salt of the same metal.

In the first instance, if we have two vessels, A and B, of which the first contains pure mercury and the second the amalgam, a cycle of changes may be performed by transferring osmotically a certain small quantity of mercury from A to B, and then connecting A with B electrolytically, and thus allowing the mercury to be returned to A. The work done in each of the above stages is of course the same, and is measured by the product of the E.M.F. into the amount of electricity, which is necessary to transfer unit weight of mercury from A to B, the latter being inversely proportional to the electro-chemical equivalent of mercury. The function may then be found which expresses the relation between the unknown molecular weight and the E.M.F. of the cell. The second method is in principle similar to the first, and differs from it only in being somewhat more complicated and difficult to treat. H. C.

Determination of Affinity Coefficients. By W. Hecht, M. Conrad, and C. Brückner (*Zeit. physikal. Chem.*, 5, 289—321; see these Abstracts, 1889, 931, and this vol., pp. 4, 327).—This paper deals with the influence of dilution on the rate of formation of ethereal salts. The action of sodium ethoxide on methyl iodide and its higher homologues is studied, the concentration of the solutions being varied from the normal, $v = 1$, to $\frac{1}{80}$ of the normal, $v = 80$. The combined influence of temperature and concentration on the affinity coefficients may be expressed by the following equation $k_v^t = k_1^t 10^{\alpha t}(1 + \lambda \log v)$, in which $\lambda = 0{\cdot}4546$ for methyl, 0·6058 for ethyl, and 0·7843 for all the other alkyl iodides. The relation between the affinity coefficients does not vary greatly with rising dilution in the case of the higher alkyl iodides, ethyl iodide, however, shows a slight variation, and methyl iodide a very marked one, in the relation of their affinity coefficients at different dilution. For infinite dilution, placing the value for methyl iodide at 100, that for the others would be ethyl 10·37, propyl 4·38, octyl 3·01, cetyl 3·10. The action of potassium and sodium ethoxides on ethyl bromide also follows a law similar to the above with regard to concentration.

H. C.

Action of the Electric Arc on Gaseous Substances and its Employment for Demonstrations. By B. Lepsius (*Ber.*, **23**, 1418—1428 and 1637—1642).—The author has successfully employed the apparatus described below for demonstrating the volumetric composition of various gases; its chief advantages over Hofmann's apparatus are that the experiments can be carried out in a comparatively short time, and a large volume of gas can be employed.



A glass tube A, 40 mm. in diameter and 300 mm. in length, is provided at its upper extremity with a glass stopcock, and, 40 mm. below the stopcock, with two lateral tubulures, 15 mm. in length and 15 mm. in diameter; it is closed below, but provided with a stopcock *a*, and an upright tube *b*, 10 mm. in diameter, as shown in the figure, the whole being placed on a suitable support. The lateral tubulures serve for the introduction of the carbon poles, which are about 2 mm. in diameter (or larger if required), and enclosed in metal necks, 12 mm. in length, which on the other side fit on to the pin (2 mm. in diameter) of a copper rod, 6 mm. in diameter, provided with a binding screw. The metal necks are made of iron or of brass (in the latter case they must be lacquered) and are slit down one side. The copper rods are fitted tightly into the lateral tubulures by means of indiarubber corks, and are of such a length that they overlap each other about 10 mm.; the corks being placed eccentrically in the tubulures in such a manner that the rods can be brought into contact by slight pressure on one of the binding screws. A current of 30 to 50 volts is sufficient to give the necessary arc, but it is better to employ a stronger current (60 to 80 volts) and a rheostat: the heat of the arc can then be regulated, so that the glass apparatus and the indiarubber corks are not damaged.

The gas is introduced in the usual way by first filling the apparatus with mercury.

The following examples serve to illustrate the use of the apparatus for lecture experiments:—*Conversion of Carbonic Anhydride into Carbonic Oxide.* Well dried carbonic anhydride (80—100 c.c.) is introduced into the apparatus, its volume, measured under the atmospheric pressure, is marked on the tube, and the arc is ignited. Decomposition takes place with a brilliant light, and the volume immediately increases; in about a minute decomposition is complete, and after a short time the temperature is sufficiently equalised to allow of the measurement of the carbonic oxide, the volume of which is found to be double that of the carbonic anhydride employed.

Conversion of Oxygen into Carbonic Oxide.—Well dried oxygen (about 100 c.c.) is introduced into the apparatus, its volume is noted, and the arc is ignited; the volume increases continuously, and in one or two minutes the oxygen is completely converted into double its volume of carbonic oxide.

The volume relationship between oxygen, carbonic oxide, and carbonic anhydride can be very conveniently and quickly demonstrated with the following apparatus, a diagram of which is given in the original paper:—A glass tube A′, of the same size as the tube A, is provided at its upper extremity with a stopcock, and with two lateral tubulures through which pass two carbon rods, fitted exactly as shown in the figure, and described above, but instead of being closed below it is continued as a narrower tube (50 cm. long and 15 mm. in diameter), open below, the stopcock *a* and the upright tube *b* being done away with. The whole is filled with mercury, and suspended over a pulley in such a way that the open end dips into a deep, narrow, cylindrical depression in a mercury trough; this trough is supported on a small table, which can be moved up and down by means of a screw. The tube A′, the broader portion of which is marked off into six parts, each of 60 c.c. capacity, is now brought into such a position that the uppermost division is exactly opposite to a fixed pointer placed about 300—400 mm above the level of the mercury in the trough, and 60 c.c. of oxygen are introduced; the arc is then ignited for about one minute, the apparatus is allowed to cool, and the level of the mercury is again brought to that of the pointer, when it is seen that 120 c.c. of carbonic oxide have been produced. The tube A′ is again raised, so that the third division is opposite to the pointer, 60 c.c. of oxygen are introduced, and the tube is raised again as much as possible, in order to rarefy the gaseous mixture; the spark is then passed, and, after the explosion, the level of the mercury is brought opposite to the pointer, when it is seen that the three volumes have become two. The two volumes (120 c.c.) of carbonic anhydride thus produced can be converted into four volumes of carbonic oxide as already described, and then into four volumes of carbonic anhydride by explosion with two volumes of oxygen, the volume in both cases being shown by bringing the level of the mercury to that of the pointer; finally, the carbonic anhydride can be completely absorbed by introducing a small piece of moist potash. The apparatus and the oxygen employed must be free from moisture.

Conversion of Sulphurous Anhydride into Carbonic Oxide.—Dry sulphurous anhydride (about 80 c.c.) is introduced into the tube A shown in the figure, the volume is measured under the atmospheric pressure, and the arc is ignited; the carbon burns with a beautiful blue light, the apparatus becoming filled with white fumes, and the volume of the gas increases, and reaches a maximum in 30—40 seconds. On measuring the volume of carbon monoxide produced it is found to be double that of the sulphurous anhydride employed.

Formation and Decomposition of Sulphurous Anhydride.—Oxygen (80—100 c.c.) is introduced into the open tube A′, described above, the pointer being placed about 300 mm. above the level of the mercury in the trough, and then a piece of sulphur melted on to the end of a sharply-curved piece of copper wire is introduced from below, and ignited by momentarily closing the circuit. The sulphurous anhydride thus produced, the volume of which is equal to that of the oxygen employed, can then be converted into double the volume of carbonic oxide as described above.

That acetylene contains its own volume of hydrogen can also be demonstrated by means of the apparatus shown in the diagram.

The formation of water-gas can be very conveniently demonstrated by decomposing steam by means of the electric arc. For this purpose a flask, 15 to 20 cm. in diameter, is provided with two lateral tubulures, through which pass the carbon poles, arranged and adjusted as described above; the mouth of the flask is closed with a cork through which pass two glass conducting tubes, one reaching almost to the carbons, the other just passing through the cork; the flask is inverted on a stand, and steam is passed in through the longer tube. As soon as the air is completely expelled, the escaping steam is led under an inverted cylinder full of cold water, if, now, the arc is ignited, a rapid evolution of gas, consisting of equal volumes of hydrogen and carbonic oxide, is observed.

The same apparatus can be used for showing the formation of water-gas from water. The flask, provided with a single delivery-tube, is filled with water, placed in an upright position, and a strong current passed; the carbons become white hot, and a mixture of hydrogen and carbonic oxide is rapidly evolved. F. S. K.

A Lecture Experiment for the Demonstration of Valency. By B. Lepsius (*Ber.*, **23**, 1642—1646).—The apparatus described and shown in the preceding abstract can be employed for explaining experimentally the meaning of the term valency. Four such apparatus, 35 mm. in diameter, and 150, 200, 250, and 300 c.c. in capacity respectively, are so arranged that the uppermost stopcocks are all at the same level, and then filled with equal volumes (about 100 c.c.) of hydrogen iodide, hydrogen sulphide, hydrogen phosphide, and methane respectively, the volume being marked on the tube immediately after the introduction of the gas. The arc is then ignited in all the four apparatus, either separately or simultaneously, whereon the gases are quickly decomposed; after allowing to cool and adjusting the pressure the volume of the liberated hydrogen in the four tubes is seen to be in the ratio of 1 : 2 : 3 : 4.

All the gases must be as dry and pure as possible, and the apparatus containing the hydrogen iodide must be filled immediately before the experiment, but the others may be filled some time previously.

The hydrogen iodide is best obtained by heating an intimate mixture of melted phosphoric acid with double its weight of potassium iodide. The hydrogen phosphide is most conveniently prepared by the action of potash on phosphonium iodide. F. S. K.

Inorganic Chemistry.

Combustions under a High Pressure. By W. Hempel (*Ber.*, **23**, 1455—1460).—The author has carried out a large number of experiments in order to ascertain the influence of increased pressure on the quantity of sulphuric anhydride formed by the combustion of sulphur, and on the quantity of nitric acid produced by the combustion of nitrogen, either alone or with carbon.

The combustion of the sulphur was carried out in dry oxygen in iron vessels, that of the nitrogen in steel autoclaves lined with platinum; ignition was effected by means of a platinum wire heated momentarily to its melting-point by an electric current.

Five quantitative experiments on the combustion of sulphur in oxygen showed that under a pressure of 40 to 50 atmos. about half the sulphur is directly oxidised to sulphuric anhydride; under a pressure of 72·5 atmos. the proportion of sulphuric anhydride produced is considerably less.

In the experiments on the combustion of nitrogen, varying quantities of air, oxygen, and electrolytic gas were compressed in an autoclave of 28 c.c. capacity, containing a little concentrated potash, and after combustion the nitric acid produced was reduced with ferrous chloride, and estimated as nitric oxide; the results showed that the quantity of nitric oxide obtained increases with the pressure. When, for example, the autoclave is filled with air under the ordinary pressure, oxygen forced in until the pressure reaches 55 atmos, then electrolytic gas until a pressure of 211·5 atmos. is attained, a quantity of nitric acid corresponding to 10 c.c of nitric oxide, is produced.

The nitric acid produced by the simultaneous combustion of nitrogen and carbon, in excess of oxygen, under various pressures was also determined; it was found that under a high pressure (88 atmos.), a very considerable quantity of nitrogen combines directly with the oxygen, but the quantity depends greatly on the relative weights of the two gases, and on that of the carbon employed.

The data of all the experiments are given in the paper.

F. S. K.

Formation of Nitrous Acid and Ammonia from free Nitrogen. By O. Loew (*Ber.*, **23**, 1443—1447)—When dry platinum black, from which water dissolves neither nitrous acid nor ammonia, is shaken with soda, both nitrous acid and ammonia are formed; if the soda is very dilute the reactions of nitrous acid are obtained, but not those of ammonia.

The platinum black employed was most carefully prepared from platinic chloride free from nitric oxide, and the experiments were carried out in a room in which no fire or gas was burning, every precaution being taken to prevent contamination with nitrogenous compounds; the result was, however, always the same.

It would seem then that under the influence of the platinum black two processes take place:—(1.) The small quantity of nitrogen, condensed together with the oxygen in the platinum black, is directly oxidised to nitric oxide, which is then rapidly converted into nitrous acid. (2.) When concentrated soda is employed the nitrogen enters into reaction with the water as well, and ammonium nitrite is produced.

If air, purified by passing through concentrated sulphuric acid, concentrated potash, and several wash-bottles containing water, is conducted through a flask containing freshly prepared platinum black and a 0·5 per cent. solution (300 grams) of potash, the coloration produced with sulphanilic acid and α-naphthylamine, after acidifying with hydrochloric acid, is four times as intense after 12 hours as it was shortly after the commencement of the experiment, and the last wash-bottle does not contain a trace of nitrous acid. Large quantities of nitrite cannot, however, be obtained in this way, as the platinum black forms a compact layer at the bottom of the flask; better results would probably be obtained if the platinum black were allowed to condense a large volume of oxygen, containing nitrogen, by previous drying in the air.

A quantity of freshly prepared moist platinum black, corresponding to 23—24 grams of the dry substance, was mixed with about 5 grams of crystalline barium hydroxide, both substances being perfectly free from nitrous acid and ammonia, the mixture quickly washed on to a filter, kept for two days in a desiccator over calcium chloride, and then washed with water (150 c.c.); the filtered washings gave a deep yellow colour with Nessler's reagent, and the total quantity of nitrous acid produced, estimated colorimetrically with Griess' reagent, was found to be about 0·7 milligram.

If active platinum black is treated with alcohol and then with chloroform, and finally placed in a desiccator over sulphuric acid for a day, it completely loses its power of causing the formation of nitrous acid and ammonia when it is shaken with air and soda, probably owing to the formation of a thin coating of platinum dichloride.

The fact that platinum at a high temperature causes the combination of oxygen and nitrogen, has been lately observed by Ilovsay (this vol., p. 447). This action commences at 180° with platinum black, at 250° with platinum sponge, and at 280° with platinum foil, but after prolonged heating at 300° the metal loses its activity.

The conversion of nitrogen into an assimilable form, at the ordinary temperature and without the aid of electricity, in the manner described above, is a fact of interest, on account of its bearing on vegetable physiology; because it may be assumed that an action which can be brought about by platinum black in presence of strong bases, can also be brought about by cells with an especially active protoplasm, even in presence of only a feeble alkali; the observations of Berthelot, Prantl, and Hellriegel and Wilfarth, on the fixation of atmospheric nitrogen by plants, seem to show that this assumption is well founded. F. S. K.

Combination of Phosphorus Pentafluoride with Nitrogen Peroxide. By E. TASSEL (*Compt. rend.*, **110**, 1264—1267).—When phosphorus pentafluoride is brought in contact with nitrogen peroxide at −10°, heat is developed, and a mass of white, elongated crystals, is formed, of the composition PF_5,NO_2. They dissociate even at the ordinary temperature and pressure, the dissociation being greatly accelerated by a slight rise of temperature; the products are phosphorus pentafluoride and nitrogen peroxide. Water decomposes the compound with formation of nitric and phosphoric acids and evolution of nitric oxide. Sulphuric acid dissolves it with liberation of phosphorus pentafluoride, whilst the nitrogen oxide remains in combination with the acid. C. H. B.

Action of Ammonia and Hydrogen Phosphide on the Haloid Compounds of Arsenic. By BESSON (*Compt. rend.*, **110**, 1258—1261).—Arsenic trifluoride vapour acts on ammonia with formation of a very light, white powder, which, after being dried over sulphuric acid until it ceases to lose ammonia, has the composition $2AsF_3,5NH_3$. It is decomposed by water with formation of a feebly acid solution.

Arsenic trichloride at first absorbs ammonia very rapidly, but towards the end of the reaction the solid product must be repeatedly pulverised, and combination takes place very slowly. The compound formed is $AsCl_3,4NH_3$. Persoz attributed to this product the formula $AsCl_3,3NH_3$, and Rose the formula $2AsCl_3,7NH_3$.

Arsenic tribromide absorbs ammonia without alteration of its crystalline form, and with formation of a straw-coloured compound, $AsBr_3,3NH_3$, which, in sealed tubes, decomposes at 300° with liberation of arsenic and nitrogen and formation of ammonium bromide.

Arsenic tri-iodide forms a pale yellow compound, $AsI_3,4NH_3$, which begins to lose ammonia at 50°, and at 300° decomposes in a manner similar to the bromide. Prolonged exposure to ammonia at 0° yields a yellow liquid of the composition $AsI_3,12NH_3$.

If the compound with arsenic chloride is added to cold concentrated sulphuric acid, energetic decomposition takes place, and drops of arsenic chloride separate in the liquid. The iodide compound behaves similarly with concentrated hydrochloric acid, arsenic iodide being liberated, and the author regards these reactions as evidence that these products are true molecular compounds.

Hydrogen phosphide forms no definite compounds with the haloid compounds of arsenic, but reacts energetically with them in accordance with the equation $PH_3 + AsX_3 = PAs + 3HX$, where X is a halogen. When the solid product is treated with water it yields a very light brown powder, $PAsO_3$, and small metallic-looking scales, $PAsO_6$, formed by the action of the water on the arsenic phosphide. The reaction between hydrogen phosphide and arsenic fluoride takes place at −23°, and with arsenic chloride at −18°. With the solid bromide and iodide the action is superficial, and phosphonium bromide and iodide are formed by the union of the haloid hydracid produced in the reaction with the excess of hydrogen phosphide. With the bromide melted at 30°, the reaction is very energetic.

C. H. B.

Arsenic Compounds. By K. Preis (*Annalen*, **257**, 178—203; compare Abstr., 1888, 914).—When arsenic trioxide (1 mol.) is dissolved in a warm solution of sodium hydrosulphide (1 mol.), arsenic bisulphide is precipitated, and from the solution sodium oxythioarsenate, disodium arsenate, and a garnet-red salt, which seems to have the composition $4Na_2O,6As_2S_2,3As_2S_4O + 3H_2O$, can be isolated.

The following thioarsenates were prepared by precipitating a solution of sodium thioarsenate with a solution of the respective metallic salts:—$Hg_3(AsS_4)_2$, $Cu_3(AsS_4)_2$, and $Zn(AsS_4)_2$; the double salt, $NaZnAsS_4 + 4H_2O$, was also obtained in yellow crystals.

F. S. K.

Carbon Fluorides. By C. Chabrié (*Compt. rend.*, **110**, 1202—1204).—Carbon tetrafluoride, prepared in tubes of Bohemian glass, contains only very minute quantities of silicon or carbonic anhydride, and its properties agree closely with those of the tetrafluoride prepared by Moissan in a metal vessel (this vol., p. 944).

Methylene fluoride, CH_2F_2, is obtained by heating 508 parts of anhydrous silver fluoride with 17 parts of methylene chloride at 180°. Analyses of the gas and its sp. gr. (1·82) show that it has the composition required by the formula. C. H. B.

Reduction of Alkaline Sulphates by Hydrogen and by Carbon. By Berthelot (*Compt. rend.*, **110**, 1106—1112).—The ordinary equation, representing the reduction of alkaline sulphates by hydrogen, is not correct; some hydrogen sulphide is always evolved, and the residue contains some alkaline hydroxide. The reduction begins at about 500°, and the primary reaction is $K_2SO_4 + 4H_2 = KOH + KSH + 3H_2O$, which corresponds with a development of +2·6 Cal. in case of the potassium salt, and + 9·3 Cal. in the case of the sodium salt. Under the influence of the heat which is being supplied from the outside, the hydrosulphide dissociates with absorption of −9 5 Cal. for KSH, this change being accelerated by the current of water vapour and hydrogen. Part of the hydrogen sulphide escapes in the free state, and the rest acts on the potassium hydroxide, forming hydrosulphide and water with development of +12·8 Cal. The hydrosulphide continues to dissociate, and this change would convert all the potassium into monosulphide if some of the hydrogen sulphide were not carried away before there is time for the reaction to take place. Moreover, part of the monosulphide is decomposed by the water vapour, with formation of hydroxide and hydrosulphide, and development of +5·8 Cal. Between these various reactions, equilibrium is established, and is determined, as usual, by the presence of a dissociable compound, the hydrosulphide, and is governed by the tendency of the products to react with the development of heat on the one hand, on the other to dissociate with absorption of heat under the influence of the heat supplied from the outside. The water and hydrogen sulphide are carried away by the current of hydrogen, and thus the sulphate is completely reduced, the product being a mixture of sulphide and hydroxide in proportions determined by the conditions of the change. Some red potassium polysulphide is also formed as a result of the partial decomposition of the hydrogen sulphide into hydrogen and sulphur.

Reduction by Carbon.—Alkaline sulphates are reduced by carbonic oxide with formation of sulphide and carbonic anhydride, and development of +33·2 Cal. in the case of potassium, and +17·6 Cal. in the case of sodium. The change requires a much higher temperature than reduction by hydrogen, and does not take place below a bright red heat.

A mixture of a dry alkaline sulphate with pure carbon, in a vessel containing air, is reduced at about the same temperature as in the case of carbonic oxide, and the products are the same, carbonic anhydride being evolved, unless the carbon is present in very large excess. In complete absence of oxygen very little change takes place, even at bright redness, and the reduction observed is to be attributed to the formation of a small quantity of carbonic oxide by the action of the alkaline silicates formed from the porcelain of the tube. Under these conditions sodium sulphate alters more readily than the potassium salt.

The reduction of alkaline sulphates, on a large scale. by means of carbon in presence of air, takes place under the same conditions as reduction by carbonic oxide, and must be regarded as due to carbonic oxide. The presence of a small quantity of this gas is essential to the reduction; it is provided by the oxygen of the air in the vessel, the oxygen in the carbon, or by the oxides of the material of the vessel. When once the reduction is in progress, the supply of carbonic oxide is furnished by the reaction; the carbonic oxide reduces the sulphate with formation of carbonic anhydride, and the latter is reconverted into carbonic oxide by the action of the excess of carbon.

It follows that in this case, as in others, carbon does not exert a direct reducing action, a result due to its polymeric constitution. In order that it may act as a reducing agent it must lose its state of condensation and be converted into a normal compound containing only one atom of carbon in the molecule.

In the reduction of salt cake, both carbonic oxide and hydrogen are active agents, the latter especially, when reduction is carried on in revolvers with the aid of gases from coal. C. H. B.

Silver Sub-Fluoride. By Guntz (*Compt. rend.*, **110**, 1337—1339).—When a saturated solution of silver fluoride is electrolysed with silver electrodes and a strong current, and the liquid is allowed to become hot, metallic silver is not deposited; but crystalline plates, with the colour of brass filings, separate at the cathode; they contain less fluorine than the normal fluoride, and when treated with water are decomposed into metallic silver and ordinary silver fluoride. The ratio of the silver dissolved as fluoride to the silver which separates in the metallic state is, practically, unity.

If finely-divided silver is heated with silver fluoride solution in a sealed tube, the liquid becomes yellow above 50°, and if the temperature does not exceed 90°, the whole of the silver is converted into the subfluoride Ag_2F, which forms a crystalline powder like brass filings. It is decomposed by water with development of heat.

$Ag_2Fl + nH_2O$ liquid = AgF diss. + Ag solid .... develops +2·73 Cal.

hence—

Ag_2 sol. + F gas = Ag_2F solid......... „ +24·9 „

and—

Ag sol. + AgF sol. = Ag_2F solid....... absorbs −0·7 „

Silver subfluoride does not alter in dry air, and decomposes very slowly in moist air. C. H. B.

Phosphates of Lithium, Beryllium, Lead, and Uranium. By L. Ouvrard (*Compt. rend.*, **110**, 1333—1336).—The oxides or carbonates were dissolved in fused alkaline phosphates in the same way as in previous experiments (Abstr., 1888, 1033, 1035, 1037).

Lithium with any potassium phosphate, and with or without potassium chloride, yields only the compound $P_2O_5,3Li_2O$ in well-defined prisms which seem to belong to the rhombic system. Lithium carbonate and sodium metaphosphate yield the compound

$$2P_2O_5,3Li_2O,Na_2O$$

in small, flattened prisms which seem to be monoclinic; they are insoluble in water, but dissolve in acids. Sodium pyro- and orthophosphates yield the compound $P_2O_5,2Li_2O,Na_2O$ in imperfect crystals, or, if excess of lithium carbonate is added, the compound $P_2O_5,3Li_2O$.

Beryllium with potassium meta-, pyro-, or ortho-phosphate yields the salt $P_2O_5.2BeO,K_2O$ in rhombic prisms with an acute, positive bissectrix, the angle between the axes being about 30°. With sodium metaphosphate, Wallroth obtained the salt $P_2O_5,2BeO,Na_2O$ in hexagonal plates identical with the mineral beryllonite. The author confirms this statement, and has obtained the same compound by means of sodium pyrophosphate. Sodium chloride assists the formation of the crystals. Sodium orthophosphate yields a different product, $P_2O_5,BeO,2Na_2O$, in nacreous lamellæ with widely separated optical axes.

Lead.—Potassium metaphosphate yields lead pyrophosphate, $P_2O_5,2PbO$, free from alkali as colourless, transparent, rhombic prisms isomorphous with the corresponding barium and strontium compounds; they melt easily, and dissolve in dilute acids; sp. gr. at 20° = 5·8.

Potassium pyro- and ortho-phosphates yield the compound $P_2O_5,2PbO,K_2O$ in fusible, transparent, optically active needles, which are decomposed by boiling water. Sodium metaphosphate at a dull red heat, with slow cooling, yields large, transparent lamellæ of the compound $9P_2O_5,10PbO,8Na_2O$. With a larger quantity of lead oxide at bright redness, the pyrophosphate $P_2O_5,2PbO$ is obtained. Sodium pyrophosphate yields the salt $P_2O_5,2PbO,Na_2O$ in small, brilliant, transparent prisms with oblique extinctions; they are readily fusible, and very soluble in dilute acids. Sodium chloride promotes the formation of the crystals, but if added in too large a proportion, causes the production of lead chlorophosphate. Sodium orthophosphate fuses at such a high temperature that no crystalline products could be obtained.

Uranium.—Potassium metaphosphate yields the pyrophosphate, P_2O_5,Ur_2O_3,K_2O, in transparent, yellow dichroic, highly birefractive, rhombic prisms of sp. gr. 4·2 at 20°. Crystallisation is promoted by the presence of potassium chloride. Potassium pyrophosphate yields highly birefractive, rhombic crystals of the phosphate $P_2O_5,2Ur_2O_3,K_2O$; potassium orthophosphate yields the salt $P_2O_5,Ur_2O_3,2K_2O$ in large, macled, yellow prisms. Sodium metaphosphate gives brilliant, sulphur-yellow, monoclinic prisms with oblique extinctions, their formation being promoted by the presence of sodium chloride. Sodium pyrophosphate dissolves large quantities of uranium oxide, and if not saturated gives products completely soluble in water. With a sufficient quantity of the oxide, the salt $P_2O_5,Ur_2O_3,2Na_2O$ is obtained in dendritic crystals. Sodium orthophosphate yields the same product mixed with a small quantity of sodium uranate.

No other metal has yielded a salt analogous to the compound $P_2O_5,Ur_2O_3,2K_2O$. C. H. B.

Dicalcium Phosphate. By H. Causse (*J. Pharm.* [5], 21, 544—547).—A phosphate, $Ca_2H_2P_2O_8 + 4H_2O$, crystallising in rhomboidal forms is obtained by adding 500 c.c. of calcium chloride solution to 1500 c.c. of sodium phosphate solution saturated in the cold, then adding 100 c.c. of hydrochloric acid and some drops of sodium acetate. The salt contains P_2O_5, 41·40 per cent.; CaO, 32·65; and H_2O, 26·10. By the action of a solution of lactic acid on this phosphate, calcium dilactate and monocalcium phosphate are formed; the solution formed is only stable in presence of excess of acid.

J. T.

Thiosulphates. By A. Fock and K. Klüss (*Ber.*, **23**, 1753—1764).—*Potassium Cadmium Thiosulphates.*—(*a.*) $5K_2S_2O_3,3CdS_2O_3$. This salt is obtained by mixing equal volumes of concentrated solutions of potassium thiosulphate and cadmium acetate, and forms yellowish, monoclinic crystals; $a : b : c = 1·3203 : 1 : 0·95646$, $\beta = 87° 34'$. (*b.*) $3K_2S_2O_3,CdS_2O_3 + 2H_2O$, is prepared by employing a large excess of the potassium salt, and crystallises from warm water in beautiful, colourless, prismatic or tabular crystals, also belonging to the monoclinic system; $a : b : c = 1·5103 : 1 : 0·9631$, $\beta = 79° 21'$.

Sodium Cadmium Thiosulphates.—(*a.*) $3Na_2S_2O_3,CdS_2O_3 + 16H_2O$ is formed when an excess of sodium thiosulphate solution is added to one of cadmium acetate, and separates as an oil on the addition of alcohol. This solidifies over sulphuric acid in a vacuum to pale-yellow, transparent, tabular crystals, identical with those prepared by Jochum (*Inaug. Diss., Berlin*, 1885). The crystals, which are very stable, are not deliquescent, and lose their water of crystallisation over sulphuric acid in a vacuum. They also crystallise in the monoclinic system; $a : b : c = 1·136 : 1 : 0·3492$, $\beta = 76° 25'$; (*b.*) $3Na_2S_2O_3,CdS_2O_3 + 3H_2O$ is obtained by avoiding an excess of the sodium salt. It forms yellow, prismatic, deliquescent crystals belonging to the triclinic system. They are not well developed, and the measurements are, therefore, inexact. The double salts described by Vortmann and Padberg, namely, $Na_2S_2O_3,2CdS_2O_3 + 7H_2O$ and $Na_2S_2O_3,3CdS_2O_3 + 9H_2O$, could not be obtained.

Ammonium Cadmium Thiosulphates.—(*a.*) $3(NH_4)_2S_2O_3,CdS_2O_3 + 3H_2O$ is formed by adding an excess of ammonium thiosulphate solution to a solution of cadmium acetate, and precipitating with alcohol; it is a white, crystalline salt, which separates from hot water in large, slightly yellow, tabular crystals belonging to the monoclinic system; $a : b : c = 0·9760 : 1 : 1·0026$, $\beta = 83° 45'$. It is stable in the air, but loses its water of crystallisation over sulphuric acid. (*b.*) $3(NH_4)_2S_2O_3,CdS_2O_3 + H_2O$ was obtained by mixing a solution of 1 mol. of cadmium acetate with 4 mols. of ammonium thiosulphate, and adding just sufficient alcohol to precipitate the yellowish oily liquid. On remaining over sulphuric acid, large rhombic tables separate; $a : b : c = 0·4317 : 1 : 0·4187$. (*c.*) $(NH_4)_2S_2O_3,CdS_2O_3$ is formed by mixing a solution of 2 mols. of cadmium acetate with one of 3 mols. of ammonium thiosulphate and adding absolute alcohol. On allowing the oil which separates to remain for some time under the mother liquor, it crystallises in large, yellow, monoclinic crystals;

$$a : b : c = 0·8216 : 1 : 1·5560, \beta = 82° 15'.$$

Barium Cadmium Thiosulphates.—(*a.*) $2BaS_2O_3,CdS_2O_3 + 8H_2O$ is prepared by digesting cadmium sulphate in aqueous solution with barium thiosulphate, and extracting the precipitate after some days with hot water. The salt separates in slender, yellow needles, sparingly soluble in water, belonging to the triclinic system; $a : b : c = 0·9871 : 1 : 0·8595$; $A = 79° 30'$, $B = 94° 15'$, $C = 57° 37'$, $\alpha = 80° 15'$, $\beta = 91° 37'$, $\gamma = 57° 50'$. (*b.*) $3BaS_2O_3,CdS_2O_3 + 8H_2O$ is formed when alcohol is added to the above hot water extract, the precipitate dissolved in hot water, and allowed to evaporate spontaneously. It forms yellowish triclinic tables or plates sparingly soluble in water; $a : b : c = 0·6997 : 1 : 0·6441$; $A = 94° 8'$, $B = 90° 30'$, $C = 79° 45'$, $\alpha = 94° 18'$, $\beta = 91° 18'$, $\gamma = 79° 11'$.

Strontium cadmium thiosulphate, $3SrS_2O_3,CdS_2O_3 + 10H_2O$, is obtained by adding alcohol to a mixture of concentrated solutions of strontium thiosulphate and cadmium acetate, and allowing the oil which separates to remain in a vacuum over sulphuric acid. It forms thick, yellowish, tabular crystals unsuitable for crystallographic examination, readily loses $5H_2O$ on remaining over sulphuric acid, and an additional 2 mols. on long-continued standing. A crystalline calcium cadmium thiosulphate could not be prepared. H. G. C.

Formation of Crystallised Metallic Oxychlorides: Copper Oxychlorides. By G. ROUSSEAU (*Compt. rend.*, **110**, 1261—1264).—The method used for preparing crystallised ferric oxychloride (this vol., p. 1063) is only available in the case of chlorides which are very soluble in water, or which form hydrates capable of aqueous fusion. Further, the decomposition of the dissolved chloride is possible only when the heat of formation of the chloride does not exceed that of the oxide by more than 4·8 Cal. The method is therefore applicable only in the case of tin, titanium, antimony, bismuth, magnesium, zinc, and iron.

Certain chlorides, cupric chloride, for example, seem to be exceptions to the second law, but in these cases the formation of the oxychloride is due, as Berthelot has shown, to its heat of hydration.

It is conceivable that in presence of a small quantity of water the hydrate of cupric chloride might dissociate more easily, giving rise to the formation of anhydrous chloride and the consequent production of new oxychlorides corresponding to special conditions of equilibrium. The hydrate $CuCl_2,2H_2O$ was heated with fragments of marble in sealed tubes at temperatures between 150° and 250°. A small quantity of an oxychloride was formed; this is readily decomposed by water, but can be isolated by dissolving the unaltered chloride in alcohol. It forms yellowish-green, hexagonal tables with oblique extinction, and the quantity formed in unit time increases with the temperature. It has the composition $CuCl_2,CuO,H_2O$, slowly loses its water above 250°, but retains its crystalline form, and is not decomposed. Below a dull red heat it melts to a black liquid, consisting of cupric chloride with the oxide in suspension.

If this oxychloride is treated with water, its colour changes to pale green, hydrochloric acid is liberated, and atacamite is formed. The oxychloride dehydrated at 300° also forms atacamite; when treated with water, the substance seems to dissolve, but the atacamite is precipitated on the addition of a small quantity of an alkaline chloride.

The limit at which the oxychloride ceases to form lies between quantities of water corresponding with the formulæ $CuCl_2 + 4\frac{1}{2}H_2O$ and $CuCl_2 + 5H_2O$. Above the latter degree of dilution, atacamite is formed, and by heating a mixture of the composition $CuCl_2 + 6H_2O$ at 180—200° for three days, the author obtained atacamite in crystals identical with those of the natural mineral. Formation of the crystals takes place much more readily in presence of native magnesium carbonate than in presence of marble. A higher degree of dilution gives only amorphous products. C. H. B.

Action of Haloïd Compounds of the Alkalis on those of Mercury. By A. Ditte (*Compt. rend.*, **110**, 1330—1333).—The decomposition of a mercurous salt into a mercuric salt and mercury is endothermic, and the combination of the mercuric salt with the excess of the haloïd salt is not sufficient to change the sign of the thermal disturbance. When mercurous chloride or bromide is treated with potassium iodide or cyanide, there is an interchange of acids and bases which determines a considerable development of heat, half the mercury being converted into mercuric iodide or mercuric cyanide, as the case may be. When mercurous iodide is treated with potassium cyanide, a similar exchange takes place, and the reaction is exothermic, but with potassium iodide the change remains endothermic. With potassium bromide and chloride, the reaction is endothermic with all the mercurous salts.

The occurrence of these endothermic decompositions is not appreciable at the ordinary temperature, but takes place more rapidly when the liquid is heated. Dilution of the liquid retards the change.

Mercurous salts are very slightly decomposed in presence of water alone, especially if the latter is heated, and in presence of a haloïd salt of an alkali metal, the mercuric salt produced will form a double salt. The formation of this double salt will destroy the equilibrium, and thus lead to a further decomposition of the mercurous salt. On the other hand, the double mercuric salt dissociates, especially if the solution is dilute, and a condition of equilibrium is established between the water, the mercurous salt, the double mercuric salt, and the products of their dissociation. If the solution is so dilute that the double mercuric salt is completely dissociated, the phenomena are the same as with pure water. A rise of temperature increases the dissociation of the mercurous salt and the double salt, but in presence of a sufficient excess of the alkaline haloid salt the double salt will be sufficiently stable to make the decomposition of the mercurous salt more rapid than at the ordinary temperature.

C. H. B.

Sodium Alum. By E. Augé (*Compt. rend.*, **110**, 1139—1140).—The properties of sodium alum are very inaccurately described in all the books. It is only very slightly efflorescent, and may be kept for several months without alteration; 100 parts of water at 16° dissolve 51 parts of the salt. A solution of the alum can be boiled for any length of time without losing the power of depositing the alum in crystals.

If a mixture of sodium and aluminium sulphate in proper proportions is concentrated without ebullition until its sp. gr. is higher than 38° Beaume, and is allowed to cool, it forms an amorphous paste, showing no trace of crystals even under the microscope, and this fact has probably given rise to the statement that the solution loses its power of crystallising. Temperature, however, has no influence in producing this result, for no matter how long the liquid is boiled, provided that its sp. gr. does not exceed 38° B., it readily deposits crystals; solutions above this degree of concentration always yield the amorphous product. If, however, the paste is allowed to remain at 7—25°, it gradually passes into crystals which have exactly the composition $Na_2Al_2(SO_4)_4 + 24H_2O$, the mother liquor being eliminated. Above 28°, crystallisation takes place very slowly; at temperatures approaching 0° hydrated sodium sulphate also separates. It is probable that the specimens of the alum which were observed to be efflorescent really contained a considerable quantity of sodium sulphate.

In the preparation of sodium alum, the mixture of the two sulphates should be concentrated to 39—43 B., and the paste should be placed on inclined lead plates so that as crystallisation takes place the mother liquor which separates, and which constitutes 25 per cent. of the paste, can readily run away, carrying almost all the impurities with it. C. H. B.

Composition of Clays and Kaolins. By G. VOGT (*Compt. rend.*, **110**, 1199—1202).—Clay cannot be separated by levigation from the very finely divided felspar, mica, or quartz with which it is mixed, since they all remain suspended in water for a long time. Mica being the only one of these minerals which sparkles when suspended in water, it may be concluded that clays which have this property contain mica, from which are derived the alkalis so often found in clays in a form soluble in sulphuric acid. When clays are treated with sulphuric acid, only the clay and the mica are dissolved; the felspar and quartz are not attacked. Both the solution and the insoluble matter will contain alkalis, that in the former (chiefly potassium) being derived from mica, and that in the latter from felspar.

C. H. B.

Manganous Acid. By A. GORGEU (*Compt. rend.*, **110**, 1134—1137).—It seems almost impossible to obtain hydrated manganese dioxide containing the theoretical quantity of oxygen, but the pure dioxide is obtained in a crystalline, anhydrous form by heating manganous nitrate at 158—170°, or by the oxidation of manganite between 270° and 310°.

The best method of obtaining the dioxide in a form with strongly marked acidic properties is to bring together cold and dilute solutions of an alkaline permanganate and manganous nitrate in presence of a considerable quantity of free acid. The precipitate thus obtained is very finely divided, and is highly hydrated; it is manganous acid in its most active form.

The difficulty of preparing manganese dioxide from manganous oxide seems to be due to the fact that nitric acid and permanganic acid exercise a reducing action on manganous acid. Potassium manganite, obtained by the action of carbonic acid on the alkaline manganate, when boiled with nitric acid yields a residue containing distinctly less oxygen than manganous acid. The decomposition of permanganic acid at the ordinary temperature or at 100° yields a product containing 0·5 to 1·0 per cent. less of oxygen than the dioxide.

The hydrated peroxides differ in several respects from the anhydrous peroxides. They redden litmus-paper. and combine with soluble bases, forming manganites. The anhydrous peroxides show no acidic properties in contact with soluble bases, and many metallic salts, but if they are finely powdered and brought in contact with excess of manganous oxide, they will combine with 1·1 to 1·7 equivalents of it. The degree of hydration varies greatly even with different products obtained by the same method. All forms of the dioxide, whether anhydrous or hydrated, begin to decompose at the same temperature, about 400°.

When the hydrated forms of the dioxide are brought in contact with potassium or sodium hydroxide or ammonia, the quantity of alkali with which they combine increases with the concentration of the solution; in contact with lime-water or baryta-water, they combine with a relatively much higher quantity of the base than in the case of the alkalis. It would seem, therefore, that the quantity of the base which enters into combination depends on its solubility in water, or, in other words, on the tendency which its solution has to decompose the manganites which are formed. The acid function of the hydrated dioxide is sufficiently energetic to decompose soluble and insoluble carbonates and certain salts, such as acetates and even sulphates. The limits of the decomposition of salts seem to depend on their heat of formation; with potassium nitrate, manganite yields the compound $K_2O,25MnO_2$, and with sodium acetate, the compound $Na_2O,15MnO_2$. The composition of the compounds formed from the true metallic acetates and sulphates lies between the limits $K_2O,3MnO_2$ and $K_2O,9MnO_2$.

Potassium permanganate mixed with 20 per cent. of potassium hydroxide does not decompose even when boiled, but if manganous acid or, better, potassium manganite, $K_2O,5MnO_2$, is added, the precipitate gradually disappears at 100°, and the liquid becomes green without any evolution of oxygen. Potassium manganate is formed by the oxidation of the manganite by the permanganate, or by the combination of the permanganate with the bibasic manganite, $2K_2O,MnO_2$. This supposition would explain the failure to isolate manganic acid, and also the action of water and carbonic anhydride on a solution of a manganate. The dilution of the alkaline liquid or the neutralisation of the base would remove from the manganite the greater part of its alkali, thus preventing it from remaining in combination with the permanganate, and causing the precipitation of the acid potassium manganite. C. H. B.

Action of Hydrogen Peroxide on Permanganic Acid and Permanganates. By A. Gorgeu (*Compt. rend.*, 110, 958—961).—When a permanganate or permanganic acid is poured into hydrogen peroxide acidified with sulphuric acid, the manganese at once passes into the condition of manganese sulphate, with evolution of oxygen. A free acid is not essential, and any substance, like ammonium chloride, which can dissolve manganous oxide, will produce a similar result, provided that it is present in sufficiently large quantity.

When hydrogen peroxide is added to pure permanganic acid, the colour is gradually discharged, heat is developed, oxygen is liberated, and manganese peroxide is precipitated. The composition of the precipitate varies, but if the solutions are dilute, and the hydrogen peroxide is added very slowly to the permanganic acid, almost pure manganous anhydride, MnO_2, is formed. If the addition of the peroxide is continued after the liquid has been decolorised, the proportion of oxygen in the precipitate may be reduced by 17·9 to 13 per cent.

With an alkaline permanganate, the precipitate retains a considerable quantity of alkali, and a larger proportion of peroxide is required for complete decolorisation. A combination of manganese peroxide and the alkali seems to be formed, and reacts readily with the hydrogen peroxide. At first a brown solution is formed, which very readily decomposes, and which probably contains potassium manganite. In presence of a large excess of alkali, the brown liquid is not formed. The permanganate is first converted into the green manganate, and the latter is then decolorised.

If hydrogen peroxide is added to a neutral solution of barium permanganate, a brownish-yellow precipitate is formed, which contains all the barium, chiefly in the form of manganite, but with a small quantity of the manganate. If the permanganate is previously mixed with 2 to 4 equivalents of barium hydroxide in solution, all the barium is precipitated in the form of the deep blue manganate on addition of hydrogen peroxide. Excess of hydrogen peroxide exerts a powerful reducing action on the manganate and a feebler action on the manganite.

When hydrogen peroxide is added very slowly to a saturated aqueous solution of silver permanganate, a brown precipitate forms gradually until the liquid is decolorised. The reaction is represented by the equation $2AgMnO_4 + 3H_2O_2 = Ag_2O.2MnO_2 + 3H_2O + 3O_2$. The precipitated silver manganite is rapidly attacked by excess of hydrogen peroxide.

In all these cases the peroxide was added to the permanganate, and the quantity of peroxide decomposed varied from 3 to 11 equivalents per equivalent of permanganate. When the permanganate is added to the hydrogen peroxide, the quantity of the latter which can be decomposed is without limit. C. H. B.

Relative Basicity of the Hydrated Sesquioxides of Iron and Aluminium. By E. A. Schneider (*Annalen*, 257, 359—380).—The author's experiments have confirmed the view at present held, that the hydrated sesquioxide of iron is a stronger base than that of aluminium When hydrated sesquioxide of aluminium is boiled with a dilute solution of ferric sulphate, the alumina does not play the part of a strong base, but simply neutralises a portion of the sulphuric acid, which is liberated by the dissociation of the iron salt, thus causing the precipitation of the whole of the iron as basic salt.

Solutions of the sulphate, chloride, and nitrate of aluminium of a certain concentration dissolve considerable quantities of ferric hydroxide. When water is added to such a solution of aluminium sulphate, in which ferric hydroxide has been dissolved, a basic iron salt is precipitated, but in the case of the aluminium chloride and nitrate solutions, the quantity of ferric hydroxide dissolved, provided it is present in excess, is increased considerably by the addition of water.

Ferric hydroxide can be readily converted into a colloidal modification which is soluble in water by treating it with a solution of aluminium chloride or aluminium nitrate.

Two modifications of aluminium hydroxide are obtained by precipitating aluminium salts with ammonia; the one dissolves in hydrochloric acid, yielding a solution which coagulates on the addition of a trace of sulphuric acid, but not in presence of excess of hydrochloric acid; the hydrochloric acid solution of the other modification is not coagulated on the addition of sulphuric acid.

F. S. K.

Crystallised Ferric Oxychloride. By G. ROUSSEAU (*Compt. rend.*, **110**, 1032—1035).—When solutions of ferric chloride, containing less than 80 per cent. of the salt, are heated in sealed tubes, only amorphous oxychlorides are obtained. With an 80 per cent. solution at 150—160°, traces of crystals of oxychloride are formed, but they dissolve readily in hydrochloric acid, and hence the formation of the oxychloride is limited by the hydrochloric acid set free at the same time. If the liquid contains fragments of marble or dolomite, a considerably larger quantity of the crystallised oxychloride is formed, but the amount never exceeds a few per cent. of the ferric chloride. As soon as the concentration of the solution falls below 80 per cent., amorphous products alone are obtained.

The crystals are red-brown, lustrous, rhombic prisms, of the composition $Fe_2Cl_6,Fe_2O_3,Fe_2(OH)_6$. In contact with hot water they lose all their chlorine as hydrochloric acid, and without loss of crystalline form pass into a ferric hydroxide, with the composition of göthite, the change being complete after 120 hours at 100°. The crystals of göthite have an amber colour, but retain the optical properties of the oxychloride, and therefore present a true case of isomorphism and not merely of pseudomorphism The optical properties are not quite the same as those of the natural crystals of göthite, though both belong to the same system.

C. H. B.

Isomeric forms of Chromic Bromide. By A. RECOURA (*Compt. rend.*, **110**, 1029—1032 and 1193—1196).—*Green chromic bromide* was obtained by boiling a saturated solution of chromic acid with a large excess of hydrobromic acid and concentrating the liquid. It crystallises in beautiful green needles of the composition $Cr_2Br_6 + 12H_2O$, which deliquesce very rapidly and dissolve in less than half their weight of water at the ordinary temperature; heat of dissolution, +0·68 Cal. It is very soluble in alcohol but insoluble in ether.

While in the solid state, green chromic bromide undergoes no change, but it begins to alter as soon as it is dissolved, the solution becoming blue and finally violet, whilst a thermometer placed in the liquid readily shows the development of heat which accompanies the change. At the ordinary temperature, it requires several hours to complete the change, but this is accomplished very quickly if the liquid is heated. If the green solution is precipitated by an equivalent quantity of alkali and the hydroxide is at once dissolved in hydrobromic acid, the violet solution is obtained. The same form of the hydroxide is precipitated from both the green and the violet bromide.

The heat developed by the action of sodium hydroxide shows that the conversion of the dissolved green bromide into the dissolved violet bromide is accompanied by the development of +23·0 Cal.

A solution of 100 parts of green chromic bromide was boiled for a short time, then cooled and saturated with hydrogen bromide, the solution being kept cool throughout the operation. The fine precipitate which is suspended in the liquid is separated by filtration through glass wool, and dried on porous plates out of contact with moist air. It forms a blue-grey powder of the composition $Cr_2Br_6 + 12H_2O$, and is an isomeric modification of the green bromide. It is extremely hygroscopic and very soluble in water, forming a violet liquid. It differs from the green modification in being insoluble in alcohol; its heat of dissolution is +25·70 Cal., whilst that of the green form is only +1·36 Cal. It yields a violet solution which when treated with sodium hydroxide gives rise to exactly the same thermal disturbance as the violet solutions obtained from the green salt. It follows that the solutions of the blue bromide, the solutions formed by the spontaneous alteration of the green bromide, and the solution formed by the action of hydrobromic acid on the hydroxide precipitated from violet salts of chromium, are identical, and represent the definite stable condition of solutions of cupric bromide.

The conversion of the green bromide in solution into the blue bromide, also in solution, develops +23·0 Cal., but the conversion of the solid green bromide into the solid blue bromide absorbs −4·34 Cal. It follows that the green form is the more stable in the solid state, whilst the blue form is much the more stable in solution.

If the solid blue bromide is heated at 100°, it changes into the green form without loss of water, but the change either does not take place at all at the ordinary temperature, or takes place very slowly. In a moist condition and in contact with a solution of the green salt, the conversion of the blue solid salt becomes complete after several days, even at the ordinary temperature, the change probably being accelerated by the presence of some crystals of the green salt deposited from the mother liquor. When a solution of the blue bromide crystallises, the first crystals are blue, but those which form subsequently are green; a solution of the green salt deposits green crystals only. A solution of the green salt mixed with hydrobromic acid remains green indefinitely, probably because the acid combines with the water and the bromide behaves as in a saturated solution.

The stability of the isomeric modifications of chromic bromide and their mutual conversions are in accord with the principle of maximum work. C. H. B.

New Double Chromates. By A. LACHAUD and C. LEPIERRE (*Compt. rend.*, **110**, 1035—1038).—When about 60 grams of lead chromate is added gradually in small quantities to 1,000 grams of fused potassium nitrate, and the mixture is heated for six or seven hours, three products are obtained, namely, (1) a brick-red, basic chromate, $PbCrO_4,PbO$, crystallising in the cubical system and insoluble in water; with acids it yields normal lead chromate and a lead salt of the acid; (2) a double chromate, $PbCrO_4,K_2CrO_4$, which crystallises in small, hexagonal plates, belonging to the rhombic system, and can also be obtained by adding a mixture of lead and potassium chromates to fused potassium nitrate; it is insoluble in hot or cold water and in alcohol, and is decomposed by acids with separation of lead chromate; (3) an orange compound, $PbCrO_4,K_2CrO_4,2PbO$, which crystallises in right rectangular prisms, and is formed more especially at a high temperature.

With sodium nitrate, the results are strictly analogous. The compound, $PbCrO_4,Na_2CrO_4$, however, crystallises in right prisms, and rarely has the appearance of hexagonal plates; it is soluble in water. The basic salt, $PbCrO_4,Na_2CrO_4,2PbO$, is obtained only in small quantity, and forms microscopic crystals belonging to the monoclinic system.

Lithium yields an analogous compound, $PbCrO_4,Li_2CrO_4$, which, however, is more readily obtained by the action of a very concentrated solution of lithium chromate on freshly precipitated lead chromate in sealed tubes at 140°. The ready decomposition of lithium nitrate interferes with the preparation of the salt in the same manner as in the case of potassium or sodium. The basic orange salt could not be obtained. C. H. B.

Electrical and Chemical Properties of Stannic Chloride. By W. COLDRIDGE (*Phil. Mag.* [5], **29**, 383—394 and 480—490).—Pure stannic chloride, heated as high as its boiling point, does not conduct electricity. The author in these papers investigates the effect of mixing foreign substances with the chloride, and discusses the whole question of electrolytic conductivity from the theoretical standpoint. Addition of chlorine had no effect on the conductivity, but dry hydrochloric acid permitted a small current to pass. Dry hydrogen sulphide had an electrical influence. It was observed, however, to precipitate white crystals from the chloride. These have the composition, $SnCl_4,5H_2S$, and are decomposed on heating, leaving a residue of SnS_2. Dumas's compound, $SnCl_4,SnS_2$, has no existence. Absolute alcohol forms white crystals with the chloride, probably $SnCl_4,5EtOH$, and these when dissolved conduct with facility, a stannous compound being formed and strong polarisation setting in. Ether behaves similarly to alcohol, forming a white, crystalline compound,

$SnCl_4,2Et_2O$, soluble in excess of ether and conducting well. Chloroform does not allow a current to pass. Concentrated aqueous hydrochloric acid, when mixed with the chloride, induces conduction and gives a considerable polarisation current. Insoluble solids have no effect when added to stannic chloride.

Taking these results into consideration, the author attributes electric conductivity to non-homogeneity of the electrolyte and consequent chemical exchange. J. W.

Action of Titanium Chloride on Metals. By L. LEVY (*Compt. rend.*, **110**, 1368—1370).—When vapour of titanium chloride is passed over silicon at a bright-red heat in an atmosphere of pure and dry hydrogen, very hard, steel-white, cubical crystals are obtained. Boron and many metals behave in the same way. Iron and antimony, however, cannot be used, and aluminium yields a mixture of the cubical crystals with hexagonal lamellæ of an alloy which has been described previously. The crystals are the same, whatever metal is employed; they have not the properties of titanium sesquioxide, and in all probability consist of almost pure titanium. They are not readily attacked by reagents, but are rapidly dissolved by fused potassium hydroxide with deflagration.

The crystals are cubes with the faces *p*, *a*′, *b*′, and are frequently macled, the hemitropic plane being one of the octahedral faces.

C. H. B.

Complex Acids. By C. FRIEDHEIM (*Ber.*, **23**, 1505—1530; compare Rosenheim, Abstr., 1889, 762).—When vanadic anhydride is added to a boiling solution of acid sodium tungstate, the salt to which Rosenheim assigned the composition, $8Na_2O,16WO_3,4V_2O_5 + 57H_2O$, is deposited in crystals; the author's analyses of the carefully crystallised salt agree better with the formula $2Na_2O,4WO_3,V_2O_5 + 14H_2O$, and its chemical behaviour and its synthesis in the manner described below seem to show that it is a double salt of the composition $5Na_2O,12WO_3 + Na_2O,3V_2O_5$, and not a salt of a complex tungstovanadic acid. When sodium trivanadate is boiled with an equivalent quantity of acid sodium tungstate, it dissolves completely, and Rosenheim's is the only salt which can be obtained from the solution by crystallisation. Rosenheim's salt is also formed, together with various other compounds, when sodium metatungstate is boiled for some time with an equivalent quantity of normal sodium vanadate, and the solution then evaporated over sulphuric acid.

The mother liquors from Rosenheim's salt, prepared by the first method described above, contain a new double salt of the composition $4Na_2O,12WO_3,3V_2O_5$, and sodium metatungstate; on adding a cold, saturated solution of barium chloride, and evaporating over sulphuric acid, a double salt of the composition $3(BaO,4WO_3) + BaO\ 3V_2O_5 + 30H_2O$ is deposited in ruby-red crystals, and on further concentration barium metatungstate separates from the solution.

The above results show that the reaction between acid sodium tungstate and vanadic acid may be expressed as follows:— $3(5Na_2O,12WO_3) + 6V_2O_5 = 2(5Na_2O,12WO_3 + Na_2O,3V_2O_5) + 3(Na_2O,4WO_3)$; on concentrating the solution, a small portion of the acid sodium tungstotrivanadate thus produced is decomposed according to the equation $(5Na_2O,12WO_3 + Na_2O,3V_2O_5) + 3(Na_2O,4WO_3) = 3(Na_2O,4WO_3 + Na_2O.3V_2O_5) + 5Na_2O,12WO_3$.

Vanadic acid and acid potassium tungstate yield compounds analogous to those obtained with acid sodium tungstate, namely, the salt $2K_2O,4WO_3,V_2O_5 + 8H_2O$, and the salt $4K_2O,12WO_3,3V_2O_5 + 30H_2O$; the ammonium salts contain 3 and 30 mols. H_2O respectively The corresponding barium salts were also prepared.

Vanadic acid dissolves in a boiling solution of normal sodium tungstate; on evaporating over sulphuric acid, sodium sesquivanadate, $2Na_2O,3V_2O_5 + 15H_2O$, is deposited in large, reddish crystals, and the mother liquors on further concentration yield crystalline crusts of the double salt, $Na_2O,3WO_3 + Na_2O,2V_2O_5 + 20H_2O$.

Potassium sesquivanadate, $2K_2O,3V_2O_5 + 7H_2O$, was prepared in a similar manner.

The compound $3(Na_2O,2WO_3) + 2Na_2O,3V_2O_5 + 36H_2O$ is formed together with Rosenheim's salt when acid sodium tungstate is boiled with excess of normal sodium vanadate; when treated with acetic acid or boiled with tungstic acid, it is converted into Rosenheim's salt.

F. S. K.

The so-called Phosovanadic Acid and its Salts. By C. FRIEDHEIM and M. SZAMATÓLSKI (*Ber.*, **23**, 1530—1535).—Two series of double salts can be obtained by the combination of phosphoric and vanadic acid, namely, luteo- and purpureo-compounds. The former are yellowish, do not crystallise well, and are only sparingly soluble in, and are decomposed by, water.

Luteo-compounds.—The compound $P_2O_5,V_2O_5 + 11H_2O$ was obtained by treating vanadic acid with phosphoric acid, and the salts, $(NH_4)_2O,V_2O_5,P_2O_5 + 3H_2O$ and $K_2O,V_2O_5,P_2O_5 + 3H_2O$, $(NH_4)_2O,2V_2O_5,P_2O_5 + 7H_2O$ and $K_2O,2V_2O_5,P_2O_5 + 7H_2O$, were prepared, but several other compounds which have been described by Gibbs (*Amer. Chem. J.*, **7**, 209) and Ditte (*Compt. rend.*, **102**, 757) could not be obtained.

Purpureo-compounds.—The compounds of this class are deep-red, and are readily soluble. The potassium and ammonium salts have the composition $7R_2O.12V_2O_5,P_2O_5 + 26H_2O$, and crystallise well; the sodium salt was obtained as a vitreous mass. F. S. K.

Bismuth Potassium Iodides. By C. ASTRE (*Compt. rend.*, **110**, 1137—1139).—By the action of different proportions of potassium iodide on bismuth iodide, the author obtained three crystallised double salts:—$BiI_3,2KI$, which crystallises from ethyl acetate in brown, quadrangular lamellæ belonging to the quadratic system; $2BiI_3,3KI + 2H_2O$, which crystallises from ethyl acetate in groups of needles derived from a quadratic prism; and $BiI_3,3KI$, which crystallises from its aqueous solution, when the latter is allowed to evaporate spontaneously, in grey metallic crystals. This last salt crystallises from ethyl acetate in ruby-red, monoclinic lamellæ. C. H. B.

Chloro-Salts and Atomic Weight of Iridium. By A. JOLY (*Compt. rend.*, **110**, 1131—1134).—Iridium, which had been prepared and especially purified by Deville and Debray, was converted into sodium iridiochloride by heating it with sodium chloride in a current of chlorine, and the potassium and ammonium salts were obtained by precipitation from a boiling solution.

The iridiochlorides were converted into the iridosochlorides by passing hydrogen sulphide into their boiling solutions until they acquired an olive-green colour and then adding an excess of alkaline chloride. *Potassium iridosochloride*, $IrCl_3,3KCl + H_2O$, forms large, deep-brown, quadratic crystals ($a : c :: 1 : 1·615$), olive-green in their sections by transmitted light. The ammonium salt, $IrCl_3,3NH_4Cl + H_2O$, forms olive-green or deep-brown, rhombic prisms of 98° 44′, $a : b : c :: 0·8581 : 1 : 0·4946$.

These salts lose all water at 120° and were reduced in hydrogen; three analyses of the potassium salt give Ir = 192·68 (H = 1), and two analyses of the ammonium salt give Ir = 192·82 (H = 1), the mean being Ir = 192·75, almost identical with the mean number 192·744 given by Seubert.

The action of nitric acid on iridiochlorides seems to yield a nitrosochloride, $IrCl_3(NO),2KCl$, analogous to the nitroso compound obtained from ruthenium under similar conditions. It forms soluble, vermilion-coloured crystals, which evolve nitrogen oxides at 440°.

C. H. B.

Iridium Phosphorus Chlorides. By G. Geisenheimer (*Compt. rend.*, **110**, 1004—1006).—One gram of hydrated iridium dioxide (this vol., p. 948) is heated in a sealed tube at 300° for 30 hours with 10 grams of phosphorus pentachloride and 15 grams of the trichloride. When all the oxide has dissolved the tube contains two layers of liquid; the heavier, which is garnet-red when hot, solidifies to a pale-yellow, crystalline mass when cold, the other contains excess of the chlorides of phosphorus and a double iridium phosphorus chloride, which crystallises on cooling.

The crystals are dissolved in phosphorus oxychloride in a sealed tube at 250°, and separate in pale-yellow crystals of the composition IrP_3Cl_{15}, which can be dried in dry air but have such a high tension of dissociation that they cannot be left in a vacuum, heated, or dissolved in any solvent which is not already perchlorinated.

If the crystals are heated gently to 70—80° and kept at this temperature for half an hour they yield the compound $Ir_2Cl_6,4PCl_3,2PCl_5$. At 120—125° the compound $Ir_2Cl_6,6PCl_3$ is formed. All three compounds have the same appearance, and are formed even in a current of chlorine. At 190° the compound $Ir_3P_6Cl_{30}$ is formed, but does not melt. If the temperature is raised rapidly instead of gradually to 150°, with reduction of pressure, the chloride melts, becomes very deep-red, loses phosphorus trichloride and pentachloride, and yields the compound $Ir_2Cl_6,2PCl_3,2PCl_5$ or $Ir_2Cl_6,2PCl_3,PCl_5$, according to the conditions.

Benzene reduces the original compound very rapidly; carbon bisulphide or phosphorus trichloride dissolves it readily but converts it into $Ir_2Cl_6,6PCl_3$. If heated with chloroform in a sealed tube at 160°, it is converted into small, red needles of the compound $Ir_2Cl_6,4PCl_3$.

It is rapidly attacked by water, and is completely dissolved if the compound is pure and the water is present in large excess; the solution when concentrated on the water-bath yields a syrupy, noncrystallisable acid, $Ir_2Cl_6,3H_3PO_3,3H_3PO_4$. If this is dissolved in a small quantity of water, and a large excess of alcohol added, it is thrown down in the form of a white, flocculent precipitate which rapidly agglomerates. The potassium salt, $Ir_2Cl_6,3PO_3H_2K,3PO_4H_2K$, is not crystallisable, dissolves in water, and is reduced by heat or by alcohol; the ammonium salt, $Ir_2Cl_6,3PO_3H(NH_4)_2,3PO_4(NH_4)_3$, is less easily reduced; the silver salt, $Ir_2Cl_6,3PO_3H_2Ag,3PO_4H_2Ag$, blackens when exposed to light and readily decomposes into silver chloride without precipitation of iridium; the lead salt, $2Ir_2Cl_6,6PO_3HPb,3(PO_4)_2Pb_3$, is white and insoluble in water or acetic acid but dissolves in nitric acid.

The compounds reduce ammoniacal silver nitrate, and with a solution of ammonium molybdate in hydrochloric acid they yield a yellow precipitate with a greenish tinge.

The compound $Ir_2Cl_6,6PCl_3$ is the easiest to prepare, and when pure and dry it is not attacked by cold water, but changes from yellow to white. After this alteration it dissolves slowly even in boiling water, and does not return to its original form even when heated at 125° in a current of chlorine or with chloroform in a sealed tube at 160°. When dissolved in water it yields a syrupy noncrystallisable acid, $Ir_2Cl_6,6PO_3H_3$; the potassium salt has the composition $Ir_2Cl_6,6PO_3H_2K$, and the lead salt $Ir_2Cl_6,6PO_3HPb$.

C. H. B.

Combination of Iridium Phosphochlorides with Arsenic Chloride. By G. GEISENHEIMER (*Compt. rend.*, **110**, 1336—1337).—Iridium phosphochloride (preceding abstract) dissolves easily in arsenic chloride, and if the solution is heated in a sealed tube at 250° and allowed to cool it becomes pale yellow and finally deep-red, and deposits ruby-red, prismatic crystals of the composition $2IrP_3Cl_{15},5AsCl_3$, which may be purified by washing with carbon bisulphide and drying in a current of air. The same product is obtained by heating hydrated iridium dioxide with arsenic trichloride and a very large excess of phosphorus pentachloride. It dissolves completely in water with liberation of hydrochloric acid, and if the solution is evaporated on a water-bath it yields the corresponding acid as a very deep-red, syrupy residue, which dissolves completely even in a very small quantity of water. The lead and potassium salts were prepared.

If, instead of an excess of phosphorus pentachloride, only so much is employed as will dissolve in the arsenic chloride, the product is the compound $IrCl_3,2PCl_3,2AsCl_3$, which crystallises in soft black needles with a violet lustre. They are insoluble in carbon tetrachloride, but dissolve in water yielding a violet solution.

C. H. B.

Mineralogical Chemistry.

Solubility of Minerals. By C. DÖLTER (*Monatsh.*, **11**, 149—150).—The author has determined the solubility in distilled water, of minerals which are usually considered as insoluble. The following were used in the investigation:—Pyrites, galena, blende, antimonite, arsenical pyrites, bournonite, copper pyrites, tinstone, rutile, specular iron ore, heulandite, anorthite, natrolite, and chabasite. The samples, reduced to a fine powder, were placed in sealed tubes, and heated at 80° with distilled water for several weeks. All the minerals proved to be more or less soluble in water, the sulphides, rutile, and tinstone showing the greatest solubility.

The presence of sodium fluoride raises the solubility of rutile, tinstone, and specular iron ore, but sodium chloride does not produce a like effect. Carbonic anhydride increases the solubility of the oxides and sulphides; sodium sulphide and hydrogen sulphide that of the sulphides, especially antimonite. G. T. M.

Pyrargyrite from Kajénel in Transylvania. By H. TRAUBE (*Jahrb. f. Min.*, 1890, i, Mem., 286—289).—The crystals of pyrargyrite from Kajénel exhibit the following eight forms:—$\infty P2$, $\frac{\infty R}{2}$, $-\frac{1}{5}R$, $-\frac{1}{2}R$, $-\frac{3}{2}R$, $\frac{1}{4}R3$, $R2$, $-2R\frac{3}{2}$. Analysis of the mineral yielded the following results:—

Ag.	As.	Sb.	S.	Total.	Sp. gr.
60·45	1·02	20·66	17·87	100·00	5·76

B. H. B.

Tridymite and Chrystobalite. By E. MALLARD (*Compt. rend.*, **110**, 964—967).—The crystals of silica from the Euganean hills, which von Lasaulx described as tridymite, have the form of tridymite crystals, but really consist of quartz into which the original tridymite seems to have been changed. This observation removes most of the doubt which existed as to the real properties of tridymite. The author has examined crystals of this mineral from Cerro San Cristobal and Mont Dore, and his results, combined with earlier observations, show that the crystals of tridymite are pseudo-hexagonal, but belong to the rhombic system with parameters $1 : \sqrt{3} : 1·629$ or $0·5774 : 1 : 0·9405$. The hexagonal plates are grouped in the same manner as aragonite; the mean index of refraction is 1·477, the acute positive bisectrix is normal to the plane 001, and the plane of the axes is normal to the ordinary axis of grouping. The change of state observed by Merian takes place at about 130°, is not accompanied by any considerable change of volume, and does not alter the crystalline form; it is therefore not a true change of the tridymite into quartz. It follows that, above 130°, silica can exist in two crystalline forms, with hexagonal symmetry and one optical axis, one of these forms being quartz and the other tridymite.

Chrystobalite is a distinct species and not merely a variety of tridymite. Its sp. gr., 2·34, is a little higher than that of tridymite, and it is somewhat easily attacked by alkalis. The crystals, which are usually imperfect, are pseudo-cubic, but really belong to the quadratic system. They are optically negative, and are grouped in such a way that the bases of six pyramids represent the six faces of a cube. The author has observed a similar grouping in analcime. Like the latter, chrystobalite is only approximately quadratic and uniaxial, and ought rather to be regarded as rhombic. At 175° it undergoes a reversible change, all birefraction disappears, and the crystals acquire the optical properties proper to their external cubical form.

C. H. B.

Crystallisation of Alumina and other Oxides in Gaseous Hydrogen Chloride. By P. Hautefeuille and A. Perrey (*Compt. rend.*, **110**, 1038).—At the ordinary pressure, hydrogen chloride has no action on alumina or zirconia at high temperatures nor on titanic anhydride at bright redness. Under a pressure of 3 atmos., however, and at a temperature below incipient redness, amorphous alumina is converted into corundum, titanic anhydride into anatase, and zirconia into rhombic tables. At the same temperature and under ordinary pressure, hydrogen chloride has a mineralising effect on the salts of these metals (carbonate, oxalates, sulphates), though not on the oxides.

The crystallisation of alumina is probably due to the successive formations and decompositions of a hydrochloride of alumina analogous to the hydrochloride of molybdic anhydride described by Debray, since under the conditions of the authors' experiments the decomposition of aluminium chloride yields amorphous alumina.

C. H. B.

Celestine from Mineral Co., West Virginia. By G. H. Williams (*Amer. J. Sci.* [3], **39**, 183—188).—Numerous crystals of celestine have recently been found in an extensive cutting on the line of the West Virginia Central Railway. They occur in an argillaceous limestone, and vary in colour from deep blue to colourless, and in length from less than a millimetre up to three inches. They are of pyramidal habit, which is not common for this species. This is due to the preponderance of the acute brachypinacoid $P\breve{4}$. Subjected to chemical examination, the crystals were found to be composed of strontium sulphate, with 0·12 per cent. of lime and a faint trace of barium oxide. These crystals acquire additional interest from their resemblance, in form as well as in their surface markings, to the well-known Sangerhausen pseudomorphs. B. H. B.

Phosphorites from the Government of Smolensk. By W. Vernadsky (*Zeit. Kryst. Min.*, **17**, 628—629, from the Russian).—The principal mass of phosphorite occurs in green sands, rich in quartz, of Upper Cretaceous age. An analysis of a phosphorite nodule from Raditschi gave the following results:—

Ignition.	Insoluble.	P_2O_5.	CaO.	MgO.	Al_2O_3.	K_2O.	Na_2O.	S.
6·60	48·49	14·11	22·02	0·43	2·73	0·26	0·09	trace

The nodules consist of wood and bones converted into phosphorite.

B. H. B.

Mineral Locality at Branchville. By G. J. Brush and E. S. Dana (*Amer. J. Sci.* [3], 39, 201—216; and *Zeit. Kryst. Min.*, 18, 7—23).—This is the fifth paper on this subject written by the authors. They now go on to a detailed account of some of the more interesting species discovered during recent developments at Branchville. Specimens have been obtained of all but one of the new species described in 1878. Besides these, the authors have found another new member of the triphylite-group, a sodium-manganese phosphate, which they term *natrophilite*, and another manganese phosphate, the rare mineral hureaulite, hitherto only known at Hureaux, in France.

Natrophilite occurs sparingly, usually closely associated with lithiophilite, with which it agrees in crystalline form. On analysis it yielded:—

P_2O_5.	MnO.	FeO.	Na_2O.	Li_2O.	H_2O.	Insol.	Total.	Sp. gr.
41·03	38·19	3·06	16·79	0·19	0·43	0·81	100·50	3·41

With the discovery of natrophilite, the triphylite-group receives an important addition, thus:

Triphylite	Li Fe PO_4,
Lithiophilite	Li Mn PO_4,
Natrophilite	Na Mn PO_4.

These three species are closely isomorphous.

The following analyses are also given:—

	P_2O_5.	FeO.	MnO.	CaO.	Na_2O.	K_2O.	Li_2O.		Quartz.	Total.	Sp. gr.
I.	38·36	4·56	42·29	0·94	—	—	—	12·20	1·76	100·11	3·149
II.	34·90	17·13	34·51	0·63	—	—	—	13·18	0·13	100·48	3·204
III.	(37·69)	3·42	17·40	30·02	—	—	—	9·81	1·66	100·00	3·070
IV.	40·89	12·96	31·83	2·09	7·37	1·80	0·22	1·63	0·82	99·61	3·143
V.	39·68	9·69	39·58	3·63	5·44	—	0·07	1·58	1·02	100·69	—

I. Hureaulite in short, prismatic crystals; the analytical results agree with those obtained by Damour, and lead to the formula $H_2R_5(PO_4)_4 + 4H_2O$. II. Reddingite, formula $R_3(PO_4)_2 + 3H_2O$. III. Fairfieldite, formula $Ca_2Mn(PO_4)_2 + 2H_2O$. This analysis confirms the earlier one by Penfield. IV. Dickinsonite, formula $R_3(PO_4)_2 + \frac{1}{2}H_2O$. The results vary considerably from those of Penfield in his original analysis of impure material, the composition now established being essentially the same as that originally deduced for fillowite. V. Fillowite. The analytical results agree with the last, showing that the two species are essentially dimorphous forms of the same species.

B. H. B.

Phosphosiderite, a new Mineral. By W. BRUHNS and K. BUSZ (*Zeit. Kryst. Min.*, 17, 555—560).—This new mineral, from the Kalterborn mine, near Eiserfeld, in the Siegen district, has a hardness of 3¾ and a sp. gr. of 2·76. It occurs in cavities in iron ore as a crystalline aggregate of a blood-red colour. Analysis gave the following results:—

Fe_2O_3.	P_2O_5.	H_2O.	Total.
44·30	38·85	17·26	100·41

Formula $(Fe_2O_3,P_2O_5)_2 + 7H_2O$. These results are very similar to those obtained by Nies on analysing strengite; formula, $(Fe_2O_3,P_2O_5)_2 + 8H_2O$. It therefore appeared not impossible for the two minerals to be identical. Whereas, however, in the mineral under examination all the water was given off at 140°, strengite gave up its water at different temperatures; of the 8 mols., 1½ being given up at 105°, and the remainder at 135°. The authors therefore propose the name of phosphosiderite for this new mineral. It crystallises in the rhombic system, the axial ratio being $a : b : c = 0·53302 : 1 : 0·87723$.

B. H. B.

Spangolite, a new Mineral. By S. L. PENFIELD (*Amer. J. Sci.* [3], 39, 370—378).—A very beautifully crystallised specimen of an unknown mineral from Tombstone, Arizona, in the collection of N. Spang, proved to be a new species, a hydrated sulphate and chloride of copper. The crystallisation is hexagonal, rhombohedral, and the chemical composition of the mineral is as follows:—

SO_3.	Cl.	Al_2O_3.	CuO.	H_2O.	Total.	Sp. gr.
10·11	4·11	6·60	59·51	20·41	100·74	3·141

Its formula is $Cu_6AlClSO_{10},9H_2O$. There is at present no known mineral similar to this in composition. The rare mineral connellite, from Cornwall, is the nearest approach to it, in that this contains copper in combination with sulphuric and hydrochloric acids; but the form and properties of the two minerals are quite distinct. As far as can be found, these two minerals, together with sulphohalite, caracolite, and kainite, are the only mineral occurrences of sulphate and chloride in combination. The occurrence, too, of alumina in a copper mineral is very unusual. B. H. B.

Hornblende of St. Lawrence Co., New York. By G. H. WILLIAMS (*Amer. J. Sci.* [3], 39, 352—358).—A perfect cross-parting due to intercalated twinning lamellæ, occurs on certain crystals of brown hornblende from Pierrepont, St. Lawrence Co. The phenomenon is analogous to the basal parting more commonly observed on pyroxene, and in view of the interest attaching to the structural planes of crystals the author has subjected these crystals to careful examination. From its composition, this hornblende is to be referred to actinolite. It presents two well-marked varieties: green (I) and brown (II), which, however, differ merely in colour. Analysis of these two varieties gave the following results:—

	SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	MgO.
I.	56·54	—	1·10	0·69	2·36	—	13·69	24·42
II.	56·44	0·11	1·77	0·84	0·73	0·11	11·83	22·98

	Na_2O.	K_2O.	Ignition.	Total.
I.	1·15	—	—	99·95
II.	2·13	0·75	2·46	100·15

Evidence afforded by thin sections of this mineral under the microscope shows that an alteration of the crystallographical symbols for the terminal planes of hornblende is necessary to show its analogy to pyroxene, on the assumption that the gliding plane, now called the orthodome $P\breve{\infty}$, is the basal pinacoid 0P. B. H. B.

Production of Sillimanite: Constitution of Porcelain. By W. VERNADSKY (*Compt. rend.*, **110**, 1377—1380).—Sillimanite is the only aluminium silicate which has been produced artificially. Kyanite and andalusite change into sillimanite at 1350° with development of heat. Andalusite becomes white and opaque; in thin sections it extinguishes in a direction parallel with the prismatic edges of the original crystals, but the optical sign in the direction of elongation has become positive.

At a white heat an intimate mixture of finely-divided silica and alumina combines with development of heat, and fuses, forming a very hard, milky-white, slightly porous mass. After the heat of combination has been developed, and the mass has fused, it becomes solid, and will not melt again even in the hottest parts of a Leclercq and Forquignon furnace. A mixture of the composition $Al_2O_3 + 2SiO_2$ fuses well, but the reaction is less distinct with $Al_2O_3 + SiO_2$, though somewhat more distinct with $Al_2O_3 + 3SiO_2$.

The product consists of acicular crystals enclosed in an amorphous substance; the former act strongly on polarised light, and the optical sign in the direction of elongation is positive. The amorphous matter dissolves in cold hydrofluoric acid, but the crystals are not affected. They are, however, readily attacked at 70—80°. Crystals separated by means of the acid were found to have the composition Al_2O_3,SiO_2; the amorphous substance is almost pure silica, but contains small quantities of alumina. In presence of a small quantity of magnesium oxide, larger crystals of sillimanite are formed, but the magnesia does not enter into combination, and is easily removed by hydrofluoric acid, and even by strong hydrochloric acid.

As a general rule, when silica and alumina act on one another at a high temperature in absence of all but a small quantity of fixed bases, sillimanite is formed; this constitutes a large part of the products of the action of a high temperature on topaz, dumortierite, kaolin, and clays.

It is known that porcelain is a mixture of a crystallised and an amorphous substance, and thin plates have the same appearance as kaolin which has been heated at a high temperature. Treatment with cold hydrofluoric acid separates the crystalline from the amorphous matter slowly and with some difficulty, and the amorphous matter contains bases which form insoluble fluorides or silicofluorides.

Crystals separated in this way had the composition Al_2O_3, 70·3; SiO_2 29·7 per cent., which differs slightly from that of sillimanite. It is possible that excess of alumina adheres to the crystals, or a compound $11Al_2O_3,8SiO_2$ (Al_2O_3, 70·1; SiO_2, 29·9 per cent.) may be formed. In any case, porcelain consists of an amorphous substance and crystals which closely resemble sillimanite in composition. C. H. B.

Phonolites from Colorado. By W. Cross (*Jahrb. f. Min.*, 1890, 1, Ref., 427, from *Proc. Colorado Sci. Soc.*, 1887, 167—170).—In the United States hitherto but one occurrence of phonolite was known (Black Hills, Dakota). The author now describes a phonolite from a second locality near Florissant, Pasolty Co., Colorado. The rock is very similar in structure to that from Zittan. On analysis it yielded the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MnO.	CaO.	MgO.	K_2O.	Na_2O.
60·02	20·98	2·21	0·51	trace	1·18	trace	5·72	8·83

Cl.	P_2O_5.	H_2O.	Total.
trace	trace	0·70	100·15

Its sp. gr. is 2·576. The portion soluble in acid (25 per cent.) consists almost exclusively of nepheline. B. H. B.

New Swedish Minerals. By L. J. Igelström (*Jahrb. f. Min.*, 1890, 1, Mem., 248—262).—1. *A New Mineral of the Olivine-group.*—A new variety of knebelite (magnesia-knebelite) has been discovered by the author at the Hilläng iron mine, in the parish of Ludvika, in the government of Dalekarlia. This mineral differs from the iron-knebelite, previously found by the author, in its pearly lustre and lighter colour. Besides which, it is invariably associated with small, red crystals of garnet, which never occur with the iron variety. An analysis of the new mineral gave the following results:—

SiO_2.	FeO.	MnO.	MgO.	Total.
31·1	42·6	21·6	4·7	100·0

The percentage of ferrous oxide must be too high on account of admixed grains of magnetite. The minerals belonging to the olivine-group, which contain iron and manganese in excess, have the following ratios between the iron and manganese-atoms:—

Fayalite	1 : 0
Knebelite	1
Iron-knebelite	2
Magnesia-knebelite	3
Eulysite-olivine	3
Tephroite	0 :

2. *Ferrostibian.*—This is a new mineral discovered by the author on July 13, 1889, at the Sjö mine, in the parish of Grythyttan, in the government of Örebro. The mineral is black, has a hardness of 4, and crystallises in the monoclinic system. Analysis gave the following results:—

SiO_2.	(Mg,Ca)CO_3.	Sb_2O_5.	FeO.	MnO.	H_2O.	Total.
2·24	2·14	14·80	22·60	46·97	10·34	99·09

Its formula is $(10RO,Sb_2O_5) + 10(RO,H_2O)$.

3. *Pleurasite.*—This is a new hydrated arsenate of manganese and iron from the Sjö mine. As yet it has only been qualitatively analysed. Its name is derived from πλευρᾶς (by the side), as it is found by the side of the arseniopleïte in bands of 1 cm. in thickness.

4. *Stibiatil.*—This is a new antimonate also from the Sjö mine. An approximative analysis yielded

FeO.	Mn_2O_3.	$Sb_2O_5 + H_2O$.	Total.
26	44	30	100

Stibiatil is thus a hydrated antimonate of manganese and iron, in which ferrous oxide is present in the greatest amount yet met with.

5. *Neotesite.*—This new mineral occurs in association with tephroite, pyrrhoarsenite, and calcite at the Sjö mine. On analysis it yielded the following results:—

SiO_2.	MnO.	FeO.	MgO.	H_2O.	Total.
29·50	40·60	trace	20·05	9·85	100·00

Formula: $(2RO,SiO_2) + H_2O$, in which RO represents MnO and MgO. As it is probable that this mineral was formed subsequently to the tephroite, the author terms it neotesite, from νεοτήσιος (young).

6. *Jacobsite and Braunite.*—The author has discovered these minerals in a new locality at Glakärn, in the parish of Linde, in the government of Örebro. Analysis shows the Glakärn jacobsite to have the same composition as that of Langban. B. H. B.

Garnet from the South African Diamond-fields. By E. Cohen (*Jahrb. f. Min.*, 1890, 1, Ref., 393—394).—With the diamonds of South Africa, numerous garnets are found. In the dry diggings they are irregularly rounded grains, and in the river diggings they are uniformly rolled and polished. Analysis of wine-red (I) and deep hyacinth-red (II) garnets gave the following results:—

	SiO_2.	Al_2O_3.	Cr_2O_3.	FeO.	MnO.	CaO.	MgO.	Total.
I.	41·34	22·75	2·96	12·12	0·36	5·17	16·20	100·90
II.	40·90	22·81	1·48	13·34	0·38	4·70	16·43	100·04

Both these varieties, as well as the garnets of other shades of colour found at the Cape, are typical pyrope. B. H. B.

Syenites and Hornblende-schists near Glatz, in Lower Silesia. By H. Traube (*Jahrb. f. Min.*, 1890, 1, Mem., 195—233).—The hornblende-bearing rocks of Glatz have been described, partly as of eruptive origin and partly as belonging to the crystalline schists. Microscopical investigation shows these rocks to have a similar mineralogical constitution, the component minerals being orthoclase, oligoclase, quartz, mica, and augite (hornblende). In all the rocks investigated, the hornblende is of secondary origin, having been formed from augite. The structure of the two rocks, the syenites and the hornblende-schists of the geological maps, is very variable. The syenite may have a fibrous or slaty texture, and the hornblende-schist frequently resembles syenite. Analysis also shows that the composition is very similar. This similarity may be well seen from the following analytical results:—

	SiO_2.	$Al_2O_3 + Fe_2O_3$.	CaO.	MgO.
I.	66·07	19·89	3·86	2·04
II.	62·91	17·23	4·48	2·95

I is a partial analysis of the syenites of Follmersdorf, Werdeck, and Hannsdorf, a mixture being prepared of 20 grams of each of these rocks. II is a partial analysis of a similar mixture of the hornblende-schists of Maifritzdorf, Droschkau, and Werdeck. The differences exhibited in these two analyses are not greater than those occurring in each of the various rocks. It follows that a division of these rocks into syenites and hornblende-schist is not feasible. Both rocks have the same origin; they are intimately connected, and form a geological whole, which, in its mineralogical constitution and its structure, exhibits numerous variations. Whether these rocks should be classed as crystalline schists or as eruptive rocks, can only be determined by a careful geological survey. The contact-phenomena in the limestone at Neudeck render the latter hypothesis the more probable. The rocks may consequently be termed quartz-bearing augite-mica-syenites.

B. H. B.

Minerals of the Syenite-pegmatite Veins of the South Norwegian Augite and Nepheline Syenites. By W. C. BRÖGGER (*Zeit. Kryst. Min.*, 16).—This memoir occupies 900 pages, and is illustrated by 38 figures, 27 lithographic plates, and 2 geological maps. Part I (pp. 1—100) is devoted to a summary of the geology of the Christiania district, with special reference to the eruptive rocks. Part II (pp. 101—235) is devoted to an account of the geology of the syenitic and nepheline-syenitic pegmatite veins of the coast between the Christiania fjord and the Langesund fjord. The remainder of the volume, the special part, contains a description of 73 minerals occurring in the syenite-pegmatite veins. In addition to the minerals previously known, the author has found iron-glance, nordenskiöldine, hambergite, xenotime, johnstrupite, epidote, calciothorite, datolite, muscovite, stilpnomelane (?), turmaline, diopside (and salite), lavenite, hiortdahlite, rosenbuschite, arfvedsonite, capelenite, melanocerite, karyocerite, soda-katapleïte, perovskite, eudidymite, thomsonite, weibyeite, and parisite. The number of well-defined mineral species known in the syenitic and nepheline-syenitic pegmatic veins occurring along the coast between the Christiania and Langesund fjords amounts to nearly 75, a number which renders this one of the richest mineral localities in the world. Of these 75 species, more than 20 have not been met with elsewhere, and 5 other rare species were first discovered here. The memoir contains a large number of important analyses. As many as 54 new analyses of minerals, and 43 new analyses of rocks have been specially made by leading Swedish and Norwegian chemists. Space will not admit of all these analyses being reproduced, and it is not possible to do more than give brief descriptions of a few of the more interesting minerals described by the author.

1. *Nordenskiöldine*, named after the celebrated traveller, is of great rarity in the Norwegian veins. It crystallises in the rhombohedral-hemihedral system, and gave on analysis the following results :—

SnO_2.	ZrO_2.	CaO.	B_2O_3.	Ignition.	Total.
53·75	0·90	20·45	23·18	1·72	100·00

Formula, $CaSnB_2O_6$, or, less probably, $Ca(BO)_2SnO_4$. The crystallography of the mineral, however, indicates that it is a borate, and not a stannate. Its colour is yellow; its hardness 5·5 to 6; and its sp. gr. 4·20.

2. *Hambergite*, discovered by A. Hamberg in 1889, and named after him by the author, crystallises in the rhombic system. Its hardness is 7·5, and its sp. gr. 2·347. Analysis gave the following results :—

BeO.	H_2O.	B_2O_3.	Total.
53·25	10·03	36·72	100·00

Formula, $HO{\cdot}Be_2BO_3$. As a basic borate, this extremely rare mineral is one of the most interesting met with in the Norwegian veins.

3. *Xenotime*. This is a very pure yttrium phosphate, which, on analysis, gave results corresponding with the formula $Y_2(PO_4)_2$. In appearance this mineral differs from occurrences previously known by its deep brown colour, by its high sp. gr. of 4·62, and by its crystal form, $0P, P\infty$.

4. *Johnstrupite*, named after Professor F. Johnstrup, of Copenhagen, resembles mosandrite crystallographically and optically, but differs in colour, being green instead of brown. Analyses of mosandrite (I) and johnstrupite (II) gave the following results :—

	SiO_2.	TiO_2.	ZrO_2.	ThO_2.	CeO_2.	$Ca(LaDi)_2O_3$.	Y_2O_3.	Al_2O_3.
I.	30·71	5·33	7·43	0·34	6·34	10·45	3·52	—
II.	30·50	7·57	2·84	0·79	0·80	12·71	1·11	1·52

	Fe_2O_3.	MnO.	CaO.	MgO.	Na_2O.	K_2O.	H_2O.	F.
I.	0·56	0·45	22·53	0·63	2·44	0·38	7·70	2·06
II.	0·50	trace	27·76	1·63	6·67	0·12	1·41	5·98

	Total.	Less O.	Total.
I.	100·87	0·86	100·01
II.	101·91	2·50	99·41

The two minerals present many points of similarity. Their differences are seen from the calculated formulæ :—

Mosandrite.... $\left[\left.\begin{matrix}F_2\\(HO)_6\end{matrix}\right\}R_4^{iv}\right]R_2^{iii}R_{10}^{ii}(R_2^{i})_7[SiO_4]_{12}$.

Johnstrupite... $\left[\begin{matrix}F_6R_3^{iv}\\F\,R^{iii}\end{matrix}\right]R_2^{iii}R_{13}^{ii}(R_2^{i})_4[SiO_4]_{12}$.

5. *Calciothorite.* This mineral was discovered by the author a few years ago. It is amorphous, has a hardness of 4·5, and a sp. gr. of 4·114, and gave on analysis results corresponding with the formula $5(ThSiO_4),2(Ca_2SiO_4) + 10H_2O$.

6. *Astrophyllite.* From the results of a new analysis of this mineral, the author deduces the formula $R''_4R'_4Ti(SiO_4)_4$. He regards astrophyllite as a perfectly independent mineral not connected with the micas, nor with the minerals of the pyroxene group.

7. *Leucophane* and *Melinophane.* New analyses of leucophane (I) and melinophane (II) gave the following results:—

	SiO_2.	Al_2O_3.	BeO.	MgO.	CaO.	Na_2O.	K_2O.	H_2O.	F.	Total.	Less O.	Total.
I.	48·50	0·45	10 03	0·27	22·94	12·42	—	1·08	5·94	101·63	2·48	99·15
II.	43·60	4 61	9·80	0·16	29·56	7·98	0·23	—	5·43	101·37	2·27	99·08

From these results the following formulæ are deduced:—

I. Leucophane.. $Na_3(FBe)_3Ca_3(SiO_3)_6$ or $R_6'R_3''(SiO_3)_6$.
II. Melinophane. $Na_2(FBe)_2(Ca_2O)_2Be(SiO_3)_6$ or $R_4'R_4''(SiO_3)_6$.

8. *Wöhlerite.* A new analysis of this mineral gave the following results:—

SiO_2.	TiO_2.	ZrO_2.	Nb_2O_5.	Ce_2O_3.	Fe_2O_3.	FeO.	MnO.	MgO.	CaO.	Na_2O.	H_2O.	F.	Total.	Less O.	Total.
30·12	0·42	16·11	12·85	0·66	0·48	1·26	1·00	0·12	26·95	7·50	0·74	2·98	101·19	1·24	99·95

9. *Rosenbuschite.* This mineral gave on analysis the following results:—

SiO_2.	$ZrOF_2$.	ZrO_2.	TiO_2.	Fe_2O_3.	Ce_2O_3.	MnO.	CaO.	Na_2O.	Total.
31·44	22·09	0·67	7·22	1·07	0 33	1·62	25·12	10·04	99·60

From these results the author deduces the formula

$$6CaSiO_3,2Na_2ZrO_2F_2,1Ti(SiO_3)(TiO_3).$$

Rosenbuschite, both in its crystal form and in its composition, presents sufficient analogies to pectolite for it to be described as a zircon-pectolite. An interesting result of this investigation of the Norwegian veins is the discovery of not merely three zircon-pyroxenes analogous to the ordinary pyroxene lengthened in the direction of the vertical axis, namely, lavenite, wöhlerite, and the asymmetrical hiortdahlite, but also of a zircon-pectolite, lengthened in the direction of the orthoaxis, corresponding with the pyroxenes of the wollastonite series.

10. *Karyocerite.* As this new mineral occurs in tablets of a nut-brown colour, the author has named it karyocerite, from *κάρυον* (nut),

and *cerium*, so as to indicate its relation to the black melanocerite. On analysis the mineral yielded—

SiO_2.	Ta_2O_5.	P_2O_5.	CO_2.	B_2O_3.	F.	ZrO_2.	CeO_2.	ThO_2.	Al_2O_3.
12·97	3·11	0·86	0·35	(4·70)	5·63	0·47	5·89	13·64	0·87

Fe_2O_3.	Mn_2O_3.	Ce_2O_3.	Di_2O_3.	La_2O_3.	Y_2O_3.	CaO.	MgO.	Na_2O.	H_2O.
1·36	0·66	14·83	6·75	14·34	2·21	7·37	0·17	1·42	4·77

Total.	Less O.	Total.
102·37	2·37	100·00

B. H. B.

Action of Solutions of Alkalis, Alkaline Earths, and certain Salts on Mica; Formation of Nepheline, Sodalite, Leucite, Orthoclase, and Anorthite. By C. FRIEDEL and G. FRIEDEL (*Compt. rend.*, **110**, 1170—1178).—The mica was heated at 500° with the various compounds and water in a steel tube lined with platinum for periods of 14 to 60 hours, according to the rate of change. The mica used was a Norwegian muscovite containing 7 per cent. of potassium oxide, and 3 per cent. of sodium oxide.

When the mica is heated with from 25 to 66 per cent. of potassium hydroxide, and not less than its own weight of water, it yields distinct brilliant, unmodified, hexagonal prisms. They are anhydrous, have the crystallographic properties of nepheline, and agree in composition with a mixture of 2 parts of soda nepheline and 1 part of potash nepheline. It is noteworthy that they contain an excess of soda, although formed in presence of an excess of potash. Fouqué and Michel-Levy have previously observed that it is not possible to obtain a pure potash nepheline in the dry way. When sodium hydroxide is used, the mica is more readily attacked, and the composition of the crystals corresponds with 3 parts of soda nepheline, and 1 part of potash nepheline.

If sodium chloride is also added in quantity varying from one-third to double the weight of the mica, sodalite is obtained in rhombic dodecahedra, modified by faces of the cube. It is identical in properties with the sodalite from Mt. Somma, and its composition is not materially affected by variations in the proportion of sodium chloride used. If, however, the quantity of salt is very little greater than that required to form sodalite, crystals of nepheline free from chlorine are obtained.

If the mica is heated with potassium silicate in the proportion required to form leucite, alteration takes place slowly, and well-formed crystals of orthoclase are obtained. If, however, it is heated with 50 per cent. of calcined silica, and 70 per cent. of potassium hydroxide for two days, the products are orthoclase, hexagonal, nepheline, and pseudo-cubic quadratic prisms, which have the composition and properties of leucite. The crystals are single prisms or macles of two or three prisms, in such a way that the quadratic axes become rectangular.

When heated with lime-water, mica yields small octahedral crystals of a hydrated aluminium calcium silicate, which seems to correspond with no known natural mineral. If calcium chloride is added in order to decompose the sodium and potassium hydroxides, which must be liberated by the action of the lime, decomposition of the mica takes place readily, and the product forms almost rectangular lamellæ, more or less modified at the angles, which have the crystallographic properties of anorthite macles, and have the chemical properties of this mineral.

It is therefore possible to obtain from mica, by the action of aqueous solutions at a high temperature and under pressure, five minerals, nepheline, sodalite, orthoclase, leucite, and anorthite, which are found in the eruptic rocks of Mt. Somma. C. H. B.

Some Secondary Minerals of the Amphibole and Pyroxene Groups. By W. Cross (*Amer. J. Sci.* [3], **39**, 359—370).—During the microscopical examination of some rocks from Custer Co., Colorado, the author observed two peculiar minerals of secondary origin, one an amphibole and the other a pyroxene. The former is a clear blue mineral occurring as a pseudomorphous replacement of common hornblende or of augite, with a pleochroism like that of glaucophane, whilst the orientation of the ellipsoïd of elasticity indicates that the mineral is closely related to the new species riebeckite. The pyroxene is bright green, and, although at first sight appearing to be orthorhombic in crystal form, is probably related to ægirite. The microscopical characteristics of these minerals are fully described. The results are of interest, inasmuch as, if the minerals in question are really ægirite and riebeckite, they appear in new associations, and were clearly formed under conditions quite different from those attending their origin in other known localities. B. H. B.

Meteoric Iron from North Carolina. By L. G. Eakins (*Amer. J. Sci.* [3], **39**, 395—396).—The iron described was found in 1880, on a farm near Ellenborough, Rutherford Co., and weighed originally about 2200 grams. In shape it has, roughly, two globular ends, with a connecting bar. The iron is very tough, and highly crystalline. Small irregular patches of troilite are visible, and schreibersite also seems to be present. Analysis of the iron yielded—

Fe.	Ni.	Co.	Cu.	P.	S.	Si.	Total.
88·05	10·37	0·68	0·04	0·21	0·08	0·02	99·45

Mineral Waters of Malaisie: a Tin Mineral in Process of Formation. By S. Meunier (*Compt. rend.*, **110**, 1083—1085).—The water of Azer-Eanas, at Ulu Klang, which issues from the spring at a temperature of 50°, has a very peculiar and disagreeable odour, but evolves practically no gas when heated, and contains only 2 parts of inorganic matter in 100,000. On the other hand, it contains a large quantity of organic matter, which forms a syrupy residue when the water is evaporated.

The water of Azer-Panas, near Chevas, is quite different. It is hot when it issues from the spring, limpid, odourless, and has a very slight saline taste. When heated it becomes turbid, and evolves a large number of small bubbles of nitrogen. The water contains chlorides, but no sulphates, and only traces of calcium; the total weight of sodium and calcium chlorides does not exceed 1·4 grams per litre.

The rocks at the spring of Azer-Panas are covered with greyish-white, earthy, vesicular concretions, of sp. gr. 2·1. They contain white, superposed scales, in which are small, black dendrites. The concretions are only slightly attacked by hydrochloric acid, even after several months. They contain SiO_2 91·8; H_2O 7·5; SnO_2 0·5; Fe_2O_3 0·2; Al_2O_3 traces = 100·0. The stannic oxide doubtless forms the black dendrites, and this is the first instance of a tin mineral in process of formation in a modern spring. C. H. B.

Organic Chemistry.

Melamine. By B. RATHKE (*Ber.*, **23**, 1675).—*Melamine*, $C_3N_3(NH_2)_3$, is obtained by heating pure melam, $C_6N_6(NH_2)_4{:}NH$, at 130°, with a 30 per cent. solution of ammonia; on evaporating to dryness and treating with water, the melamine dissolves; the residue consists of ammeline, which is simultaneously formed. J. B. T.

Synthesis of Ammeline and Cyanuric Acid. By E. BAMBERGER (*Ber.*, **23**, 1856—1860).—The formation of ammeline from dicyanodiamide and cyanic acid is explained by assuming that cyanoguanylcarbamide, $CN{\cdot}NH{\cdot}C(NH){\cdot}NH{\cdot}CO{\cdot}NH_2$, is first formed, and that, by the transference of a hydrogen-atom it changes spontaneously into the ammeline ring,  $HN<\begin{matrix}C(NH){\cdot}NH\\CO\text{——}NH\end{matrix}>C{:}NH$. This is in agreement with the conclusions of Smolka and Friedrich (compare this vol., p. 856), but not with those of Rathke (compare Abstr., 1886, 217), who refers all the additive properties of dicyanodiamide to the influence of the cyanide radicle, while the author assumes that this group only reacts in the case of compounds formed with water, hydrogen sulphide, and ammonia, the substances obtained by the addition of cyanic acid or thiocyanic acid being produced by interaction with the amido-group. The combination of carbonic anhydride and dicyanodiamide to form melanurenic acid,  $NH<\begin{matrix}CO{\cdot}NH\\CO{\cdot}NH\end{matrix}>C{:}NH$, also belongs to the second class. In a similar manner, the reactions of cyanamide may be separated into two divisions; accordingly the compound obtained from cyanamide and cyanic acid should be represented as cyanocarbamide, $NH_2CO{\cdot}NH{\cdot}CN$, and not as amidodicyanic acid,  $CO<\begin{matrix}NH\\NH\end{matrix}>C{:}NH$, as hitherto; its properties, and formation from dicyanodiamide by the action of barium hydroxide, being in agreement with this theory. The polymerisation of cyanoamide to form dicyanodiamide may be represented as being strictly analogous to the aldol condensation, and to the formation of imidoacetyl methyl cyanide from methyl cyanide; the same relation is observed during the further changes into cyanoacetone and cyanocarbamide (amidodicyanic acid) respectively. In a similar manner, melamine,

$$NH<\begin{matrix}C(NH)\cdot NH\\C(NH)\cdot NH\end{matrix}>C{:}NH,$$

is produced from dicyanodiamide by a second condensation with cyanamide, the hypothetical intermediate product being cyanobiguanide, $NH_2\cdot C(NH)\cdot NH\cdot C(NH)\cdot NH\cdot CN$.

In addition to the methods already known, ammeline may be prepared by heating dicyanodiamide with finely powdered, anhydrous potassium cyanate, at 200—205°, for about 20 minutes; when cold, the product is dissolved in boiling water containing a little sodium hydroxide, and the ammeline precipitated with acetic acid. On evaporation of the mother liquor, a second portion of ammeline is obtained; this is removed, and the liquid further concentrated and treated with dilute sulphuric acid, when crystals of melamine sulphate separate; the yield of ammeline is 100 per cent. of the dicyanodiamide employed.

Cyanuric acid may be prepared by heating together equal parts of biuret and ethyl carbamate for two hours at 160—170°; a considerable evolution of ammonia occurs, and the product when dissolved in hot water, yields pure cyanuric acid on cooling. Potassium cyanurate is obtained on substituting potassium cyanate for the ethyl carbamate in the above reaction. For this purpose a mixture of biuret with potassium cyanate in molecular proportion is heated at 130°; the reaction is somewhat violent; the potassium salt crystallises out on treating the product with hot water.

These syntheses of cyanuric acid are represented as being completely analogous to the formation of ammeline, and, in the author's opinion, they afford a further proof of the correctness of this condensation theory. J. B. T.

Stereochemistry of Ethane Derivatives. By K. AUWERS and V. MEYER (*Ber.*, 23, 2079—2083).—The recent researches of Bethmann, Graebe, and Baeyer have confirmed the conclusion previously arrived at by the authors, namely, that in certain compounds the singly-bound carbon atoms are not capable of free rotation.

The results obtained by Bethmann and Graebe seem to indicate that Wislicenus' theory as to the free rotation of singly-bound carbon atoms must be limited to certain cases; absolutely free rotation is probably possible only when the substituting atoms or groups are identical; where, as is the case in the majority of compounds, the atoms or groups are not identical, there will be some definite position of equilibrium; only in cases where the substituting atoms or groups are equally negative will there be several positions of equilibrium.

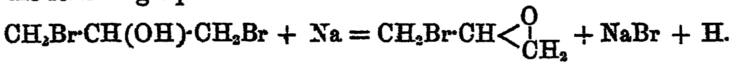
F. S. K.

Constitution of *α*-Dibromhydrin. By O. ASCHAN (*Ber.*, 23, 1826—1831).—*α*-Dibromhydrin yields bromodinitromethane and bromacetic acid on oxidation with nitric acid of sp. gr. 1·48.

α-Dichlorhydrin gives the corresponding chlorinated-compounds.

α-Dibromopropyl acetate is prepared by heating α-dibromhydrin with acetic anhydride at 120°; it is a colourless strongly refractive liquid, of sp. gr. 1·8248 at 16°; it boils at 227—228°, and undergoes decomposition on exposure to light. *αβ-Dibromopropyl acetate* is obtained in a manner similar to the α-compound, which it closely resembles; it boils at 227—228°, and has a sp. gr. of 1·8281 at 16°. The author considers that his results prove the correctness of the generally accepted formula for α-dibromohydrin. J. B. T.

Atomic Re-arrangement of Allyl Compounds. By O. Aschan (*Ber.*, **23**, 1831—1839).—α-Dibromhydrin, on distillation, decomposes into epibromhydrin, allyl aldehyde, and hydrobromic acid. Allyl alcohol and epibromhydrin are formed by the action of sodium on α-dibromhydrin or α-dibromopropyl acetate. The author explains these observations by assuming that the changes take place according to the following equations:—



$$CH_2Br{\cdot}CH(OH){\cdot}CH_2Br + Na = CH_2Br{\cdot}CH\!<\!\begin{array}{l}O\\ |\\ CH_2\end{array} + NaBr + H.$$

The remaining atom of bromine is then eliminated in a similar manner by the action of a second atom of sodium, giving the compound $CH_2{:}C\!<\!\begin{array}{l}O\\ |\\ CH_2\end{array}$, from which allyl aldehyde, $CH_2{:}CH{\cdot}CHO$, is formed by re-arrangement, and this is then reduced to allyl alcohol by the hydrogen liberated in the previous stages. J. B. T.

Greater or Less Rotation (Multi-Rotation) of Sugars. By E. Parcus and B. Tollens (*Annalen*, **257**, 160—178).—The authors propose to employ the term "multi-rotation" to denote the change (increase or decrease) of rotatory power which takes place in a sugar solution, from immediately after its preparation in the cold until constant rotation is attained; a sugar solution, the rotatory power of which increases on keeping, may be said to show "greater rotation," when the opposite is the case "less rotation."

A number of sugars have been examined in order to obtain more exact knowledge of the phenomenon of multi-rotation, special pains having been taken to determine the rotatory power as soon as possible after solution; the observations were made at 20°, and the solutions employed contained about 10 per cent. of the sugar. From the data thus obtained the authors have, in the case of each sugar, constructed a curve, the ordinates representing the change of rotation, the abscissæ the time that has elapsed since solution; the form of the curves is, generally speaking, very regular, and the values obtained for constant rotation agree very well on the whole with those obtained by previous investigators. The experiments also show that dextrose is the only sugar that shows bi-rotation; in the case of xylose, the proportion between the initial and the constant specific rotatory power is rather more than 4 : 1, whilst in the case of arabinose and lactose it is about 8 : 5. Galactose, maltose, and levulose were also examined.

F. S. K.

Melitriose and Melibiose. By C. SCHEIBLER and H. MITTELMEIER (*Ber.*, 23, 1438—1443; compare this vol., p. 226).—In the preparation of melibiose by the hydrolysis of melitriose with sulphuric acid, the authors have observed that in extracting the concentrated syrup, previously freed from acid, with absolute alcohol, not only levulose, but also considerable quantities of melibiose, pass into solution; on cooling, however, the alcoholic extracts deposit the greater portion of the melibiose as a colourless powder, free from levulose.

Anhydrous, amorphous melibiose has the composition $C_{12}H_{22}O_{11}$, and its specific rotatory power was found to be $[\alpha]_D = 126\cdot8°$ as a mean of two determinations.

Melibiosephenylhydrazine, $C_{18}H_{28}O_{10}N$, forms yellow, microscopic crystals, melts at 145°, decomposes at 160°, and is readily soluble in water, but only sparingly in alcohol, and insoluble in ether, benzene, and chloroform; when warmed with an aqueous solution of phenylhydrazine acetate, it yields phenylmelibiosozone.

Octacetylmelibiose, $C_{12}H_{14}O_{11}Ac_8$, prepared by boiling melibiose with acetic anhydride and sodium acetate, crystallises from hot alcohol in small needles, melts at 170—171°, and has a very bitter taste. It is almost insoluble in cold water, and only sparingly soluble in carbon bisulphide, light petroleum, and hot water, but readily in chloroform, hot alcohol, glacial acetic acid, and benzene. Its specific rotatory power is $[\alpha]_D = 94\cdot2°$. It reduces Fehling's solution on warming, and dissolves unchanged in phenylhydrazine.

Undecylacetylmelitriose, $C_{18}H_{21}O_{16}Ac_{11}$, is formed when melitriose is boiled with acetic anhydride and sodium acetate. It separates from alcohol very slowly in small crystals, has a bitter taste, and is readily soluble in alcohol, ether, phenylhydrazine, aniline, chloroform, benzene, and glacial acetic acid, but only sparingly in carbon bisulphide and light petroleum. It melts at 99—101°, does not reduce Fehling's solution, and its specific rotatory power is $[\alpha]_D = 92\cdot2°$.

F. S. K.

Carbohydrates. By A. WOHL (*Ber.*, 23, 2084—2110).—In investigating the inversion of sugar by hydrofluoric acid, the author found that the inversion in concentrated solutions is the more complete, that is to say, the maximum levo-rotation is the greater, the smaller the quantity of acid employed. This is also true in the case of other mineral acids, and it was found that for each acid there is, within narrow limits, a certain concentration which is dependent on the conditions of the experiment whereby sugar, even in 80 per cent. solution, can be almost completely inverted, and the formation of decomposition products minimised. By heating pure cane-sugar (80 parts) with water (20 parts) containing only 0·004 part of hydrochloric acid for an hour at 95—100°, a colourless solution of pure inverted sugar (84 parts) is obtained.

Experiments were then commenced in order to ascertain the cause of the seemingly incomplete inversion of sugar in concentrated solutions. For this purpose, cane-sugar (13·024 grams) was heated at 100° for half an hour with 0·04 per cent. hydrochloric acid (3·3 c.c.), in a closed flask, the solution being then diluted to 100 c.c., kept for 24 hours, and examined in a saccharimeter (200 mm. in length), at a temperature of 20°; the observed polarisation was −12·0°, from which the quantity of sugar inverted is calculated to be about 95 per cent., whilst estimations by Allihn's method gave 96 per cent. If the solution is heated for more than half an hour, both its polarisation and its reducing power are diminished; after an hour's heating, for example, the polarisation is −10·5°, after two hours, only −9·0°, and in the last case the solution turns yellow. The rotatory and reducing power are also diminished when the concentration of the sugar solution or the quantity of acid employed is increased. This decrease of levo-rotatory power is due to the fact that the inverted sugar, formed in concentrated solutions, is, partially at least, chemically different from that obtained by the inversion of dilute solutions; that this difference is not caused by a partial decomposition of the levulose was proved by special experiments, so that it can only be due to incomplete inversion, or to a condensation of the inverted sugar similar to that observed by Degner, or to a combination of the two phenomena.

Further experiments proved that a solution of pure inverted sugar, prepared from pure levulose and pure dextrose, shows the same behaviour with hydrochloric acid as the solution of inverted sugar obtained from cane-sugar, and, therefore, the diminution in rotatory and reducing power is in both cases due to the same cause; it was also found that the condensation of inverted sugar is principally the effect of the action of the acid, not of that of the water.

It follows, therefore, that the inversion of sugar in concentrated solutions is not really incomplete, but is accompanied by a condensation process of an opposite kind, brought about by the acid employed.

When a concentrated solution of dextrose is heated with a small quantity of hydrochloric acid under conditions similar to those employed in the case of the inverted sugar, no appreciable effect is produced, but the rotatory and reducing power of a solution of levulose are considerably diminished, and to about the same extent as is the case with a solution of inverted sugar; hence the condensation of inverted sugar is a condensation of levulose alone.

When levulose (13·7 grams) is heated at 100° for an hour with 0·136 per cent. hydrochloric acid (0·25 c.c.), the mixture then dissolved in warm alcohol (50 c.c.), and kept for 12 hours, a dextrin-like substance is deposited which, after having been washed with cold, and redissolved in warm, alcohol, is obtained as a colourless, very hygroscopic powder. The rotatory power of this substance is about one-half, and its reducing power less than one-third that of levulose; it is probably a mixture of various dehydration products, and when its dilute solution is heated with hydrochloric acid it is slowly reconverted into levulose.

Dextrin-like products are also formed when an 80 per cent. solution of dextrose is heated at 105° with moderately concentrated (0·05 to 1·0 per cent.) hydrochloric acid.

The above experiments prove that the hydrolytic decomposition of di- and poly-saccharoses is not a simple change, but that the inverting action of the acid is accompanied by a reverting action, which transforms the simple glucoses into dextrin-like substances.

When sugar, in 80 per cent. aqueous solution, is heated at 100° with 0·005 per cent. of hydrochloric acid, the maximum levo-rotation (−12·35°) is attained in about 35 minutes, the solution being then perfectly colourless; on further heating, however, the rotation gradually diminishes, and after two hours from the commencement of the experiment it is only −10·15°, and the solution has become distinctly yellow. The maximum levo-rotation. which corresponds very closely with the maximum reducing power, shows the point at which the subsequent inversion in the unit of time is exactly counterbalanced by the reversion which takes place. It is not, therefore, the point of complete inversion in the sense that no unchanged sugar remains, although the quantity of the latter, under the dominating conditions, is extremely small; the apparent inversion at this point, ascertained by estimating the reducing power, is 95·8 per cent., but as that portion of the inverted sugar which has already undergone reversion, has a far smaller reducing power than that which has not, the quantity of changed and unchanged inverted sugar together, must be considerably greater than appears from the reducing power, and the quantity of cane-sugar correspondingly less. Considering also that the reducing power of a solution of a mixture of equal parts of pure levulose and pure dextrose undergoes approximately the same diminution in the same time, there can be only an extremely small quantity of reverted sugar present in the above solution. That the reversion has not proceeded very far, and that the product thereof is closely allied to levulose is also proved by the fact that the concentrated solution is almost colourless, and that on subsequent inversion in dilute solution it attains almost the theoretical levo-rotation.

The maximum levo-rotation, either of a dilute or concentrated solution, shows, therefore, the point of relatively most complete inversion, that is to say, at this point the quantity of unchanged inverted sugar has reached its maximum for the degree of concentration in question.

Since then it has been shown that decomposition does not necessarily accompany the inversion of concentrated sugar solutions by mineral acids, but is simply the effect due to excess of acid being used; if such excess is avoided by adjusting the quantity of acid according to the percentage of ash contained in the sugar, the completeness of inversion will no longer be dependent on any particular concentration of the solution. That this has not been previously observed is probably due to the fact that in the case of hydrochloric acid—the acid which is most used for inversion experiments—the quantity which is exactly requisite is very nearly the same as the quantity which is just within the extreme limit permissible. For example, in order to convert pure sugar into colourless, inverted sugar, by heating its solution for half an hour at 95°, the amount of hydrochloric acid employed should be, at the most, 0·01 per cent. of the sugar; if the quantity is below the limit, the inversion is greatly and disproportionately retarded, and if the limit is exceeded, the solution quickly turns yellow, and the product is useless.

Preparation of Levulose.—A very small quantity (0·01 per cent.) of hydrochloric acid is sufficient to convert pure inulin, free from ash, into levulose; in the case of inulin that contains up to 0·2 per cent. of ash, the percentage of acid employed is about one-half the percentage of ash; when the ash amounts to 0·2 to 0·4 per cent., the percentage of hydrochloric acid is about two-fifths the percentage of ash; further purification of commercial inulin is unnecessary when the ash does not exceed 0·4 per cent.

The necessary quantity of hydrochloric acid, calculated from the ash, and water (50 c.c.), are placed in a flask of 500 c.c. capacity; commercial inulin (200 grams) is then introduced, and the flask is heated in boiling water for half an hour, starting from the time when the whole mass begins to soften; the acid is then neutralised with a slight excess of calcium carbonate, or with the calculated quantity of sodium hydrogen carbonate, the syrup poured into a litre of warm (commercial) absolute alcohol, a little blood-charcoal thrown in, the solution kept for 12 hours, decanted from the small quantity of syrup, and filtered. The filtrate, evaporated under reduced pressure, at a gentle heat, until it attains the consistency of a thick syrup, is then mixed with absolute alcohol (3 to 4 parts), kept for 12 hours, and the solution decanted; if a crystal of levulose is now introduced into the clear solution, and crystallisation promoted by rubbing, pure anhydrous levulose, equal in weight to one-third of the syrup, is deposited in 24 hours; after three days' time, a second crop of crystals is deposited, and further quantities can be obtained by evaporating the mother liquors at a gentle heat.

The hydrolytic decomposition of sugars in concentrated solution, by the minimum quantity of acid, which must be separately determined for each sugar, the percentage of ash being taken into consideration, will probably be found to be the most convenient and rapid method for the preparation of other glucoses. Under suitable conditions, the reversion which occurs in the hydrolysis of concentrated solutions is less than that which takes place in the evaporation of dilute solutions to the same degree of concentration. Hydrochloric acid should be employed for the purer materials, as the quantity necessary is generally so small that, as free acid, sodium chloride or calcium chloride, it does not affect the purity of the product to any appreciable extent. For substances richer in ash, sulphuric acid is used, when the product is to be purified by solution in alcohol; and hydrofluoric acid, when the product can only be crystallised from water, the acid being eliminated, after hydrolysis, by means of calcium carbonate.
F. S. K.

A New Crystalline Carbohydrate. By A. v. PLANTA and E. SCHULZE (*Ber.*, **23**, 1692—1699).—The carbohydrate here described occurs in the roots of *Stachys tuberifera*, and is isolated by pressing the tubercles, extracting with water, and precipitating the liquid thus obtained with lead acetate and mercuric nitrate successively, the excess of lead and mercury being removed by sulphuretted hydrogen. The solution, after being neutralised with ammonia, is evaporated to a thin syrup and poured into alcohol, when a dark-coloured syrup is precipitated, which is dissolved in water, and phosphotungstic acid added as long as a precipitate falls. The filtrate is then treated with baryta-water, again filtered, and carbonic anhydride passed, the precipitated barium carbonate separated, and the liquid evaporated to a small volume, and poured into absolute alcohol. After redissolving in water, and precipitating with alcohol several times, the aqueous syrup was finally poured into such a quantity of alcohol that after the addition of the syrup 9 per cent. of water was present. Part of the carbohydrate separates at once, and the filtrate on remaining for some time deposits a further quantity in hard, lustrous crystals. These may also be obtained by boiling the amorphous compound with 90 per cent. alcohol, and allowing the solution to remain.

The carbohydrate, for which the authors propose the name *stachyose*, has a slightly sweet taste, and forms a neutral solution, which rotates the plane of polarisation to the right ($[\alpha]_D = 148{\cdot}1$ in 9 per cent. solution). Its formula appears to be $C_{18}H_{32}O_{16} + 3H_2O$, the water of crystallisation being given off at 103—104°, whilst at 110—115° decomposition commences. It forms asymmetric (?) crystals ($\alpha = 88° \ 41\frac{1}{2}'$, $\beta = 90° \ 32\frac{1}{2}'$, $\gamma = 153° \ 43\frac{1}{2}'$, $a : b : c = 0{\cdot}7848 : 1 : ?$).

One of the products of inversion is galactose, the quantity of the latter formed being apparently equal to one-half that of the stachyose, and on oxidation with nitric acid it yields mucic acid.

Of the three compounds already known having the composition $C_{18}H_{32}O_{16}$, namely melitose or raffinose, gentianose, and lactosine, the last is the one with which stachyose appears to be most nearly related. H. G. C.

Products of the Saccharification of Amylaceous Substances by Acids. By G. FLOURENS (*Compt. rend.*, **110**, 1204—1206).—The constancy of the coefficient *c*, representing the rotatory power of dextrin relatively to saccharose, shows that only one dextrin is produced, as Payen supposed, and this is distinguished by its very high rotatory power, which approaches that of soluble starch. The constancy of this coefficient at different stages of saccharification shows that no maltose is formed. The results of chemical and optical examinations are in perfect agreement.

In industrial operations, the quantities of acid used are much smaller than those used in the laboratory to produce complete saccharification, and beyond a certain limit, at which 75 to 80 per cent. of the amylaceous matter has been converted into glucose, the results of the two methods of examination do not correspond. The coefficient *c* gradually diminishes, owing to decomposition and production of caramel. C. H. B.

Geometrically Isomeric Nitrogen Compounds. By C. WILLGERODT (*J. pr. Chem.* [2], **42**, 63—64).—This paper consists of further remarks on Hantzsch and Werner's paper on the subject (this vol., p. 348; compare, also, this vol., p. 576). A. G. B.

Derivatives of Propylamine. By W. E. LAUER (*Chem. Centr.*, 1890, i, 899; from *Inaug. Diss., Berlin*).—*γ-Hydroxypropylphthalimide*,

 $C_6H_4{<}{}^{CO}_{CO}{>}N{\cdot}C_3H_6{\cdot}OH$, prepared from bromopropylphthalimide by the action of potassium hydroxide, melts at 50—51°. *γ-Thiocyanopropylphthalimide*, $C_6H_4{:}C_2O_2{:}N{\cdot}C_3H_6{\cdot}CNS$, prepared from bromopropylphthalimide by the action of potassium thiocyanate, melts at 95°; by the action of potash it is resolved into the compound $C_{22}H_{24}KN_2S_2O_6$, potassium cyanate, potassium cyanide, and water. The white, crystalline substance melts at 136°, and has the constitution $S_2(C_3H_6{\cdot}NH{\cdot}CO{\cdot}C_6H_4{\cdot}COOH)_2$. By the action of dilute hydrochloric acid on potassium di-γ-propyldisulphide diphthalamate, the free acid is obtained.

When heated with concentrated hydrochloric acid at 200°, the disulphide is resolved into *dipropylamido-γ-disulphide*,

$$S_2(C_3H_6{\cdot}NH_2)_2,2HCl,$$

melting at 218—219°, and phthalic acid. The picrate of the former melts at 145—146°.

γ-Bromopropylamine hydrobromide reacts with silver sulphate, forming *γ-amidopropylsulphuric acid*, $NH_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2{\cdot}HSO_4$, melting at 221°. This has a neutral reaction, and it is, therefore, probable that the sulphuryl radical is combined with the amide radical.

From the same bromo-compound the following substances are obtained. (1.) *Bromopropylthiocarbamide*, $NH_2{\cdot}CS{\cdot}NH{\cdot}C_3H_6Br$, is prepared by the action of potassium thiocyanate, it melts at 127°, *trimethylenepseudothiocarbamide*, melting at 127°, obtained from the latter by separation of hydrogen bromide. (2.) *Trimethylenepseudocarbamide*, melting at 199°, is obtained by the action of potassium cyanate. (3.) μ-Mercaptopenthiazoline,  $CH_2{<}{}^{CH_2\cdot S}_{CH_2\cdot N}{>}C{\cdot}SH$, obtained by the action of carbon bisulphide, melts at 132°. It is oxidised by bromine-water to *γ-amidopropylsulphonic acid*, which melts above 300°.

J. W. L.

Action of Amines on Diketopentamethylene-derivatives.

By W. H. INCE (*Ber.*, 23, 1478—1483).—The *hydrochloride* of a base of the constitution  $CH_2{<}{}^{CHCl\cdot C:NPh}_{CH_2\ -C:NPh}$ is precipitated in blood-red, microscopic needles, when the sodium-derivative of 1.2-diketochloropentamethylene is treated with aniline in dilute acetic acid solution, and the acetate thus produced is decomposed with hydrochloric acid. It crystallises from boiling alcohol in dark-red plates, melts at 142° with decomposition, and is moderately easily soluble in alcohol, acetone, and acetic acid, but almost insoluble in water, benzene, chloroform, and dilute mineral acids; it is only slowly decomposed by alkalis, is not changed by boiling concentrated hydrochloric acid, and has the composition $C_{17}H_{15}N_2Cl,HCl + H_2O$. The free *base*, obtained by decomposing the salt with soda, is a yellow, semi-crystalline-compound, which begins to turn brown at 120°, and melts at 129° with decomposition; it gradually turns red on exposure to the air, and it yields a reddish-violet sulphate.

The *salt*, $C_{18}H_{19}N_2Cl,2C_2H_4O_2$, separates in yellowish-red crystals, when the sodium-derivative of 1 . 2-diketochloropentamethylene is treated with paratoluidine in acetic acid solution. It melts at about 160° with decomposition, and is readily soluble in alcohol, ether, and chloroform, but only moderately easily in acetic acid. The *hydrochloride*, $C_{19}H_{19}N_2Cl,HCl$, separates from alcohol, in which it is readily soluble, in reddish-violet crystals, and decomposes at about 130°. The free *base* crystallises from ether in long, yellowish needles, melting at 135° with decomposition.

A *base* of the composition, $C_{12}H_{12}ClNO$, is precipitated as an oil when the sodium-derivative of 1 . 2-diketochloropentamethylene is added to a concentrated, neutral solution of methylaniline hydrochloride. It separates from alcohol in yellow crystals which melt at 126—127°; the *hydrochloride* is readily soluble, but the *platinochloride* can be precipitated directly. A crystalline *base*, melting at 153°, can be obtained with methylamine in like manner, but in the case of ethylamine and dimethylamine no definite product could be isolated.

The *acetate* of a base separates in microscopic crystals when 1 . 3-diketochloropentamethylene is treated with aniline in acetic acid solution. It melts at 190° with decomposition, and is soluble in acetone and dilute acids, but insoluble in ether; it is slowly decomposed by soda, and quickly by concentrated hydrochloric acid.

The crystalline *salt*, $C_{19}H_{18}Cl_2N_2,C_2H_4O_2$, obtained from 1 . 3-diketochloropentamethylene and paratoluidine in like manner, melts at 150° with decomposition; the free base is a yellow powder almost insoluble in ether. F. S. K.

Breaking the Pentamethylene Ring. By A. HANTZSCH (*Ber.*, 23, 1483—1489).—Ince's investigations (preceding abstract) have shown that the derivatives of the diketopentamethylenes behave like diketones with amines and with amido-compounds; it is nevertheless probable that under the influence of water or alkalis these pentamethylene-compounds are converted into open-chain-derivatives, which are reconverted into pentamethylene-derivatives when they separate from their solutions. The sodium-derivative of 1 . 2-diketochloropentamethylene, for example, which is an intensely yellow, solid compound, gives colourless, neutral solutions; this phenomena may be explained by assuming that the solid has the constitution  $CH_2<\begin{matrix}CClNa\\CH_2\cdot CO\end{matrix}>CO$ or  $CH_2<\begin{matrix}CCl:C(ONa)\\ \quad | \\CH_2\cdot CO\end{matrix}$, but that in solution it exists as the true sodium salt of the aldehyde acid, $COOH\cdot CHCl\cdot CH_2\cdot CH_2\cdot CHO$. Some observations which were made by Ostwald, whilst engaged in measuring the electrical conductivity of these compounds, lend probability to this view.

Tri- and tetra-chlorodiketopentamethylenehydroxycarboxylic acids both behave like true dicarboxylic acids, a fact which can be explained only by assuming that in aqueous solution and in their salts they have the constitution $COOH\cdot CO\cdot CHCl\cdot C(OH)(COOH)\cdot CHCl_2$ and $COOH\cdot CO\cdot CCl_2\cdot C(OH)(COOH)\cdot CHCl_2$ respectively.

1 . 3-Diketodichloropentamethylene, under the influence of alkalis, is probably converted into the salt of the ketone acid

$$COOH{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}CHCl_2,$$

just as dichlorodiketohydrindene is converted into salts of dichloroacetophenonecarboxylic acid (compare Zincke, Abstr., 1888, 1192).

F. S. K.

Formaldehyde. By K. Kraut, W. Eschweiler, and G. Grossmann (*Annalen*, **258**, 95—110).—Crude formaldehyde, prepared from sodium hydroxymethylsulphonate, contains about 0·04 to 0·07 per cent. of formic acid and considerable quantities of methyl alcohol, but it can be obtained free from these impurities by first shaking with calcium carbonate and then fractionating; the methyl alcohol accumulates in the lower boiling (80—90°) fractions, whilst the highest boiling (98·5—99°) fractions consist of pure aqueous formaldehyde. This solution can be concentrated by distillation over calcium carbonate until it contains 52·4 per cent. of formaldehyde, but a stronger solution cannot be obtained owing to polymerisation.

The authors' experiments seem to show that oxymethylene dissolves unchanged in water, and then gradually becomes converted into formaldehyde, this change taking place more quickly in warm dilute than in cold concentrated solutions. Determinations of the molecular weight of formaldehyde in aqueous solution gave results which show, as did those obtained by Tollens (Abstr., 1888, 809), that a freshly prepared solution of formaldehyde, diluted with cold water, contains a substance, the molecular weight of which is higher than that of the aldehyde.

Sodium hydroxymethylenesulphonate (*formaldehyde sodium hydrogen sulphite*), $CH_2O,NaHSO_3 + H_2O$, is deposited in well-defined, transparent plates, $a : b : c = 1·7750 : 1 : 0·6251$, $\beta = 68° 1'$, when an aqueous solution of formaldehyde, or when solid oxymethylene is treated with a concentrated solution of sodium hydrogen sulphite, and the salt precipitated with alcohol. It loses 1 mol. H_2O over sulphuric acid, is decomposed by boiling water, and is readily soluble in water and methyl alcohol, but only very sparingly in ethyl alcohol. The *potassium* salt, obtained in like manner, forms large anhydrous plates, and also monosymmetric crystals,

$$a : b : c = 2·8400 : 1 : 1·0368, \beta = 81° 47\tfrac{2}{3}',$$

which rapidly effloresce.

Methylenedipiperidine, $C_{11}H_{22}N_2$, is formed when piperidine is added to an aqueous solution of sodium hydroxymethylsulphonate; it boils at 234—235·5°, and is decomposed by hydrochloric acid. Methylenedibenzamide (hipparaffin), $C_{15}H_{14}N_2O_2$, melts at 220°. F. S. K.

Action of Hydrogen Sulphide on Aldehydes. By E. Baumann (*Ber.*, **23**, 1869—1876; compare this vol., p. 477).—A neutral solution of formaldehyde is well cooled and saturated with hydrogen sulphide; a colourless liquid is obtained, from which a voluminous crystalline precipitate is deposited on the addition of an equal bulk of hydrochloric acid (5 per cent.); the substance is washed with water, and treated with a saturated alcoholic solution of iodine, a resinous mass is formed, from which *trimethylene tetrasulphide*,  $CH_2<\begin{matrix}S\cdot CH_2\cdot S\\ S\cdot S\cdot CH_2\end{matrix}>$ is extracted by repeatedly boiling with alcohol; it crystallises in colourless needles melting at 83—84°. This compound is derived from dithiomethylenemercaptan, $SH\cdot CH_2\cdot S\cdot CH_2\cdot S\cdot CH_2\cdot SH$. The resinous mass remaining after the removal of the tetrasulphide is insoluble in all media; it may be purified by treatment with alcohol, and melts at 135—137°. *Dimethyldimethylenetrisulphone*,

$$SO_2(CH_2\cdot SO_2Me)_2,$$

is prepared by treating formaldehyde with hydrogen sulphide and extracting the solution with ether; the residue, obtained after evaporating the ether, is dissolved in dilute aqueous soda and treated with excess of methyl iodide; a mixture of thioethers is thus formed, which cannot be separated without their undergoing decomposition; the oily liquid is treated with an acid solution of potassium permanganate, and, on evaporating the solution, the trisulphone crystallises in long, thin prisms melting at 184—185°; it is very sparingly soluble except in hot water, and forms uncrystallisable salts with the alkalis. This compound is formed from thiodimethylenemercaptan, $S(CH_2\cdot SH)_2$. *Tetrabromodimethyldimethylenetrisulphone*,

$$SO_2(CBr_2\cdot SO_2Me)\ ,$$

is prepared by the action of bromine-water on an aqueous solution of the sulphone; it crystallises in small scales melting at 190° with decomposition. *Diethyldimethylenetrisulphone*, $SO_2(CH_2\cdot SO_2Et)_2$, obtained from ethyl bromide in a manner similar to the dimethyl compound, crystallises in colourless scales; it melts at 149°, and yields a *tetrabromide*.

On further concentrating the mother-liquors remaining after the separation of the dimethyldimethylenetrisulphone, tabular crystals of dimethylmethylenedisulphone, $CH_2(SO_2Me)_2$, are deposited, melting at 141°; diethylmethylenedisulphone, $CH_2(SO_2Et)_2$, is obtained in the same way from the mother-liquors of diethyldimethylenetrisulphone. Both these compounds are already known; they are evidently derived from methylenemercaptan, $CH_2(SH)_2$, which has not yet been obtained in the pure state. J. B. T.

Chloralimide and its Isomeride. By **Béhal** and **Choay** (*Compt. rend.*, **110**, 1270—1273).—500 grams of chloral ammonia is mixed with 200 grams of anhydrous chloral and distilled on a water-bath until 100 grams of chloroform have been collected. From this point distillation is continued in a vacuum until nothing more passes over. The residue is exhausted with cold alcohol of 95°; chloralimide remains undissolved (this vol., p. 230) and isochloralimide passes into solution. Isochloralimide is precipitated by the addition of dilute alcohol and purified by repeated crystallisation from boiling alcohol of 90°. It is insoluble in water, melts at 103—104°, is decomposed by mineral acids with liberation of chloral and formation of the corresponding ammonium salt, and is even decomposed by platinic chloride with formation of ammonium platinochloride. When heated with alkalis, it evolves an odour of carbylamines, ammonia is liberated, and a formate and chloroform are produced.

Isochloralimide and chloralimide have the same composition, and determinations of the molecular weight by Raoult's method, in solution in benzene, gave a number corresponding in both cases to the molecular weight 439·5, which agrees with the triple formulæ previously adopted (*loc. cit.*).

If isochloralimide is heated with methyl chloride in a sealed tube at 100°, it is converted into chloralimide, and if the latter is dissolved in chloroform and mixed with 3 mols. of bromine, it is converted into isochloralimide. Acid chlorides give the same compounds with both isomerides, and these products, which are very stable, will be described subsequently.

The authors ascribe to the two isomerides the following constitution:—

$$\mathrm{NH}{<}\genfrac{}{}{0pt}{}{\mathrm{CH(CCl_3)\cdot NH}}{\mathrm{CH(CCl_3)\cdot NH}}{>}\mathrm{CH\cdot CCl_3}.$$

Chloralimide.

$$\mathrm{NH_2}{<}\genfrac{}{}{0pt}{}{\mathrm{C(CCl_3)\cdot NH_2}}{\mathrm{C(CCl_3){:}NH_2}}{>}\mathrm{C\cdot CCl_3}.$$

Isochloralimide.

The presence of the amido-group in isochloralimide is indicated by its greater solubility, and by the production of chloroform and a carbylamine when treated with an alkali.

The ready migration of the hydrogen which is combined with the nitrogen throws considerable light on the splitting up of diazoamido-derivatives.

Adopting Bonveault's nomenclature, chloralimide is tertrichlormethyl triazidine (1:3:5) and the authors propose to denote the analogous compounds containing the amido- group by the name triazidiniums. Isochloralimide will then be tertrichloromethyltriazidinium (1:3:5). C. H. B.

The so-called Cyanacetone. By A. HANTZSCH (*Ber.*, 23, 1472—1474).—An energetic reaction sets in when chloracetone (1 mol.) is poured into an aqueous solution of potassium cyanide; the product, which is not cyanacetone, but a complicated condensation-product, crystallises from alcohol, in which it is readily soluble, in small needles, melts at 176°, and has the composition $C_{10}H_{13}N_3O_2$. It is tasteless and odourless, and only moderately easily soluble in hot water and ether. It is doubtless identical with the "cyanacetone" described by Glutz (*J. pr. Chem.* [1], 39), but its chemical behaviour indicates a high molecular weight; it cannot be readily decomposed into acetone or acetic acid and carbonic anhydride, and when treated with acids or alkalis it yields a complex compound melting at 65°.

When potassium cyanide is treated with chloracetone in alcoholic solution, a dark oil, boiling above 120°, is obtained in very small quantity (compare Matthews and Hodkinson, Abstr., 1883, 311), together with considerable quantities of non-volatile substances.

F. S. K.

Cyanacetone. By A. HANTZSCH (*Ber.*, **23**, 1816; compare preceding abstract).—An apology for overlooking the fact that Holtzwart (Abstr., 1889, 683) had already prepared cyanacetone. The constitution of the compound formed by the action of potassium cyanide on chloracetone is probably best represented by the formula CN·CH·Ac·C·OH·Me·CH$_2$·CN. J. B. T.

Chloro-substitution-products of Ethyl Chloroformate.—By H. MÜLLER (*Annalen*, **258**, 50—66; compare Hentschel, Abstr., 1887, 1099; 1888, 248 and 249).—Various chloro-substitution-products are formed, together with small quantities of hexachlorethane, when chlorine is passed into boiling ethyl chloroformate which is exposed to direct sunlight; the liquid is fractionated after the gas has been passed for a short time in order to isolate the compounds of lower boiling point, the lowest and the highest fractions are then chlorinated and fractionated again. In this way the compounds described below were isolated.

α-Chlorethyl chloroformate, ClCO·O·C$_2$H$_4$Cl, is a colourless liquid of sp. gr. 1·325 at 15°, and boils at 118—119°; when treated with a small quantity of aluminium chloride, it is decomposed into ethylidene chloride and chlorethylene, and when warmed with water, it yields carbonic anhydride, hydrochloric acid, and acetaldehyde; hot alcohol converts it into α-chlorethyl ethyl carbonate,

OEt·CO·O·CHClMe,

which on further boiling is completely decomposed into hydrogen chloride, ethyl chloride, and acetaldehyde.

The fraction boiling at 153·5—154·5° consists of a compound of the composition C$_6$H$_7$Cl$_5$O$_4$, which seems to be formed by the combination of an equal number of molecules of α-chlorethyl chloroformate and dichlorethyl chloroformate. Determinations of the vapour density of this compound showed that it decomposes into its constituents at its boiling point; it cannot, however, be separated into its constituents by fractional distillation, nor can it be formed by mixing them in the right proportion. When treated with aluminium chloride, it is decomposed into carbonic anhydride, ethylidene dichloride, and chlorethylene dichloride.

αβ-Dichlorethyl chloroformate, ClCO·O·C$_2$H$_3$Cl$_2$, is a colourless liquid of sp. gr. 1·510 at 15°, and boils at 159—160°; aluminium chloride decomposes it into carbonic anhydride and chlorethylene dichloride, and alcohol converts it into ethyl αβ-dichlorethyl carbonate, a colourless oil boiling at 195—196°.

Trichlorethyl chloroformate, ClCO·O·CCl$_2$·CH$_2$Cl, is an oil of sp. gr. 1·584 at 15°, and boils at 169—170°; it is decomposed by aluminium chloride into carbonic anhydride, hydrochloric acid, asymmetrical tetrachlorethane (b p. 134—136°), and a liquid—probably trichlorethylene—which boils at 85—90°.

Tetrachlorethyl chloroformate, ClCO·O·CCl$_2$·CHCl$_2$, is an oil of sp. gr. 1·660 at 15°, and boils at 176—177°; it is decomposed by aluminium chloride into carbonic anhydride, hydrogen chloride, and tetrachlorethylene.

Perchlorethyl chloroformate, $ClCO{\cdot}O{\cdot}C_2Cl_5$, is an oil of sp. gr. 1·702 at 15°, and boils at 140—141° (110 mm.); under the ordinary pressure it boils at 184—185° with slight decomposition into carbonyl chloride, carbonic anhydride, hexachlorethane, and trichloracetic chloride (compare Cloez, *Annalen*, **60**, 259). It is decomposed by aluminium chloride into carbonic anhydride and hexachlorethane, and when boiled with water it also yields hexachlorethane and carbonic anhydride, only small quantities of trichloracetic acid being formed. When treated with ammonia, the principal product is either chloroform or trichloracetamide, according to the conditions of the experiment, small quantities of hexachlorethane being also produced.

All the chlorinated ethyl chloroformates produce sores on the skin and their vapour is exceedingly irritating. F. S. K.

Action of Bromine on Trimethylacetic Acid. By S. Reformatzky (*Ber.*, **23**, 1594—1598).—Trimethylacetic acid was prepared according to the method of Friedel and Silva from pinacone hydrate by gently boiling it in a reflux apparatus with dilute sulphuric acid, and oxidising the pinacoline formed by adding chromic acid mixture and again gently boiling the solution. Water was then added, and the liquid distilled until sulphuric acid began to vaporise. The distillate was freed from unaltered pinacoline by extraction with ether, evaporated, treated with dilute sulphuric acid, and extracted with ether. After evaporating the ether from the extract, a residue of trimethylpyruvic, acetic, and trimethylacetic acids was obtained, and the trimethylacetic acid was separated by fractionation; it boiled at 155—163°. By treating it with bromine and phosphorus, and pouring the product into alcohol, ethyl trimethylacetate and small quantities of bromine-derivatives of hydrocarbons were obtained, but no bromotrimethyl acetate. Trimethylacetic chloride was then made by the action of phosphorus trichloride on the acid; it boiled at 100—110°. When heated with bromine in a sealed tube at 100° and finally to 135°, it yielded a mixture of bromine-derivatives of hydrocarbons, but no bromotrimethylacetic derivative. It appears that in general, acids which contain no hydrogen in the α-position are incapable of exchanging a hydrogen atom for bromine. C. F. B.

Action of Alcohols on Ethyl Acetoacetate. By T. Peters (*Annalen*, **257**, 353—358).—When ethyl acetoacetate (30 grams) is mixed with methyl alcohol (150 grams) in which a small quantity of sodium (0·5 gram) has been dissolved, and the mixture is kept at the ordinary temperature, the ethyl acetoacetate is gradually and completely converted into the methyl salt; isoamyl alcohol, under the same conditions, converts the ethyl into the isoamyl salt. The same changes take place, but much more quickly (in 16 to 20 hours), when ethyl acetoacetate is boiled with either of the above-named alcohols, and isobutyl alcohol, under the same conditions, transforms the ethyl into the isobutyl salt. Isobutyl and isoamyl alcohol convert ethyl acetoacetate into the isobutyl and isoamyl salts respectively, even in absence of sodium, but prolonged boiling is required, and a large excess of the alcohol must be employed; methyl alcohol has no action on ethyl acetoacetate and ethyl ethylacetoacetate in absence of sodium. Ethyl isobutylacetoacetate boils at 198—202°, isobutyl ethylacetoacetate at 211—215°, isoamyl acetoacetate at 217—219°, and isoamyl ethylacetoacetate at 226—230°. F. S. K.

Behaviour of Ethereal Salts of Alkyl-substituted Acetoacetic Acid with Ammonia. By T. PEIERS (*Annalen*, **257**, 339—353).—Two classes of compounds are formed by the action of ammonia on ethereal salts of the alkyl-derivatives of acetoacetic acid, namely, the ethereal salt of an α-alkyl-β-amidocrotonic acid and the amide of an alkylacetoacetic acid; the former is alone produced when anhydrous ammonia is employed.

With ammonia, methyl ethylacetoacetate yields methyl ethylamidocrotonate (m. p. 35—36°) and ethylacetoacetamide (m. p. 96°), but not methylacetoacetamide, as stated by Brandes.

Methylacetoacetamide, $COMe\cdot CHMe\cdot CO\cdot NH_2$, prepared from ethyl methylacetoacetate, crystallises from ether in colourless needles melting at 73°. Ethyl α-methyl-β-amidocrotonate melts at 53° and is readily soluble in alcohol, ether, and benzene.

Isobutylacetoacetamide melts at 88°; *ethyl α-isobutyl-β-amidocrotonate* at 41—42°.

Isoamylacetoacetamide, $COMe\cdot CH(C_5H_{11})\cdot CO\cdot NH_2$, melts at 129°; *ethyl α-isoamyl-β-amidocrotonate*, $NH_2\cdot CMe\colon C(C_5H_{11})\cdot COOEt$, at 50°.

Ethyl diethylacetoacetate is not acted on either by anhydrous or aqueous ammonia. F. S. K.

Decomposition-products of the Sodium Salts of the Chlorolactic Acids. By E. REISSE (*Annalen*, **257**, 331—338).—When an aqueous solution of sodium trichlorolactate is heated at about 75—80°, it is decomposed into sodium chloride and dichloraldehyde with evolution of carbonic anhydride; the presence of the dichloraldehyde was proved by oxidising a portion of the distilled solution with nitric acid and isolating the dichloracetic acid thus produced, as well as by various other tests.

An aqueous solution of sodium dichlorolactate is slowly decomposed at 95° into chloraldehyde and sodium chloride, with evolution of carbonic anhydride; a solution of the chlorolactate, at the same temperature, undergoes decomposition into aldehyde, carbonic anhydride, and sodium chloride, small quantities of glyceric acid being also formed. F. S. K.

Brominated Pyrotartaric Acids. By C. A. BISCHOFF (*Ber.*, **23** 1924—1929).—The author has previously shown, in conjunction with Guthzeit (Abstr., 1881, 579), and with Emmert (Abstr., 1882, 1191), that the products of bromination of propenyltricarboxylic acid are a monobromopyrotartaric acid melting at 202—204°, a brominated crotonic acid melting at 107—109°, apparently identical with Michael and Norton's α-bromocrotonic acid, and a dibromopyrotartaric acid melting at 127—128°. Two isomerides of the latter acid are known, melting at 204° and 170° respectively, both of which can be converted into bromomethacrylic acid, $CHBr\colon CMe\cdot COOH$. The first-mentioned dibromopyrotartaric acid, on the other hand, is converted by alkalis into α-bromocrotonic acid, which has, according to Wislicenus, the constitution  $\begin{array}{c} \mathrm{H{\cdot}C{\cdot}CH_3} \\ \| \\ \mathrm{Br{\cdot}C{\cdot}COOH} \end{array}$. The acid from which it is obtained must therefore contain both bromine-atoms combined with the same carbon-atom,  $\begin{array}{c} \mathrm{CH_3{\cdot}CH{\cdot}COOH} \\ | \\ \mathrm{Br_2C{\cdot}COOH} \end{array}$.

In addition to the above monobromopyrotartaric acid melting at 202—204°, two isomeric acids are known which melt at 137° and 148° respectively. The first of these gives paraconic acid on boiling with water, and itaconic acid on treatment with soda, and has therefore probably the constitution  $\begin{array}{c} \mathrm{CH_2{\cdot}Br} \\ | \\ \mathrm{H{\cdot}C{\cdot}COOH} \\ | \\ \mathrm{H{\cdot}C{\cdot}COOH} \\ | \\ \mathrm{H} \end{array}$, whilst the second when treated with soda yields methacrylic acid, which leads to the constitution  $\begin{array}{c} \mathrm{CH_3} \\ | \\ \mathrm{Br{\cdot}C{\cdot}COOH} \\ | \\ \mathrm{H{\cdot}C{\cdot}COOH} \\ | \\ \mathrm{H} \end{array}$. The acid melting at 202—204° was obtained in larger quantity by adding bromine to an aqueous solution of propenyltricarboxylic acid, and concentrating the solution, carbonic anhydride being given off. It was thus obtained in hard prisms melting at 203·5°. Only one structural formula is possible for this acid, which can, however, exist in two geometrically isomeric forms, namely,  $\begin{array}{c} \mathrm{CH_3} \\ | \\ \mathrm{H{\cdot}C{\cdot}COOH} \\ | \\ \mathrm{Br{\cdot}C{\cdot}COOH} \\ | \\ \mathrm{H} \end{array}$ and  $\begin{array}{c} \mathrm{CH_3} \\ | \\ \mathrm{H{\cdot}C{\cdot}COOH} \\ | \\ \mathrm{Br{\cdot}C{\cdot}H} \\ | \\ \mathrm{COOH} \end{array}$. On heating it at 210° in an oil-bath, hydrogen bromide and water are given off, and citraconic anhydride distils over. The acid may be termed "parasymmetrical bromomethylsuccinic acid." H. G. C.

Determination of the Structure of Aliphatic Acids, and the so-called "Dynamical Isomerism." By K. Auwers and L. L. Jackson (*Ber.*, **23**, 1599—1617).—This paper is the first of a series which is to describe a study of the action of bromine on aliphatic acids, and of the electric conductivity of the latter, and to show how these data may be used to determine the constitution of such acids. In the first or introductory portion of the paper, it is shown that the acid obtained by treating ethyl methylsodiomalonate with ethyl-α-bromisobutyrate and saponifying the product with sulphuric acid is not trimethylsuccinic, but symmetrical αα-dimethylglutaric acid. The isomeric derivatives of succinic acid lately discovered by Bischoff (this vol., pp. 741—744) are then discussed, and it is stated that there is no need to resort to "dynamical isomerism" to explain the existence of these, as many of them are probably derivatives of glutaric acid, formed by a molecular transformation similar to that mentioned above, and are thus *chemical* isomerides of the succinic acid derivatives.

αα-Dimethylglutaric acid, $COOH\cdot CHMe\cdot CH_2\cdot CHMe\cdot COOH$, was obtained by dissolving 4·6 grams of sodium in 80 c.c. of absolute alcohol, cooling the solution, adding 34·8 grams of ethyl methylmalonate, and warming on the water-bath, cooling, adding 39 grams of bromisobutyric acid, and again warming. The product was isolated and purified, and the portion boiling at 250—290° (38 per cent. of the theoretical yield) saponified by boiling with dilute sulphuric acid. On cooling the solution, αα-dimethylglutaric acid was obtained in needles melting at 105—106°, soluble in all ordinary solvents except light petroleum, and not volatile with steam. Its coefficient of electrical conductivity (K) is 0·00524. When boiled for a few minutes, it forms an *anhydride*, which can be isolated by treating the liquid with soda, and crystallises from light petroleum in thin, rectangular prisms melting at 92—93°. By treating the acid with red phosphorus and bromine, *αα-dibromo-αα-dimethylglutaric anhydride*, $CH_2<\begin{matrix}CMeBr\cdot CO\\CMeBr\cdot CO\end{matrix}>O$, is obtained. It is an unstable substance, crystallising from light petroleum in oblique prisms which melt at 92—93°, and sublime without decomposition. When it is treated with cold aqueous soda, and the solution neutralised with sulphuric acid, ether extracts a substance which crystallises in colourless, hexagonal plates melting at 95—96°, and is probably *dihydroxydimethylglutaric acid*, $CH_2[CMe(OH)\cdot COOH]_2$.

Glutaric acid was then prepared by decomposing its silver salt with hydrogen sulphide, and was treated with excess of bromine in the presence of phosphorus. No brominated acid was obtained in this way, but an unstable substance which decomposed when heated, and was doubtless glutaric bromide. It was poured into excess of alcohol, and the solution evaporated; the residue consisted of a mixture of ethyl dibromo- and monobromo-glutarates in the proportion of about three parts of the former to one of the latter. C. F. B.

Trimethylsuccinic Acid and Dimethylglutaric Acid. By C. A. Bischoff (*Ber.*, 23, 1464—1468).—A symmetrical dimethylglutaric acid melting at 100—101° can be obtained by treating ethyl sodiomethylmalonate (2 mols.) with methylene iodide, hydrolysing the ethereal salt thus produced, and heating the acid until the evolution of carbonic anhydride is at an end. The electrical conductivity of this acid is the same as that of the trimethylsuccinic acid obtained from ethyl methylmalonate and ethyl bromisobutyrate, and that of Zelinsky's symmetrical dimethylglutaric acid (m. p. 102—103°); the three acids have also the same crystalline form and the same solubility, so that a further comparison of the derivatives of the three compounds will probably prove their identity. The author has succeeded in synthesising mesaconic and citraconic acids from ethyl malonate. F. S. K.

γ-Ketone-Acids. By C. Paal and T. Hoffmann (*Ber.*, 23, 1495—1505).—*Ethyl isoamylmalonate*, $C_5H_{11}\cdot CH(COOEt)_2$, prepared by treating ethyl sodiomalonate with isoamyl bromide in alcoholic solution, is a colourless, mobile oil, with an agreeable fruity odour; it boils at 240—242°, and is insoluble in water. The free *acid*, $C_8H_{14}O_4$, is obtained by boiling the ethereal salt for several hours with concentrated potash; it crystallises from a mixture of benzene and light petroleum in colourless needles, melts at 93° with evolution of carbonic anhydride, and is readily soluble in water, alcohol, ether, ethyl acetate, and hot benzene, but only sparingly in light petroleum. The *ammonium* salt crystallises in needles or prisms. The *sodium* salt separates from dilute alcohol in ill-defined crystals. The *calcium* salt, $C_8H_{12}O_4Ca$, and the *barium* salt seem to be amorphous, and are insoluble in water. The *silver* salt, $C_8H_{12}O_4Ag_2$, is amorphous and moderately stable. In aqueous solutions of the ammonium salt, ferric chloride produces a red, and copper sulphate a bluish-green precipitate. The *amide*, $C_5H_{11}\cdot CH(CO\cdot NH_2)_2$, prepared by heating the ethereal salt with concentrated alcoholic ammonia at 150°, crystallises from alcohol in colourless needles, melts at 210°, and is readily soluble in hot alcohol but only sparingly in benzene, and insoluble in ether and light petroleum.

Isoamylacetic acid, $C_7H_{14}O_2$, is obtained by heating isoamylmalonic acid; it is a colourless, disagreeably smelling oil of sp. gr. 0·912243 at 19°, compared with water at the same temperature; it boils at 208—210°, and is very sparingly soluble in water. The *ethyl* salt, $C_9H_{18}O_2$, prepared by passing hydrogen chloride into an alcoholic solution of the acid, is a colourless oil of pleasant odour, boiling at 177°. The *calcium* salt, $C_{14}H_{26}O_4Ca$, is crystalline and only sparingly soluble in hot water.

Ethyl phenacylisoamylmalonate, $COPh\cdot CH_2\cdot C(C_5H_{11})(COOEt)_2$, can be prepared by gradually adding phenacyl bromide to a well-cooled ethereal solution of ethyl sodioisoamylmalonate and then warming the mixture for a short time, but it is obtained in a less impure condition by passing hydrogen chloride into an alcoholic solution of phenacylisoamylmalonic acid; the crude product is a thick, colourless oil. The free *acid*, $C_{16}H_{20}O_5$, prepared by hydrolising the crude ethereal salt with alcoholic potash, crystallises from dilute alcohol, or acetic acid, in long, colourless needles, melts at 160°, and is readily soluble in alcohol, ether, ethyl acetate, and glacial acetic acid, but almost insoluble in benzene and light petroleum; when crystallised from water or from solvents containing water, it invariably contains small quantities of water, from which it cannot easily be freed. The *potassium* salt crystallises in plates and is readily soluble in water and hot alcohol. The *ammonium* salt, $C_{16}H_{19}O_5\cdot NH_4$, crystallises in needles, melts at 165°, and is moderately easily soluble in cold water. When the acid is heated with phosphoric chloride and phosphorus oxychloride, it is converted into the chloride, which is so unstable that it cannot be obtained in a pure condition. Both the acid and the ethyl salt combine with hydroxylamine, yielding oximes.

Attempts to convert phenacylisoamylmalonic acid and phenacylisoamylacetic acid (see below) into 1.3-phenylisoamylthiophen, by heating with phosphorus trisulphide, were unsuccessful.

Octylbenzene, $CHMe_2\cdot[CH_2]_4\cdot CH_2Ph$, is obtained when phenacylisoamylmalonic acid is distilled over zinc-dust and the product fractionated over sodium; it is a colourless, mobile oil, boiling at about 245—255°, and possessing an aromatic odour.

β-Phenyl-β-hydroxy-α-isoamylethylmalonic acid,

$$\mathrm{OH\cdot CHPh\cdot CH_2\cdot C(COOH)_2\cdot C_5H_{11}},$$

can be prepared by reducing a dilute alcoholic solution of phenacylisoamylmalonic acid with sodium amalgam, the solution being kept slightly acid by the frequent addition of dilute sulphuric acid. It is a gum-like substance, readily soluble in ether, alcohol, and glacial acetic acid, but almost insoluble in water; when heated, it is converted into *γ-phenyl-α-isoamylbutyrolactone*,  $\mathrm{CHPh}<^{\mathrm{-CH_2}}_{\mathrm{O\cdot CO}}>\mathrm{CH\cdot C_6H_{11}}$, with evolution of water and carbonic anhydride.

Phenacylisoamylacetic acid (*β-benzoyl-α-isoamylpropionic acid*), $\mathrm{COPh\cdot CH_2\cdot CH(C_5H_{11})\cdot COOH}$, prepared by heating the preceding compound above its melting point, crystallises from dilute alcohol or light petroleum in colourless plates, melts at 103°, and is readily soluble in alcohol, ether, and benzene, but only sparingly in light petroleum, and insoluble in water. The *ethyl* salt is a colourless oil boiling at 260°. When the acid is boiled for some time, it is converted into *γ-phenyl-α-isoamylbutenyllactone* (b p. about 310—320°), which, however, cannot be obtained in a pure condition. F. S. K.

Synthesis of Mesaconic and Citraconic Acids from Ethyl Propenyltricarboxylate. By C. A. Bischoff (*Ber.*, 23, 1930—1937).—In previous papers by the author and by Guthzeit, it has been shown that almost all alkyl-substituted ethyl malonates are readily acted on by chlorine at 100°. Ethyl acetylenetetracarboxylate forms an exception, as it is only attacked at 200°, and then passes into the ethyl salt of a tribasic acid. By the action of chlorine on ethyl propenyltricarboxylate on the water-bath, no chloro-derivative corresponding with ethyl chloromalonate can be obtained; if, however, the ethyl salt is heated to 130—200°, substitution takes place in the normal manner, *ethyl chloropropenyltricarboxylate*,  $\begin{array}{l}\mathrm{Cl\cdot C(COOEt)_2}\\ \quad\mid\\ \mathrm{Me\cdot CH\cdot COOEt}\end{array}$, being obtained as a yellow oil with a pungent odour, boiling at 287—288° under 770 mm. pressure. By the action of hydrochloric acid, it yields mesaconic acid and carboxymesaconic acid,

$$\mathrm{COOH\cdot CMe{:}C(COOH)_2},$$

melting at 168°; the latter readily loses carbonic anhydride with formation of mesaconic acid. A third product was also obtained, which appears to be impure citraconic acid.

Ethyl butenyltricarboxylate, when treated with chlorine in an analogous manner, yields a monochloro-derivative of a similar character, boiling at 292°. On hydrolysis, it is converted into ethylmaleic acid,  $\begin{array}{l}\mathrm{H\cdot C\cdot COOH}\\ \quad\parallel\\ \mathrm{Et\cdot C\cdot COOH}\end{array}$, melting at 90—92°, which is quite stable, whereas the isomeric pyrocinchonic acid exists only as an anhydride.

H. G. C.

Citraconanil and Pyranilpyroïnlactone. By A. REISSERT (*Ber.*, **23**, 1620—1621).—A reply to the paper of Anschütz (compare Abstr., this vol., p. 774) regarding the identity of these compounds. The author points out that the production of anilidopyrotartaric acid by reduction affords no proof of the constitution of either citraconanil or pyranilpyroïnlactone, as its formation is equally well explained by either of the formulæ in dispute. On oxidation, citraconanil yields oxanilic acid, whilst anilosuccinic acid is obtained from pyranilpyroïnlactone. These facts, together with the different physical properties of the two compounds, confirm the author in his opinion that they are distinct substances. J. B. T.

Condensation of Ketone Acids with Dicarboxylic Acids. By R. FITTIG and G. PARKER (*Ber.*, **23**, 1535—1536).—The compound of the composition $C_8H_6O_3$, which was obtained by the condensation of pyruvic acid with sodium succinate (Abstr., 1889, 1146), is not an acid, but the anhydride of pyrocinchonic acid.

F. S. K.

Combination of Malic Acid with normal Potassium and Sodium Tungstates. By D. GERNEZ (*Compt. rend.*, **110**, 1365—1368; compare this vol., 744).—The solutions examined contained 1·1166 grams of malic acid, various proportions of the tungstate, and water sufficient to make the volume of the solution up to 24 c.c. at 15°; the rotation of the malic acid solution alone was 15′ at 17° in a tube 201·5 mm. long.

The addition of equal weights of the alkaline tungstate increases the rotatory power by equal increments until a maximum is reached, when equal equivalents of the acid and the tungstate are present. Further addition of tungstate results in a gradual reduction of the rotatory power, which changes its sign and attains a second maximum when two equivalents of the salt are present to one of malic acid. Beyond this point the rotatory power again diminishes, again changes in sign, and reaches another maximum when five equivalents of the salt are present to two equivalents of malic acid. If further quantities of tungstate are added, the rotatory power again passes from left to right, and a gradual increase in the rotatory power indicates the formation of a combination of one equivalent of the acid and eight equivalents of the tungstate. C. H. B.

Distillation Products of Citrates. By C. A. BISCHOFF and A. HAUSDORFER (*Ber.*, **23**, 1915—1918).—When a mixture of citric acid, quicklime, and iron filings is distilled in an iron retort, a distillate is obtained which consists of an aqueous and an oily portion. The latter on repeated fractionation gave products boiling at 58—60°, 90°, 120°, and 210°. The first consisted of acetone, and the authors regarded the second as metacetone until the publication of E. Fischer and Laycock's researches showed this to be a mixture (Abstr., 1889, 487). None of the other fractions consists of hydrocarbons.

The distillation was next repeated on a larger scale, 6·5 kilos. of sodium citrate being employed. The fractions of the oil boiling at 45—80° and 80—115° were washed with soda solution and dried over potassium carbonate. The portions boiling above 90°, collected in fractions of 10° range, were treated with phenylhydrazine, heated on the water-bath, and finally dried on the oil-bath at 180°. The residue, on fractionation in a vacuum, yielded propaldehydephenylhydrazone as a yellow oil, which was converted into scatole on heating with zinc chloride.

The higher boiling portions likewise reduce silver solution, but are stable towards oxidising agents, and are therefore probably not aldehydes. The fractions analysed show the characteristic reactions of substituted furfurans, and the numbers obtained on analysis in two cases agree with those required for triallylfurfuran and dipropylfurfuran.

Action of Ethyl α-Bromisobutyrate on Ethyl Propylmalonate and Isopropylmalonate. By C. A. Bischoff and A. Tigerstedt (*Ber.*, **23**, 1937—1911).—When ethyl propylmalonate is mixed with an alcoholic solution of sodium ethoxide, and ethyl α-bromisobutyrate added, the normal reaction takes place, the ethyl salt of a tricarboxylic acid being formed. This has the composition $C_{16}H_{28}O_6$, and forms a slightly yellowish oil, which boils at 300—301°. It cannot be obtained from ethyl isobutenyltricarboxylate by the action of sodium ethoxide and propyl iodide.

On hydrolysis, the ethyl salt yields the corresponding *propylisobutenyltricarboxylic acid*, $C_{10}H_{16}O_6$, which crystallises in colourless nodules, readily soluble in water and ether. At 167—168°, it melts, giving off carbonic anhydride and forming a dicarboxylic acid. The latter was found to be a mixture of two geometrically isomeric acids, melting at 51—53° and 101—102° respectively. They readily pass one into the other, and are probably *symmetrical methylpropylglutaric acids*, $COOH{\cdot}CHPr^{\alpha}{\cdot}CH_2{\cdot}CHMe{\cdot}COOH$.

When ethyl isopropylmalonate is treated with sodium ethoxide and ethyl α-bromisobutyrate, no corresponding reaction takes place, a mixture of high and low boiling substances being obtained.

H. G. C.

Dialkyl Cyanothiocarbamides. By O. Hecht (*Ber.*, **23**, 1658—1668; compare Wunderlich, Abstr., 1886, 435).—Methylthiocarbamide, in alcoholic solution, combines with sodium cyanide to form sodium methylcyanothiocarbamide, $NHMe{\cdot}CS{\cdot}NNa{\cdot}CN$; by the action of alkyl halogens, the sodium in this compound may be displaced. Since the higher thiocarbamides react in the same manner as the methyl compound, there is no difficulty in preparing the members of two homologous series, and a comparison of their properties would show the influence of the relative position of the alkyl-groups in the molecule.

I. Methylthiocarbamidealkyl Cyanides, $NHMe{\cdot}CS{\cdot}NR{\cdot}CN$.—*Methylthiocarbamidemethyl cyanide*, $NHMe{\cdot}CS{\cdot}NMe{\cdot}CN$, crystallises from alcohol in transparent, lustrous plates; on heating to 185°, it becomes yellow, and melts at 194—195° with decomposition; it is readily soluble in all the usual menstrua except light petroleum. *Methylthiocarbamidepropyl cyanide*, $NHMe{\cdot}CS{\cdot}NPr{\cdot}CN$, crystallises from hot water in very lustrous plates or needles melting at 90·5°;

it is less soluble than the methyl compound. *Methylthiocarbamideallyl cyanide*, $NHMe{\cdot}CS{\cdot}N(C_3H_5){\cdot}CN$, is deposited from alcohol in long, lustrous, white needles melting at 77·5°. *Methylthiocarbamidebenzyl cyanide*, $NHMe{\cdot}CS{\cdot}N(C_7H_7){\cdot}CN$, crystallises from hot alcohol in needles melting at 173°; it is only sparingly soluble in ordinary solvents.

II. ETHYLTHIOCARBAMIDEALKYL CYANIDES, $NHEt{\cdot}CS{\cdot}NR{\cdot}CN$.—*Ethylthiocarbamideethyl cyanide*, $NHEt{\cdot}CS{\cdot}NEt{\cdot}CN$, is obtained from sodium ethylcyanothiocarbamide and ethyl iodide; it crystallises from strong alcohol in white, lustrous laminæ melting at 98·2°, and resolidifying at 94°. *Ethylthiocarbamidepropyl cyanide*,

$$NHEt{\cdot}CS{\cdot}NPr{\cdot}CN,$$

forms a loose, white, crystalline mass of small needles or leaves melting at 74·7° and resolidifying at 71°. *Ethylthiocarbamideallyl cyanide*, $NHEt{\cdot}CS{\cdot}N(C_3H_5){\cdot}CN$, crystallises in small, lustrous plates melting at 81·2° without decomposition. *Ethylthiocarbamidebenzyl cyanide*, $NHEt{\cdot}CS{\cdot}N(C_7H_7){\cdot}CN$, is deposited from dilute alcohol as a white powder, consisting of small, flat crystals melting at 143·5°.

III. PROPYLTHIOCARBAMIDEALKYL CYANIDES, $NHPr{\cdot}CS{\cdot}NR{\cdot}CN$.—*Propylthiocarbamidemethyl cyanide* crystallises from alcohol in fine, white, lustrous plates melting at 115° without decomposition. *Propylthiocarbamideethyl cyanide* is obtained from hot water in plates melting at 56°. *Propylthiocarbamidepropyl cyanide* is deposited from hot water as a crystalline powder melting at 56°. *Propylthiocarbamideallyl cyanide*, crystallises in small, white, lustrous needles melting at 50·3°. *Propylthiocarbamidebenzyl cyanide* crystallises from hot water in needles melting at 113°.

IV. ALLYLTHIOCARBAMIDEALKYL CYANIDES, $NH(C_3H_5){\cdot}CS{\cdot}NR{\cdot}CN$.—Sodium allylcyanothiocarbamide is less soluble than the lower homologues, and the yield of alkyl-derivatives is comparatively small. *Allylthiocarbamideethyl cyanide* crystallises from dilute alcohol in fine, white needles melting at 63·2°. *Allylthiocarbamidepropyl cyanide* melts at 57·3°, and is deposited from dilute alcohol in small, lustrous needles. *Allylthiocarbamideallyl cyanide* forms fine, white, interlaced needles melting at 52·4°. *Allylthiocarbamidebenzyl cyanide* is difficult to purify; it is obtained from dilute alcohol in white, lustrous needles melting at 116° without decomposition.

V. PHENYLTHIOCARBAMIDEALKYL CYANIDES, $NHPh{\cdot}CS{\cdot}NR{\cdot}CN$.—*Phenylthiocarbamidemethyl cyanide* is very sparingly soluble, except in acetic acid; it is deposited from a mixture of acetone and alcohol in white, lustrous, crystalline aggregates melting at 186° with decomposition. *Phenylthiocarbamideethyl cyanide* crystallises from water in white, interlaced needles and plates melting at 144°. Wunderlich (*loc. cit.*) gives the melting point of this compound as 119°. *Phenylthiocarbamidepropyl cyanide* melts under water; it is sparingly soluble, and separates as an oil, on cooling a hot solution; after remaining for some time, the oil solidifies, forming white, interlaced, needle-shaped crystals melting at 108°. *Phenylthiocarbamideallyl cyanide* is obtained in the form of slightly yellow, lustrous plates and needles melting at 100°. *Phenylthiocarbamidebenzyl cyanide* crystallises from a mixture of acetone and alcohol in white, lustrous aggregates of needles and plates melting at 182° with decomposition. The melting points of the above compounds, except the allyl and aromatic derivatives, decrease with rising molecular weights; the position of the alkyl groups does not affect this rule. A comparison of the six pairs of metamerides shows that the compounds containing the group ·NMe·CN, have always the highest melting point; in the absence of a methyl-group, that metameride melts higher which has the alkyl of larger molecular weight linked to the :N·CN group. J. B. T.

Fucusol. By K. Bieler and B. Tollens (*Annalen*, **258**, 110—128; compare Abstr., 1890, 238; Maquenne, Abstr., 1890, 33; and Hill, Abstr., 1889, 695).—Fucusol, prepared from *Fucus* by distillation with sulphuric acid, can be separated by fractional distillation into furfuraldehyde and a much smaller fraction which consists of methylfurfuraldehyde (b. p. 182—184°). The furfuraldehyde was proved to be identical with that obtained from bran by a direct comparison of a number of derivatives of the two substances.

Methylfurfuraldehyde gives a deep orange-red coloration with aniline acetate.

Methylfurfurine, prepared by boiling the hydramide with soda, is an oil The *nitrate* is crystalline. The acid *oxalate*, $C_{18}H_{18}N_2O_3,C_2H_2O_4$, crystallises in microscopic needles. The *platinochloride*,

$$(C_{18}H_{16}N_2O_3)_2,H_2PtCl_6,$$

crystallises in microscopic plates.

When a trace of isatin is added to a solution of methylpyromucic acid in concentrated sulphuric acid, and the mixture warmed slowly, a yellow, then a brown, and finally an intense green coloration is produced; in an aqueous solution of ammonium methyl pyromucate, ferric chloride produces a brown precipitate.

The authors have succeeded in extracting a sugar from *Fucus*, but have not yet obtained it in crystals. This sugar yields a crystalline *hydrazone*, melting at 163—165°, which seems to have the composition $C_{12}H_{18}N_2O_4$, and a crystalline *osazone*, melting at 154—156°; when distilled with dilute hydrochloric acid, it yields furfuraldehyde or methylfurfuraldehyde. F. S. K.

Configuration of the Benzene and Hexamethylene Molecule. By F. Herrmann (*Ber.*, **23**, 2060—2062).—The author complains that Sachse (Abstr., 1888, 1181, and *Ber.*, **23**, 1363) has not noticed his (the author's) previous paper (Abstr., 1888, 1026) on the configuration of the benzene and hexamethylene molecule; he points out the similarity between his and Sachse's diagrams, and proceeds to discuss the conclusions which follow from the comparison.

F. S. K.

Chlorine Substitution-products of Metaxylene. By A. Claus and H. Burstert (*J. pr. Chem.* [2], **41**, 552—563).—Chlorine substitution-products of metaxylene are best obtained by slowly passing chlorine into a solution of metaxylene (100 grams) in chloroform (300 grams) containing finely powdered iron (6—7 grams). When crystals begin to form in the liquid, the current of chlorine is stopped, and the product poured into water and shaken therewith; the chloroform solution is dried with calcium chloride, evaporated, and the residue distilled. Mono-, di-, and tri-chlorometaxylene distil over below 250°, and tetrachlorometaxylene remains. The first three are separated by fractional distillation, but the last cannot be distilled without decomposition; it may, however, be completely freed from the others by distillation with steam, with which it is not volatile.

Chlorometaxylene boils at 180—181° (uncorr.), not 186·5° (corr.; Jacobsen, Abstr., 1885, 1052).

4 : 6-*Dichlorometaxylene* crystallises in colourless, pearly, large plates; it strongly resembles dichloroparaxylene in properties, but its crystalline form is not so well marked; it melts at 68° (uncorr.), boils at 222°, and dissolves easily in most solvents, more sparingly in alcohol. The crystals have an aromatic odour, and become liquid when exposed for some time to the air; they sublime unchanged.

4 : 6-*Dichloro-3-methylbenzoic acid* is formed when 4 : 6-dichlorometaxylene (1 part) is heated with nitric acid of sp. gr. 1·18 (15 parts) in a sealed tube for 5—6 hours at 150°. It crystallises in colourless, lustrous needles which melt at 170° (uncorr.), and dissolve in hot water and the other usual solvents. It is not formed when chromic acid acts on 4 : 6-dichlorometaxylene in glacial acetic acid, so it is not identical with Hollemann's dichloromethylbenzoic acid (m. p. 161°, *Annalen*, **144**, 269); its *barium salt* (with 2 mols. H_2O) is described.

4 : 6-*Dichlorisophthalic acid* is the product of the action of chromic acid on 4 : 6-dichlorometaxylene; it is best obtained by heating the dichloroxylene (1 part) with nitric acid of sp. gr. 1·18 (20 parts) in a sealed tube for several hours at 220°, and crystallising the product from alcohol. It forms a white powder, consisting of small needles, and melts at 280° (uncorr.); it dissolves in the usual solvents except cold water, but its solution in hot water may be cooled to 0° without crystallising. Its *barium* (with 1 mol. H_2O), *silver*, *copper*, *lead*, *nickel*, and *cobalt* salts were obtained.

Trichlorometaxylene crystallises in colourless, lustrous needles which melt at 117° (uncorr.), and sublime unchanged. It dissolves freely in glacial acetic acid, benzene, ether, and chloroform, sparingly in alcohol; its constitution is uncertain. By oxidation either with nitric or chromic acid, it yields *trichlorisophthalic acid* only. This acid crystallises in slender needles which melt at 223° (uncorr.), and sublime; it is soluble in the usual solvents. The *barium* (with 5 mols. H_2O) and the *silver* salts are described.

Tetrachlorometaxylene crystallises from a mixture of chloroform and alcohol in brilliant, white, brittle needles which melt at 210° (uncorr.), and are soluble in most solvents except alcohol. All attempts to obtain an acid by oxidising tetrachlorometaxylene have failed.

A. G. B.

Action of Sulphuric Acid on Iodometaxylene. By H. HAMMERLICH (*Ber.*, **23**, 1634—1636).—Iodometaxylene [Me : Me : I = 1 : 3 : 4] is prepared by treating diazoxylidine sulphate with a concentrated solution of potassium iodide. The dark coloured oil which collects at the bottom of the vessel is purified by washing with sodium hydroxide solution. After distilling several times, the compound is obtained as a colourless, strongly refractive liquid of sp. gr. 1·6609 at 13°; it boils at 232°, and does not solidify in a freezing mixture.

Diiodoxylene, $C_6H_2Me_2I_2$, is obtained by treating iodometaxylene with 2—3 times its weight of concentrated sulphuric acid. After remaining for about five weeks, the crystals which form are separated, and purified by washing and distillation. The compound crystallises from alcohol in tufts of long, white needles melting at 72°. On treating the acid filtrate from the diiodoxylene with barium carbonate, the barium salt of the corresponding *iodoxylenesulphonic acid* is obtained, crystallising in small, lustrous needles which are sparingly soluble in hot water.

Iodoisophthalic acid is formed by the oxidation of iodometaxylene with dilute nitric acid; the compound crystallises with great difficulty, and is best purified by treating the barium salt with hydrochloric acid; it melts at 215° with decomposition. The barium salt crystallises in small, white, lustrous needles. J. B. T.

Metadichlorophenol and Metadibromophenol. By L. Garzino (*Chem. Centr.*, 1890, i, 820—821; from *Atti R. Acad. Sci, Torino*, **25**).—The author nitrated propionyldichlorophenols and propionyldibromophenols with the object of preparing monochloro- and monobromo-nitroquinones. Instead of these, a dinitrodichlorophenol and a dinitrodibromophenol were obtained.

Dinitrodichlorophenol, $C_6HCl_2(NO_2)_2·OH$, forms yellow crystals melting at 105—106°, readily soluble in alcohol, ether, chloroform, and in hot water. It volatilises with steam, and decomposes when heated rapidly. It decomposes metallic carbonates in the cold. The *potassium salt* crystallises in red needles with $\frac{1}{2}$ mol. H_2O, and is very soluble in water. The *barium salt* crystallises with 3 and with 2 mols. H_2O. The former is yellowish, whilst the latter is reddish, and is less soluble in water.

By nitrating propionyldibromophenol without cooling, the principal product is dinitrodibromophenol, but if the mixture is carefully cooled during the nitration, a propionylnitrodibromophenol is also formed in some quantity.

Dinitrodibromophenol, $C_6HBr_2(NO_2)_2·OH$, forms reddish-yellow crystals melting at 146° with decomposition. It is readily soluble in alcohol and ether, but little so in cold water, rather more soluble in hot water. From ether, it crystallises in beautiful rhombohedrons. It is volatile in steam, and decomposes metallic carbonates in the cold. The *potassium salt* crystallises with $\frac{1}{2}$ mol. H_2O in the form of dark-red needles little soluble in water. The *barium salt* crystallises with 3 and with 2 mols. H_2O in the form of small, red prisms.

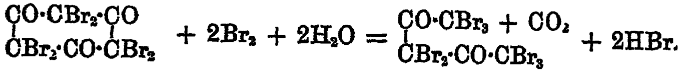
Propionylnitrodibromophenol, $C_6H_2Br_2(NO_2)O·C_3H_5O$, crystallises from dilute alcohol in beautiful, monoclinic crystals melting at 54—55°. By saponification, the nitrodibromophenol is obtained; it has a beautiful, yellow colour, and melts at 90—91°. The positions of the nitro-groups in these compounds is not determined. J. W. L.

Chlorodibromo- and Bromodichloro-phenol, and their Conversion into Quinones. By L. Garzino (*Chem. Centr.*, 1890, i, 821; from *Atti R. Acad. Sci., Torino*, 25).—*Chlorodibromophenol*, $C_6H_2Br_2Cl{\cdot}OH$ [= 2 : 4 : 5 : 1 ?], is prepared by treating metadibromophenol with dry chlorine at 40°. It crystallises from dilute alcohol in white, silky, lustrous crystals, very soluble in ether, chloroform, and benzene, soluble in dilute acetic acid, nearly insoluble in water; it is volatile with steam, and sublimes at ordinary temperatures. The *barium salt* crystallises with $2\frac{1}{2}$ mols. H_2O in small, yellowish-white needles; the aqueous solution is decomposed partially by evaporation; it is not readily soluble in water. *Benzoylchlorodibromophenol*, $C_6H_2Br_2Cl{\cdot}OBz$, forms small, white prisms, and melts at 65—65·5°.

Propionylchlorodibromophenol, $C_6H_2Br_2Cl{\cdot}O{\cdot}C_3H_5O$, crystallises from 80 per cent. alcohol in white crystals melting at 31·5—32°. By nitrating this, *chlorobromonitroquinone* is obtained in small quantity; it decomposes at its melting point, 227—228°; it is insoluble in water, sparingly soluble in ether, insoluble in cold 95 per cent. alcohol, and but little soluble in hot alcohol; this solution becomes brown and acid. It reacts with hydroxylamine hydrochloride, phenylhydrazine, and aniline. On nitrating the propionylbromodichlorophenol, no quinone is obtained; a propionyl-derivative of nitrobromodichlorophenol and a substance of the formula $C_{12}H_4Cl_3BrN_2O_7$, but whose constitution could not be determined, were obtained. The latter melts at 215—217°. The propionylnitrobromodichlorophenol melts at 88·5—89°, is sparingly soluble in water, and crystallises from boiling alcohol in greenish-white rhombohedra. J. W. L.

Action of Bromine on Phloroglucinol. By T. Zincke and O. Kegel (*Ber.*, 23. 1706—1732).—By the action of bromine on phloroglucinol, Benedikt (Abstr., 1878, 499; *Jahresb.*, 1880, 645), and Benedikt and Hazura (Abstr., 1886, 52) obtained three compounds, phlorobromine, C_6Br_9HO: hexabromophloroglucinol, $C_6Br_6O_3$; and octobromophloroglucinol, $C_6Br_8O_3$. The observations made by the authors in their investigation of the action of chlorine on phloroglucinol (this vol., p. 488) have induced them to repeat these experiments, and it has been found that phlorobromine has not the formula C_6Br_9HO, but $C_5Br_8O_2$, and is in reality *perbromacetylacetone*, $CBr_3{\cdot}CO{\cdot}CBr_2{\cdot}CO{\cdot}CBr_3$. It forms thick, lustrous needles which melt at 154—155°, and give off bromine at a higher temperature. It dissolves sparingly in light petroleum, but readily in benzene, chloroform, and acetic acid, and is not attacked by soda solution or by nitric acid. Ammonia converts it into tribromacetamide and methylene bromide, whilst with alcohol it yields bromoform and ethyl di- and tri-bromacetate.

The formation of perbromacetylacetone is probably preceded by that of hexabromophloroglucinol, which is then acted on by bromine-water in the following manner:—



$$\begin{array}{l} CO{\cdot}CBr_2{\cdot}CO \\ | \qquad\quad | \\ CBr_2{\cdot}CO{\cdot}CBr_2 \end{array} + 2Br_2 + 2H_2O = \begin{array}{l} CO{\cdot}CBr_3 + CO_2 \\ | \\ CBr_2{\cdot}CO{\cdot}CBr_3 \end{array} + 2HBr.$$

From this, one would expect that tribromophloroglucinol would yield by the action of chlorine the compound $CCl_2Br{\cdot}CO{\cdot}CBrCl{\cdot}CO{\cdot}CCl_2Br$, and that trichlorophloroglucinol would form with bromine the compound $CBr_2Cl{\cdot}CO{\cdot}CBrCl{\cdot}CO{\cdot}CBr_2Cl$. The latter supposition has proved correct, but not the first, as in that case the pentabromo-compound is also formed, together with compounds richer in chlorine. It appears probable that, on the one hand, the mixed trichlorotribromotriketohexamethylene is formed; whilst, on the other, bromine is set free, which then acts on the first-named compound, forming pentabromotrichloracetylacetone. This compound forms hard, colourless, vitreous needles which melt at 93—95° to a milky liquid which becomes clear at 98°. It is soluble in the ordinary solvents, the solutions quickly undergoing decomposition. Ammonia converts it into dibromochloracetamide, which forms thick, colourless needles or broad plates melting at 127—128°.

By the action of bromine on phloroglucinol in concentrated aqueous solution, the authors have not been able to obtain Benedikt's octobromophloroglucinol, but have isolated hexabromophloroglucinol and a new compound having the composition $C_5Br_7HO_2$. If the bromination be incomplete, a compound $C_6H_3Br_5O_4$ or $C_6Br_5HO_3,H_2O$ is also obtained.

Both this compound and the hexabrominated derivative are much more stable than the corresponding hexachlorotriketohexamethylene, not being split up by water, alcohol, or ammonia.

Hexabromotriketohexamethylene forms large, well-developed tablets, which are colourless or slightly yellow, melt at 146—147°, and decompose at 170—180°. It is readily soluble in ether, chloroform, hot benzene, and hot acetic acid, and is exceptionally susceptible to light. On reduction, it yields tribromophloroglucinol, and, under favourable conditions, phloroglucinol. Bromine converts it into phlorobromine.

The second compound, $C_6Br_5HO_3,H_2O$, is probably a *pentabromodiketohydroxyhexene*,

$$\begin{matrix} CBr{\cdot}CO{\cdot}CBr_2 \\ \| \qquad\qquad \vert \\ HO{\cdot}C \cdot CBr_2{\cdot}CO \end{matrix},H_2O$$

as it yields an acetyl-derivative, $C_6Br_5O_2{\cdot}OAc$, by the action of acetic anhydride with elimination of 2 mols. of water. This, on reduction and further treatment with acetic anhydride, yields *tribromophloroglucinol triacetate*, $C_6Br_3(OAc)_3$. The first-named compound forms slender needles melting at 142°, whilst the second melts at 183—184°.

Pentabromodiketohydroxyhexene crystallises in transparent, amber-yellow, apparently monoclinic forms, which are easily soluble in water and ether, less readily in chloroform and acetic acid. It melts at 119—120° with decomposition, and does not lose its water of crystallisation without further decomposition. This is probably combined in the same manner as in mesoxalic acid, which would account for the solubility of the compound in water. It behaves on reduction in the same manner as the hexabromo-compound, and by the action of bromine yields the compound $C_5Br_7HO_2$, which, as already stated, is also obtained direct from phloroglucinol. It crystallises from a mixture of carbon bisulphide and light petroleum in colourless, monoclinic prisms which melt at 93—94°, and give off bromine at a higher temperature. It greatly resembles phlorobromine, and by the action of water yields pentabromacetone, and a compound which is possibly tetrabromacetone hydrate. Ammonia converts it into tribromacetamide. From these facts, it would appear that the compound is a *heptabromacetylacetone* having the constitution

$CBr_3{\cdot}CO{\cdot}CBr_2{\cdot}CO{\cdot}CBr_2H$. H. G. C.

Methyl-derivatives of Phloroglucinol. By A. Spitzer (*Monatsh.*, **11**, 104—119).—The methyl-derivatives of phloroglucinol may be obtained in satisfactory yield and in unvarying proportions if the methyl iodide and phenol are both perfectly dry, and if in their preparation sodium be substituted for potassium. The phloroglucinol (1 mol.), dried at 100°, and the sodium (6 atoms) are separately dissolved in absolute methyl alcohol, the solutions are mixed, and the methyl iodide (6 mols.) run in, drop by drop, from a funnel. The mixture is then heated in a reflux apparatus, so arranged as to exclude moisture, until it no longer gives an alkaline reaction. The remainder of the operation is carried out in accordance with the directions of Herzig and Zeisel (Abstr., 1888, 822). On treating the product with dilute aqueous potash, hexamethylphloroglucinol and an oily portion remain undissolved, whilst penta- and tetra-methylphloroglucinol and a product not yet investigated are soluble in it.

Hexamethylphloroglucinol showed the same melting point (80°) as given by Margulies, and boiled at 247·7° (corr.). On treating the compound with hydrogen iodide, Margulies obtained carbonic anhydride, isobutyric acid, and diisopropylmethane, the latter being presumably secondary products from dimethylmalonic acid and diisopropyl ketone, which would decompose under the influence of the reducing agent at the high temperature (200°) employed. To test the truth of this supposition, the author has made experiments substituting 40 per cent. hydrochloric and 50 per cent. sulphuric acids for the hydrogen iodide. On heating the mixtures in sealed tubes at 190°, carbonic anhydride, diisopropyl ketone, and a small quantity of isobutyric acid were simultaneously formed.

Pentamethylphloroglucinol.—This compound melts at 114°, and boils at 261·6—263·8° (corr.), and has been described under the name of tetramethylphloroglucinol by Margulies. When an alcoholic solution is treated with bromine, *monobromopentamethylphloroglucinol*, crystallising in beautiful, small, white needles, is obtained; it melts at 75—76°. On heating for several hours in a reflux apparatus with 1 per cent. sodium hydroxide, this compound gradually dissolves, and on distilling the product, an oil boiling at 123·7—126·5° (corr.) passes over. This oil is diisopropyl ketone, since, on oxidation, it gives a mixture of acetic and isobutyric acids. On heating pentamethylphloroglucinol (2 grams) with 20 per cent. hydrochloric acid (20 c.c.) at 180° in a sealed tube, isobutyric, propionic, and carbonic acids, diisopropyl ketone, and perhaps ethyl isopropyl ketone are formed.

Since the action of bases on the brominated pentamethylphloroglucinol indicates the existence of symmetrical tetramethylacetone, and since its hydroxylic character has been established, the constitution of pentamethylphloroglucinol must be expressed by the formula

$$OH{\cdot}C{<}\begin{matrix}CMe_2{\cdot}CO\\ CMe\cdot CO\end{matrix}{>}CMe_2.$$

On oxidation with atmospheric air, four of the methyl-groups of pentamethylphloroglucinol are converted into diisopropyl ketone, and the fifth into acetic acid. It may be supposed that in this action the double-bonded carbon-atoms are split asunder, and the free valencies occupied by oxygen, the compound

$$COOH\cdot CMe_2\cdot CO\cdot CMe_2\cdot CO\cdot COMe$$

being formed, and that this hypothetical triketonic acid, in presence of water and oxygen, is finally split up into carbonic anhydride, acetic acid, and tetramethylacetone. G. T. M.

Homofluoresceïn. By E. Grimaux (*Compt. rend.*, **110**, 1074—1076).—The sodium-derivative of homofluoresceïn, prepared by Schwarz's method (Abstr., 1880, 551), was twice recrystallised from acetic acid. At 100°, the crystals lost 31·3 per cent. of acetic acid; Schwarz's product lost 31·55 per cent.

Orcin-aurin, prepared by Nencki's process (Abstr., 1882, 1201), was also crystallised from acetic acid; the crystals lost 32·2 per cent. at 100°.

Both products had precisely the same appearance, and formed needles, with a brown-red kermes-like colour, which did not melt at 300°. When heated in small closed tubes, they melt and decompose with evolution of red vapours and formation of a carbonaceous residue. With barium hydroxide solution, they yield a red, crystalline precipitate of a barium salt, very slightly soluble in cold water, but soluble in boiling water; with nitric acid, they yield nitro-derivatives which crystallise from water in rhombic lamellæ; and with alkalis, they yield two compounds which have the same intense fluorescence.

The homofluoresceïn of Schwarz is, in fact, identical with the orcin-aurin of Nencki. The formula $C_{23}H_{18}O_5$ agrees better with the properties described by Schwarz and with his analyses of the nitro-derivatives than does the formula $C_{23}H_{16}O_5$, which he ascribed to the compound.

Resorcinol, when treated with chloroform and an alkali, yields a bright-red, non-fluorescent solution which becomes brown-red on prolonged boiling. Acids precipitate a yellow powder which should be identical with the resaurin obtained by Nencki by heating resorcinol with formic acid and zinc chloride at 140°. Resorcinphthaleïn is fluorescent, and orcinphthaleïn is non-fluorescent, but the reverse holds good for the products of the action of chloroform.

C. H. B.

The Phenol contained in Sassafras Oil. By C. Pomeranz (*Monatsh.*, **11**, 101—103).—According to Grimaux and Ruott (*Compt. rend.*, **68**, 928), the ethereal oil obtained from the American cinnamon-tree, *Laurus sassafras*, consists of 10 per cent. of a terpene $C_{10}H_{16}$, 90 per cent. of safrole, $C_{10}H_{10}O_2$, and a small quantity of a substance of a phenolic nature, which can be abstracted from the oil by shaking with potash. In order to further investigate it, the author has exhausted 3 kilos. of crude sassafras oil with dilute potash. On adding dilute sulphuric acid to the alkaline solution, an oil separated; this was washed, dried with calcium chloride, and distilled. The whole of the oil passed over between 246° and 247°, giving 7 grams of a colourless liquid, having an odour greatly resembling eugenol. It is heavier than water, in which it is nearly insoluble, and dissolves readily in alcohol, forming a solution which is turned blue by ferric chloride. All these properties agree perfectly with those of eugenol, $OH\cdot C_6H_3(OMe)\cdot C_3H_5$. The elementary analysis and the conversion of a portion of the substance into its characteristic benzoyl-derivative (compare Cahours, *Annalen*, **108**, 321), crystallising in colourless, gleaming prisms melting at 69°, show that the substance is, in fact, eugenol. G. T. M.

Action of Zinc Chloride on Methylacetanilide. By A. Pictet and J. Fert (*Ber.*, **23**, 1903—1904; compare Abstr., 1889, 971).—Methylacetanilide is heated with zinc chloride at 290° for some time; when no further evolution of gas occurs, the fused mass is poured into dilute hydrochloric acid, excess of alkali added, and the solution extracted with ether; on evaporation of the ether, an oily residue is obtained consisting chiefly of quinoline and paratoluidine. The decomposition of methylacetanilide is therefore strictly analogous to that of ethylacetanilide. J. B. T.

Isomerism of Organic Substances containing Nitrogen. By L. Gattermann (*Ber.*, **23**, 1733—1737).—Nitroparacetyltoluide, $CH_3\cdot C_6H_3(NO_2)\cdot NHAc$ (1 . 3 . 4), can be obtained in two modifications, one of which is yellow and the other white, according as it is crystallised from water or alcohol. These two modifications readily pass into one another under various conditions. Thus the white variety is converted into the yellow compound a few degrees below its melting point, and either modification can be obtained at will by adding a crystal of the one required to the melted substance. The butyryl compound behaves, according to Broemme, in a similar manner. Another compound, closely related to the foregoing, acetylazimidotoluene, also exists in two similar forms (Bössneck, Abstr., 1886, 874; Zincke and Lawson, *Annalen*, **240**, 119); and the author and Ritschke, in their investigation of azoxyphenol ethers, find that a yellow and a white modification of parazoxyanisoïl can also be obtained.

To determine whether we have here to do with a case of physical or chemical isomerism, or with an example of stereometrically isomeric nitrogen compounds, further investigation is necessary. H. G. C.

Anilides and Toluidides of Tartaric Acid. By C. A. Bischoff and O. Nastvogel (*Ber.*, **23**, 2047—2051).—An amorphous compound, which seems to have the composition C_6H_5NO, is formed, together with tartranilic acid and various amorphous substances, when acid aniline tartrate is heated; it softens and decomposes at 200—225°, but without melting, and it is readily soluble in alcohol and glacial acetic acid, but only sparingly in benzene.

Tartaric diorthotoluidide, $C_{18}H_{20}N_2O_4$, is obtained when orthotoluidine tartrate (m. p. 151—152°) is heated with orthotoluidine at 160°; it crystallises from dilute alcohol in plates, melts at 182—183°, and is readily soluble in hot acetone, xylene, glacial acetic acid, and alcohol, but only sparingly in hot benzene, chloroform, and carbon bisulphide, and almost insoluble in ether and water. The *diacetyl*-derivative, $C_{22}H_{21}N_2O_6$, is formed when the ditoluidide is heated at 135—140° with acetic anhydride; it melts at 221—222°, and resembles the ditoluidide in its behaviour with solvents.

Tartaric diparatoluidide, $C_{18}H_{20}N_2O_4$, prepared from acid paratoluidine tartrate (m. p. 198° with decomposition), crystallises from hot alcohol in colourless needles, and melts at 264° with decomposition. The *diacetyl*-derivative, $C_{22}H_{21}N_2O_6$, separates from alcohol in crystals and melts at 202°. F. S. K.

Orthonitrodiphenylamine. By M. Schöpff (*Ber.*, 23, 1839—1844; compare Abstr., 1889, 772).—An increased yield of orthonitrodiphenylamine is obtained by preparing it from orthobromonitrobenzene, instead of orthochloronitrobenzene, aniline or glycerol being used as a solvent in place of alcohol. The result is still more satisfactory if the orthobromonitrobenzene is first sulphonated and then treated with aniline, nitranilidobenzenesulphonic acid [$NO_2 : NHPh : SO_3H = 1 : 2 : 5$] is formed, and on heating with hydrochloric acid in a sealed tube, it is converted, almost quantitatively, into orthonitrodiphenylamine. All attempts to prepare an acetyl-derivative of orthonitrodiphenylamine were fruitless.

Orthonitrophenylparamidotoluene, $NO_2·C_6H_4·NH·C_6H_4Me$ [$NH : NO_2 = 1 : 2$; $NH : Me = 1 : 4$], is obtained by heating orthobromonitrobenzene with excess of paratoluidine, the product is poured into dilute hydrochloric acid, and purified by distillation in a current of steam. The compound melts at 68°, and resembles the aniline-derivative in appearance. Experiments with the naphthylamines were unsuccessful, and no satisfactory results were obtained with bromonitrotoluene [$Me : NO_2 : Br = 1 : 3 : 4$].

Orthamidodiphenylamine, $NH_2·C_6H_4·NHPh$, is prepared by heating the nitro-compound with alcoholic ammonium sulphide in a sealed tube for four hours at 120°; the alcohol is evaporated, the residue treated with hydrochloric acid, boiled, filtered, and the base precipitated with ammonia. The compound crystallises from water in colourless needles melting at 79—80°; it is readily soluble in benzene, chloroform, and acetone, but less so in light petroleum; it is identical with the substance obtained from anilidoamidobenzoic acid [$COOH : NH_2 : NHPh = 1 : 3 : 4$] by distillation. The *hydrochloride* is prepared by adding concentrated hydrochloric acid to a solution of the base in dilute acid; it crystallises in needles, and gives a dark red coloration with ferric chloride; the same coloration is produced on exposure to air of an aqueous solution of the hydrochloride.

Orthophenylazimidobenzene,  $C_6H_4<\genfrac{}{}{0pt}{}{N:N}{NPh}>$, is obtained by the action of sodium nitrite on orthamidodiphenylamine dissolved in excess of dilute hydrochloric acid; the precipitate which forms is dissolved in alcohol, water is added, and after some time reddish needles are deposited, melting at 89—90°. This compound is isomeric with the substance obtained by Gattermann and Wichmann (compare Abstr., 1888, 829) from aniline and diazoamidobenzene. From its constitution, and the manner of its formation, Gattermann's compound should be called phenylpseudoazimidobenzene. J. B. T.

Derivatives of Diphenylamine and Phenazine. By R. Nietzki and O. Ernst (*Ber.*, 23, 1852—1856).—Toluylene-blue, $C_{15}H_{18}N_4$, has been shown to belong to the group of indamine dyes; it is prepared by the action of nitrosodimethylamine on diamidotoluene [$Me : NH_2 : NH_2 = 1 : 2 : 4$]. Toluylene-red, $C_{15}H_{16}N_4$, which is formed from toluylene-blue by the action of heat, is known to be an amidoazine (eurhodine). Since the indamines are derived from amidodiphenylamine, the leuko-base of toluylene-blue should have the formula $C_6H_2Me(NH_2)_2·NH·C_6H_4·NMe_2$ [$NH : (NH_2)_2 : Me = 1 : 2 : 4 : 5$; $NH : N = 1 : 4$], and the simplest analogue would be triamidodiphenylamine, $C_6H_3(NH)_2·NH·C_6H_4·NH_2$ [$NH : (NH_2)_2 = 1 : 2 : 4$; $NH : NH_2 = 1 : 4$].

Dinitramidodiphenylamine, $C_6H_3(NO_2)_2·NH·C_6H_4·NH_2$, is prepared from dinitrochlorobenzene [$Cl : (NO_2)_2 = 1 : 2 : 4$] and paradiamidobenzene by warming the alcoholic solution. The compound crystallises from benzene or chloroform in small, brownish-red leaves, having a metallic sheen, and melting at 177°; it is sparingly soluble in alcohol, and has tolerably well marked basic properties. The *hydrochloride* forms slightly yellow needles. The *picrate*,

$$C_{12}H_{10}N_4O_4,C_6H_2(NO_2)_3·OH,$$

crystallises in brown needles. On warming with acetic anhydride, the *monacetyl*-derivative is obtained, crystallising in ruby-red needles melting at 238°; the same compound may also be prepared by the action of dinitrochlorobenzene on monacetylparadiamidobenzene.

Diacetyldinitroamidodiphenylamine is formed by boiling the dinitro-compound for some time with acetic anhydride; it crystallises in brownish-yellow plates.

Triamidodiphenylamine hydrochloride is prepared by reducing the dinitro-compound with stannous chloride and hydrochloric acid, the stannochloride is precipitated by saturating with gaseous hydrogen chloride, and the tin eliminated with hydrogen sulphide; the compound crystallises in flat needles; which speedily become blue-violet on exposure to air. The *sulphate* crystallises in colourless, lustrous needles. A violet-blue compound is obtained by the oxidation of these salts, and although somewhat unstable, it still shows all the characteristic properties of the indamine dyes, and is undoubtedly the analogue of toluylene-blue.

2 . 2-*Diamidophenazine*, $C_{12}N_2H_6(NH_2)_2$, is prepared by boiling triamidodiphenylamine stannochloride with calcium carbonate and manganese dioxide. After filtration, the solution is treated with a little hydrochloric acid, and the hydrochloride precipitated with sodium chloride. The free base is obtained by the action of ammonia; it crystallises from water in dark yellow needles melting at 280°; the alcoholic and ethereal solutions are strongly fluorescent; with concentrated sulphuric acid, it gives a green coloration. which changes successively to blue, violet, and red on adding water. All the salts are red in solution. The *nitrate*, $C_{12}H_{10}N_4,HNO_3$, crystallises in greenish,

lustrous needles. The *picrate* forms needles having a brownish sheen. The *platinochloride*, $(C_{12}H_{10}N_4)_2,H_2PtCl_6 + H_2O$, is obtained as a fine crystalline precipitate, with a yellowish-green lustre.

Diacetyldiamidophenazine is prepared by heating diamidophenazine with acetic anhydride and acetic acid; it crystallises from dilute alcohol in yellow needles melting at 330°, and gives, with concentrated sulphuric acid, a red colour, which changes to yellow on adding water; if this solution is boiled, the acetyl-groups are eliminated.

The salts of diamidophenazine dye silk red; the tint is yellower than that obtained from the simpler saframines, but the dye can be of no technical importance on account of the yellow shade which is produced by relatively small quantities of alkalis.

Diamidophenazine may also be obtained by the oxidation of para- and meta-diamidobenzene, or by the action of quinonedichlorimide on meta-diamidobenzene. Phenazine is formed by treating diamidophenazine with sodium nitrite and dilute sulphuric acid. J. B. T.

Diacetylorthodiamines. By A. BISTRZYCKI and F. ULFFERS (*Ber.*, 23, 1876—1880); compare this vol., p. 969).—The following compounds have been prepared in addition to those already described; they are obtained by boiling the diamine (1 mol.) with the anhydride (3—4 mols.) for a few minutes; solid anhydrides may be dissolved in boiling benzene.

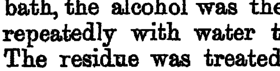
Diacetylorthophenylenediamine, $C_6H_4(NHAc)_2$, is deposited from water in long, slender, lustrous needles, or in thick crystals, melting at 185—186; it is readily soluble in water, alcohol, chloroform, acetone, and glacial acetic acid, but more sparingly in ether, benzene, and light petroleum. Dibenzoylorthophenylenediamine,

$$C_6H_4(NHBz)_2,$$

has already been prepared by a different method. *Diacetylorthodiamidotoluene*, $C_6H_3Me(NHAc)_2$ [Me : NHAc : NHAc = 1 : 3 : 4], is obtained from hot water in long, slender prisms melting at 210°; it resembles the phenylene compound in solubility; on distillation at ordinary pressure, it is converted into ethenyltoluyleneamidine. *Dipropionylorthodiamidotoluene*, $C_6H_3Me(NH{\cdot}COEt)_2$, crystallises from water in long, flat needles melting at 133°; it is very sparingly soluble in the ordinary menstrua. *Propenyltoluyleneamidine*, $C_6H_3{<}\genfrac{}{}{0pt}{}{NH}{N}{>}CEt$, is obtained in small quantity by distilling dipropionyldiamidotoluene under a pressure of 84 mm.; the distillate is dissolved in alcohol and the amidine precipitated with ammonia. It crystallises from dilute alcohol in characteristic interlaced needles melting at 166°. *Dicinnamylorthodiamidotoluene*, $C_6H_3Me(NH{\cdot}CO{\cdot}C_8H_7)_2$, is deposited from dilute alcohol in small, concentric needles, melting at 205—206° with previous softening. 1 . 2-*Dipropionylnaphthylenediamine*, $C_{10}H_6(NH{\cdot}COEt)_2$, crystallises from alcohol in fine prisms melting at 191—192; it is insoluble in ether and light petroleum. J. B. T.

Diazobenzene: a Correction. By T. SANDMEYER (*Ber.*, 23, 1880—1881).—The author refers to the papers of L. Gattermann and of G. Tobias (compare this vol., pp. 970, 1149), and points out that, owing to a printer's error in his original paper (compare Abstr., 1884, 1311); the word "water" was omitted from the description of the process for the preparation of diazobenzene chloride. J. B. T.

Intramolecular Transformation between a Diazo-salt-group and a Phenol-residue. By E. LELLMANN and H. BOYE (*Ber.*, 23, 1781—1783).—Orthonitrobenzyl chloride (1 mol.) was heated with ethylmetamidophenol (2 mols.) in alcoholic solution on the water-bath, the alcohol was then distilled off, and the residual oil extracted repeatedly with water to remove ethylamidophenol hydrochloride. The residue was treated with dilute hydrochloric acid, and a grey, crystalline powder of the *hydrochloride* of *orthonitrobenzylethylmetamidophenol*, $HO\cdot C_6H_4\cdot NEt\cdot CH_2\cdot C_6H_4\cdot NO_2,HCl$, was obtained. This was reduced by dissolving it in strong hydrochloric acid, and allowing the solution to remain with rather more than the calculated quantity of stannous chloride. The greater part of the hydrochloric acid was then evaporated, the residue diluted with much water, cooled, and poured into a cold solution of ammonium sulphide; *orthamidobenzylethylmetamidophenol*, $HO\cdot C_6H_4\cdot NEt\cdot CH_2\cdot C_6H_4\cdot NH_2$, then separated in small, brilliant, nearly colourless plates, which after recrystallisation from ether melted at 145°. It was dissolved in dilute hydrochloric acid and heated with sodium nitrite (1 mol.); the solution turned brown. After remaining for 24 hours, the colouring matter was precipitated by adding sodium acetate, and when dried formed a dark-brown powder with a green fluorescence. It may be called *azobenzylethylamidophenol* or *azoxyethylbenzylaniline*, as it has the constitution



$HO\cdot C_6H_3{<}\genfrac{}{}{0pt}{}{N{=\!=}N}{NEt\cdot CH_2}{>}C_6H_4$ [N : NEt : OH = 1 : 2 : 4, N : CH₂ = 1 : 2];

probably the diazochloride, $HO\cdot C_6H_4\cdot NEt\cdot CH_2\cdot C_6H_4NNCl$, is formed as a stage in the reaction. It behaves like an azo-colouring matter, and dyes silk a yellowish-brown which is hardly altered by acids or alkalis. It is decolorised by reducing agents, and dissolves easily in alcohol, acetic acid, and phenol. C. F. B.

Reduction of Nitro-azo-compounds by Alcoholic Ammonium Sulphide. By C. WILLGERODT (*J. pr. Chem.* [2], 42, 49—56). —*Dihydroparadinitro-azobenzene* has been obtained by the author from paradinitro-azobenzene (m. p. 215—220°) by the action of alcoholic ammonium sulphide; it melts at 248—250°, but by recrystallisation the melting point falls, owing to decomposition; the compound obtained by Lermentoff (this Journal, 1872, 503), and called dinitro-hydrazobenzene by him and by Janovsky (Abstr., 1885, 789), is undoubtedly identical with it, notwithstanding that Lermentoff gives the melting point as 220°. Janovsky (*loc. cit.*) describes a nitro-azo-benzenenitrolic acid (m. p. 218°), which gives very similar reactions to the author's dihydroparadinitro-azobenzene. By carefully following Janovsky's directions, the author has failed to obtain this nitrolic acid, but has always obtained dihydroparadinitro-azobenzene; he, therefore, concludes that all these three substances are identical.

When ortho- or paranitro-azobenzene is shaken with alcoholic ammonium sulphide, and the solution precipitated by water, the corresponding azoxybenzenes (m. p. 212°, uncorr.) are obtained; they are very similar to each other, and are identical with Janovsky's hexazoxybenzene (Abstr., 1886, 794). When the precipitated azoxybenzene is dissolved in alcohol, precipitated by water, and dried over calcium chloride, a compound,  $O<\begin{matrix}NH(OH)\cdot C_6H_4\cdot N_2Ph\\ | \\ NH(OH)\cdot C_6H_4\cdot N_2Ph\end{matrix}$, is obtained. When an ethereal solution of the azoxybenzene is mixed with alcoholic platinic chloride, 'a *platinochloride*, $ON_2(PhN_2\cdot C_6H_4)_2,H_2PtCl_6$, is produced. When the compound precipitated by water from alcoholic solution (see above) is further dried at 40—50° over calcium chloride, an azohydroxyazobenzene, $PhN_2\cdot C_6H_4\cdot NOH$ (Janovsky's nitrolic acid), is obtained; a *platinochloride* thereof is described. A. G. B.

Isomeric Hydrazones of Orthonitrophenylglyoxylic Acid. By H. C. Fehrlin (*Ber.*, 23, 1574—1587).—When the hydrazones of phenylglyoxylic acid, acetophenone, and benzaldehyde are heated with either aqueous or alcoholic potash, and sulphuric acid added to the solution, the original substance is regenerated, and the same is the case with the hydrazone of metanitrophenylglyoxylic acid; but orthonitrophenylglyoxylic acid hydrazone, though not acted on by aqueous potash, is converted, even in the cold, by alcoholic potash into an isomeric compound, which is precipitated by the addition of acids.

Metanitrophenylglyoxylic acid hydrazone was obtained by adding an acetic acid solution of phenylhydrazine to an aqueous solution of the acid. It crystallises from glacial acetic acid in transparent, yellow, quadrangular plates which melt with decomposition at 174—175°. It yields no isomeric compound when treated with potash.

Orthonitrophenylglyoxylic Acid Hydrazone.—The acid was prepared by Claissen and Shadwell's method, the improvements introduced being described in detail. Orthonitrobenzoyl chloride was heated for 24 hours 100° in a sealed tube with silver cyanide. The contents of the tube were extracted with ether, and the oil (cyanide) left after evaporating the ether was shaken with fuming hydrochloric acid, and allowed to remain; in three to four hours it was converted into the amide, which, after recrystallisation from benzene, melted at 199° (if from water, at 192°). This was dissolved in water and heated with potash until a slight smell only of ammonia could be perceived; the solution was then acidified, when orthonitrophenylglyoxylic acid was obtained as a brownish oil, solidifying to groups of small, colourless needles, which melted at 49°. The acid was dissolved in water, phenylhydrazine dissolved in acetic acid was added, and the hydrazone obtained by concentrating the solution. When recrystallised from alcohol, it forms transparent, red crystalline aggregates; from acetic acid, it crystallises in small, yellow, transparent tables; it melts with decomposition at 165—166°. When treated with an alcoholic alkaline solution, it is converted into an isomeric compound, which separates as a yellow precipitate when the solution is acidified, and crystallises from alcohol in brilliant, golden needles melting with decomposition at 189—190°, and becoming superficially green when exposed to light. A saturated solution in acetic acid (sp. gr. 1·06) contains at 19° and 20°, 1·06 and 1·24 parts of the hydrazone, and

0·24 and 0·28 parts of the isomeride. Both are insoluble in water and light petroleum, and nearly so in benzene, but dissolve in alcohol, ether, and acetic acid, the isomeride less readily. They are not acted on by dilute acids or strong hydrochloric acid; in concentrated sulphuric acid they give yellow solutions, which yield a resinous product when diluted with water. The original hydrazone dissolves easily in strong nitric acid, and on pouring the solution into water, yellow crystals are obtained, melting at 77—80°. The isomeric compound dissolves with difficulty, and only when the solution is heated; the product melts at 98—100°. Both these compounds give unstable, purple solutions with alkalis, and an unstable, deep-violet substance when treated with gaseous ammonia. The hydrazone is easily soluble in aqueous alkalis, the isomerides only with difficulty; the addition of an acid reprecipitates the substance in both cases.

Orthophenylglyoxylic acid methylhydrazone was prepared as above, using methylphenylhydrazine instead of phenylhydrazine; it separates out when the solution is warmed, and crystallises from alcohol in reddish-yellow needles melting at 141—142°. It forms no isomeric compound when treated with alkalis. With strong nitric acid, it yields a deep blue-green solution; with strong sulphuric acid, a violet solution.

The fact that the two hydrazones of orthonitrophenylglyoxylic acid give different compounds when treated with strong nitric acid, shows that they are chemically, and not merely physically, isomeric. And that the isomerism is due to a change in place of the hydrogen-atom of the hydrazone-group is shown by the methylhydrazone yielding no isomeride. The following two formulæ are therefore proposed:—

$NHPh\cdot N{:}C(COOH)\cdot C_6H_4\cdot NO_2.$

The hydrazone (165—166°).

$$\begin{matrix}NH-\\ |\\ NPh\end{matrix}\!>C(COOH)\cdot C_6H_4\cdot NO_2.$$

The isomeride (189—190°).

These are to some extent supported by the fact that the two substances appear to behave in the same manner when reduced, both yielding a yellow product of amido-oxindol. C. F. B.

Azohydrazine and Polyazo-compounds. By C. Willgerodt (*J. pr. Chem.* [2], 41, 563—565).—The author and his pupils have obtained the following compounds by methods which will be fully detailed in a future communication.

Picrylparachlorophenylhydrazine.—This occurs in two modifications; the *red* variety crystallises in slender, reddish-yellow prisms which melt with decomposition at 170—175°; the *yellow* variety crystallises in very small, transparent, yellow needles which melt with decomposition at 176°, and are unstable, being converted into the red variety by heating with alcohol. Long digestion with alcohol converts both varieties into *dinitrosonitroparachlorazobenzene*,

$$C_6H_4Cl\cdot N_2\cdot C_6H_2(NO)_2\cdot NO_2,$$

melting at 199—200°. Similar treatment with glacial acetic acid converts them into *dinitronitrosoparachlorazobenzene*, melting at 241—242°, whilst oxidation with chromic acid converts them into *trinitroparachlorazobenzene*, $C_6H_4Cl\cdot N_2\cdot C_6H_2(NO_2)_3$, melting at 138—139°.

Tetranitroparachlorazobenzene, $NO_2\cdot C_6H_3Cl\cdot N_2\cdot C_6H_2(NO_2)_3$, melts at 184—185°. *Trinitronitrosoparachlorazobenzene*,

$$NO_2\cdot C_6H_3Cl\cdot N_2\cdot C_6H_2(NO_2)_2\cdot NO,$$

melts at 180—181°. *Trinitronitrosoazobenzenephenylhydrazine*,

$$NHPh\cdot NH\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_2(NO_2)_2\cdot NO,$$

melts at 130—131°. *Trinitronitrosoazobenzeneparachlorophenylhydrazine*, $C_6H_4Cl\cdot NH\cdot NH\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_2(NO_2)_2\cdot NO$, melts at 145—156° (? 146°). *Trinitronitrosoazobenzeneazoparachlorobenzene*, $C_6H_4Cl\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_2(NO_2)_2\cdot NO$, melts at 98—99°. *Trinitronitrosoazobenzenenitroazoparachlorobenzene*,

$$NO_2\cdot C_6H_3Cl\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_2(NO_2)_2\cdot NO,$$

melts at 111—112°. *Tetranitronitrosodisazobenzeneparachlorophenylhydrazine*, $C_6H_4Cl\cdot N_2H_2\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_3(NO_2)\cdot N_2\cdot C_6H_2(NO_2)_2\cdot NO$, melts at 238—239°. *a-Dinitrophenylparachlorophenylhydrazine*,

$$C_6H_4Cl\cdot N_2H_2\cdot C_6H_3(NO_2)_2\ [Cl:(NH) = 4:1, \text{ and } (NO_2)_2 = 2:4],$$

melts at 146—147°. *Dinitroparachlorazobenzene*,

$$C_6H_4Cl\cdot N_2\cdot C_6H_3(NO_2)_2,$$

melts at 151—152°. *Nitronitrosoparachlorazobenzene*,

$$C_6H_4Cl\cdot N_2\cdot C_6H_3(NO_2)\cdot NO,$$

melts at 141—142°. *Dinitrosoparachlorazobenzene*,

$$C_6H_4Cl\cdot N_2\cdot C_6H_3(NO)_2,$$

melts at 135—136°.

Picrylmetachlorophenylhydrazine forms orange prisms which melt at 178—179° (uncorr.). Two bromo-derivatives of the picrylorthohydrazine compound have been obtained; the lower one crystallises in yellow needles melting at 269°; the higher one in red-yellow needles melting at 170°. A. G. B.

Azoxyphenol Ethers. By L. GATTERMANN and A. RITSCHKE (*Ber.*, **23**, 1738—1750).—In many reactions the phenol ethers behave in a similar manner to the hydrocarbons, and the authors have therefore examined the reduction-products of their nitro-compounds in order to ascertain whether isomerides exist similar to those described by Janovsky for azoxytoluene. In the meantime, however, Hantsch and Werner have shown that in the latter case no isomerism exists, and the authors also find that with the azoxyphenol ethers no isomerism of the ordinary kind exists. As already mentioned, however (see preceding abstract), one of these compounds, namely, parazoxyanisoïl, exists in a yellow and white modification.

Paranitrophenetoïl gave, on reduction with sodium in methyl alcohol solution, a mixture of two compounds, of which the one occurring in larger quantity, is azoxyanisoïl, $O\langle\begin{matrix}N\cdot C_6H_4\cdot OMe\\ | \\ N\cdot C_6H_4\cdot OMe\end{matrix}$, and not, as expected, azoxyphenetoïl, $O\langle\begin{matrix}N\cdot C_6H_4\cdot OEt\\ | \\ N\cdot C_6H_4\cdot OEt\end{matrix}$. In presence of an excess of methyl alcohol, the ethyl-group is therefore displaced by methyl. This compound is also obtained by the reduction of paranitranisoil with sodium in methyl alcohol solution, but if ethyl alcohol is employed, the chief product is azoxyphenetoïl. A subsidiary product is also obtained in this case, identical with the second of the two compounds obtained from paranitrophenetoïl; it has the constitution  $O<\begin{matrix}N\cdot C_6H_4\cdot OMe\\ |\\ N\cdot C_6H_4\cdot OEt\end{matrix}$.

An attempt was made to prepare this in larger quantity by reducing a mixture of paranitroanisoil and paranitrophenetoïl in molecular proportion, with sodium and methyl alcohol. It was found, however, that the paranitrophenetoïl is first completely converted into paranitroanisoil, which is then reduced to azoxyanisoïl. The same mixture was then reduced with sodium and a mixture of methyl and ethyl alcohols, when a compound was obtained having a different melting point from the mixed compound above described; it is at present being further investigated.

All these compounds when first melted form a milky liquid, which only becomes clear on raising the temperature. Thus azoxyanisoil melts at 116°, and becomes clear at 134°; azoxyphenetoïl melts at 134°, and becomes clear at 165°; whilst the mixed compound melts at 86°, and becomes transparent at 116°. They belong, therefore, to the class described by Lehmann as fluid crystals. H. G. C.

Phenylsuccinazone. By G. Ciamician and C. U. Zanetti (*Ber.*, **23**, 1784—1787).—A dilute aqueous solution of succinaldioxime, prepared from pyrroline (compare Abstr., 1889, 1208), was gently warmed with five times the quantity of phenylhydrazine acetate; the solution was cooled, and the precipitated phenylsuccinazone purified by recrystallising it once from boiling alcohol; it melted at 124—125°. When it is rubbed in a mortar with 25 times its weight of strong hydrochloric acid, phenylhydrazine hydrochloride separates, and a yellow solution is obtained containing a weak base, which is precipitated in white or pinkish flakes when the solution is diluted with water. It was boiled repeatedly with alcohol and recrystallised from ethyl acetate, forming thin, white needles which melt with decomposition at 184—185°. It dissolves in strong acids, but is precipitated when the solutions are diluted; with sulphuric acid and potassium chromate, it gives a deep blue colour; it yields a yellow, amorphous platinochloride, and it disssolves in ether, boiling ethyl acetate, hot benzene, and acetic acid, sparingly in alcohol, and not at all in light petroleum. An analysis and a molecular weight determination by Raoult's method showed that it has the formula $C_{20}H_{20}N_4$. It appears to be neither a pyrroline- nor a pyridazine-derivative, but is probably closely allied to, perhaps a lower homologue of, the compound $C_{22}H_{21}N_4$, obtained by Ach (this vol., p. 70), by reducing methylphenylpyridazone,  $<\begin{matrix}CMe{:}N\cdot NPh\\ CH{:}CH\cdot CO\end{matrix}>$ with sodium and alcohol. C. F. B.

Cyanogen Additive Products of some Amidoximes. By O. Nordenskjöld (*Ber.*, **23**, 1462—1464).—*Dicyanobenzenylamidoxime*,

$C_9H_8N_4O$, is precipitated in needles when cyanogen is passed into an alcoholic benzene solution of benzenylamidoxime. It melts at 116°, is only sparingly soluble in benzene, and is gradually decomposed by boiling alcohol and boiling water; it is decomposed by dilute hydrochloric acid and warm soda, and when warmed with acetic anhydride it yields acetylbenzenylamidoxime (m. p. 96°).

Dicyano-β-naphthenylamidoxime, $C_{13}H_{10}N_4O$, separates in crystals when cyanogen is passed into an alcoholic solution of β-naphthenylamidoxime; it melts at 118—119°, and resembles the preceding compound, than which, however, it is rather more readily soluble in benzene. F. S. K.

Isomerism of the Aldoximes. By E. Beckmann (*Ber.*, **23**, 1680—1692).—The author's previous researches on the two isomeric benzaldoximes (Abstr., 1889, 607, 979) have led to the conclusion that their constitution is represented by the formulæ CHPh:N·OH and  $\left.\begin{array}{l}\mathrm{NH}-\\ |\\ \mathrm{CHPh}\end{array}\right>\mathrm{O}$, the chief ground for this supposition being that their benzyl ethers, in the preparation of which only small quantities of bye-products are formed, contain the benzyl-group attached to the oxygen-atom and to the carbon-atom respectively. Goldschmidt, on the contrary, regards the two oximes as structurally identical, inasmuch as both combine with phenyl cyanate in the absence of water (this vol., p. 253), and his conclusions have been further adopted by Hantzsch and Werner (this vol., p. 318). The author has investigated this reaction more closely, and finds that with the reagent in question intramolecular change readily takes place, even at a low temperature, and that, further, the β-benzyl ether itself can combine with a molecule of phenyl cyanate. Hence, no conclusion as to the presence or absence of a hydroxyl-group can be drawn from the behaviour of this reagent. As regards the formation of benzonitrile from β-benzaldoxime, from which certain theoretical conclusions have been drawn by Hantzsch and Werner (*loc. cit.*), the author shows that this is not formed directly, but that the first product of the reaction is benzamide.

For the preparation of α-benzaldoxime, benzaldehyde is mixed with an excess of 20—25 per cent. soda solution, and hydroxylamine hydrochloride added in small portions at a time; the solution is then extracted with ether, and the oxime precipitated by passing in carbonic anhydride. For further purification, the oxime is added to an alcoholic solution of sodium ethoxide, when the α-sodium salt is precipitated, whilst the β-compound present remains in solution.

β-Benzaldoxime is most readily obtained by passing dry hydrogen chloride into an ethereal solution of the α-compound; the precipitated hydrochloride is washed with ether, and passed into a separating funnel containing ether and a concentrated soda solution. After shaking, the oxime remains in the ether, and is obtained on evaporating the latter in almost the theoretical quantity. It crystallises in rhombic tablets ($a : b : c = 0·5612 : 1 : 0·404$), and if washed with or crystallised from benzene does not undergo spontaneous conversion into the α-oxime.

α-Anisaldoxime is always formed by the direct action of hydroxylamine on anisaldehyde. It is thus obtained in vitreous, rhomboidal crystals which melt at 61—62°, and are soluble in alcohol and still more readily in benzene. Its *benzyl ether*, $C_{15}H_{15}NO_2$, may be obtained from it by the action of sodium ethoxide and benzyl chloride, or by the action of α-benzylhydroxylamine on anisaldehyde. It forms small plates which melt at 46·5°, and does not yield a hydrochloride.

β-Anisaldoxime is prepared from the α-compound in a manner similar to β-benzaldoxime. It is very sparingly soluble in benzene, and may thus be readily separated from the α-compound. It crystallises in slender needles melting at 130—130·5°, and is much more stable towards alcohol than the corresponding β-benzaldoxime, but not towards ether. Its *benzyl ether*, formed from it by the action of sodium ethoxide and benzyl chloride, or obtained directly from anisaldehyde and β-benzylhydroxylamine, crystallises in square, colourless tables melting at 106—107°. Its *hydrochloride* melts at 167—168° with evolution of gas.

By the action of a solution of hydrogen chloride in acetic acid containing acetic anhydride on α-benzaldoxime, the latter is at once converted into the β-compound, and after remaining for two days at the ordinary temperature, large quantities of benzamide separate. If no anhydride is employed, benzamide can only be detected after four days, but in this case no benzonitrile is formed. With anisaldoxime, the same reactions occur, but the formation of the nitrile takes place more readily. For anisamide, the author finds the melting point 163—164°, instead of 137—138°, as given by Henry (*Ber.*, **2**, 666), and has confirmed this by preparing the compound direct from anisic acid.

The above results show that both β-compounds form an intermediate product between the α-oximes and the amide; this is in full agreement with the constitutional formulæ given above.

H. G. C.

A Dimolecular Isomeride of Benzaldoxime. By R. BEHREND and E. KÖNIG (*Ber.*, **23**, 1773—1779).—To an acetic acid solution of β-benzylhydroxylamine, ether was added, and then a solution of potassium dichromate. Some benzaldoxime was formed, and, in addition, a white, crystalline substance separated, and was collected, washed with water, alcohol, and ether, and recrystallised from hot acetic acid or from chloroform. It forms prisms or tables melting at about 127—128°, and is an isomeride of benzaldoxime. It is not, however, isobenzaldoxime, for although it has the same melting point as the latter, it differs in crystalline form, in solubility, in resisting the action of acids, and in being insoluble in alkalis. It dissolves easily in chloroform, sparingly in alcohol, ether, benzene, and acetic acid, and not at all in water. By Raoult's method it was shown to have double the molecular weight of benzaldoxime, and it yields very distinctly Liebermann's reaction for the nitroso-group; hence it is probably a *di-nitrosotoluene*, $(CH_2Ph)_2N_2O_2$, perhaps

$$\begin{array}{l} CH_2Ph\cdot N\cdot O \\ \quad\quad\quad\;\; | \quad\;\; > \\ CH_2Ph\cdot N\cdot O \end{array}$$

. When boiled with alcohol, it is transformed quantitatively into isobenzaldoxime. When treated with sodium ethoxide and benzyl chloride, it yields *benzyl-isobenzaldoxime*,  $O<\begin{matrix}N\cdot CH_2Ph\\ | \\ CHPh\end{matrix}$, melting at 81—82°; some benzylbenzaldoxime being probably formed at the same time. When warmed with phenol and sulphuric acid, it gives an intense reddish-violet solution; if potash is now added, the colour becomes greenish-yellow to blue-green, and further changes to a pure deep blue on the addition of water. It does not form salts.

The rest of the paper is devoted to a reply to Willgerodt, who has reproached Behrend with not mentioning, in his paper on the stereochemistry of nitrogenous compounds, his (Willgerodt's) work on hydrazines. C. F. B.

Mercurobenzamide. By H. Schiff (*Ber.*, 23, 1816—1817; compare Tafel and Enoch, this vol., p. 973).—Mercurobenzamide may be recrystallised from aqueous potash; it is not acted on by either potassium iodide or ethyl bromide. A neutral aqueous solution of mercurobenzamide may be boiled with copper turnings without decomposition taking place. No reaction occurs on boiling ethyl chlorocarbonate with mercurobenzamide suspended in anhydrous ether; if absolute alcohol is used in place of the ether, ethyl carbonate, mercuric chloride, and benzamide are formed. Mercurobenzamide is readily decomposed by acids, or by hydrogen sulphide. Ethyl chlorocarbonate has no action on benzamide suspended in ether, but on boiling with 95 per cent. alcohol, ethyl benzoate and ammonium chloride are obtained. J. B. T.

Derivatives of Amidocinnamic Acid. By F. W. Rothschild (*Chem. Centr.*, 1890, i, 905—906; *Inaug. Diss., Berlin*).—Orthoamidocinnamic acid is converted into the corresponding carbamide or *orthouramidocinnamic acid*, $NH_2\cdot CO\cdot NH\cdot C_6H_4\cdot C_2H_2\cdot COOH$, by treatment with potassium cyanate in hydrochloric acid solution. If treated with potassium thiocyanate, *thiocyanamidocinnamic acid*,

$$CNS\cdot NH_3\cdot C_6H_4\cdot C_2H_2\cdot COOH,$$

is formed, melting at 152°. When heated at 110—120°, it is converted into *orthothiouramidocinnamic acid*,

$$NH_2\cdot CS\cdot NH\cdot C_6H_4\cdot C_2H_2\cdot COOH,$$

melting at 236—239°. When heated at 100° in a sealed tube with allyl isocyanate, *orthoallylthiouramidocinnamic acid*,

$$C_3H_5\cdot NH\cdot CS\cdot NH\cdot C_6H_4\cdot C_2H_2\cdot COOH,$$

is formed, melting at 204—208°; in like manner, with phenyl isocyanate, it yields *orthophenylthiouramidocinnamic acid*,

$$NHPh\cdot CS\cdot NH\cdot C_6H_4\cdot C_2H_2\cdot COOH,$$

melting point 235—237°. With carbon bisulphide, *orthocarboxycinnamyldithiocarbamic acid*, $CSSH\cdot NH\cdot C_6H_4\cdot C_2H_2\cdot COOH$, is formed, melting at 185—187°.

With meta- and para-amidocinnamic acids, only the thiocyano-derivatives could be obtained. *Metathiocyanamidocinnamic acid*, obtained by means of cuprous thiocyanate, melts at 148—149°. The para-acid does not melt at 272°.

If it is heated rapidly, it suffers decomposition. The corresponding carbamide was obtained. J. W. L.

Oxanilic Acid. By O. Aschan (*Ber.*, 23, 1820—1825).—Oxanilic acid is best prepared by heating 20 grams of aniline with 25 grams of anhydrous oxalic acid, in an oil-bath, at 130—140° for about an hour. The finely divided product is boiled with 300—400 c.c. water, and filtered hot; the aniline oxanilate, which crystallises out on cooling, is well washed with cold water, and decomposed with boiling dilute sulphuric acid—25 c.c. concentrated acid, 475 c.c. water, and 50 grams oxanilate. When cold, the solution is shaken with ether, the ether evaporated, and the residual oxanilic acid purified by recrystallising from water; the yield is 73 per cent. of the aniline employed, as against 15—20 per cent. obtained by the usual method. The salts of oxanilic acid are all sparingly soluble in water, and are very stable towards dilute acids. The *silver*, *lead*, and *mercuric* salts form crystalline precipitates. Hydrogen salts of the alkali metals are prepared by adding a 5 per cent. solution of oxanilic acid to a concentrated solution of an alkaline nitrate. *Hydrogen potassium oxanilate*, $C_{16}H_{13}N_2O_6K + H_2O$, crystallises in long, flat prisms; the corresponding *ammonium salt* forms transparent prisms. *Hydrogen sodium oxanilate*, $C_{16}H_{13}N_2O_6Na + 3H_2O$, is deposited in lustrous leaves, which are very sparingly soluble. *Oxanilyl chloride*, NHPh·CO·COCl, is prepared by the action of phosphorus pentachloride on oxanilic acid; it is deposited from light petroleum in large, lustrous leaves, or flat prisms, melting at 82·5°; it is very hygroscopic. Oxanilide is formed by the action of aniline on oxanilyl chloride, whilst with alcoholic ammonia phenyloxamide is obtained. On adding a large excess of water to oxanilyl chloride, oxanilic acid is immediately formed; if the chloride is treated with half its weight of water, it is decomposed into oxanilide, hydrochloric acid, carbon monoxide, and carbonic anhydride. Phenylcarbamide is obtained by the distillation of the chloride; the yield is 75 per cent. of the theory. J. B. T.

Toluyleneurethane and Tolueneoxamethane. By H. Schiff and A. Vanni (*Ber.*, 23, 1817—1819).—Toluylenediurethane is best prepared by gradually adding ethyl chlorocarbonate to a well cooled solution of diamidotoluene, dissolved in dilute alcohol; the diurethane immediately separates in crystals melting at 137°. The mother liquor contains diamidotoluene hydrochloride, and toluenesemiurethane hydrochloride. Toluylenediurethane is scarcely affected by heating with alcoholic ammonia at 130—140°. No reaction takes place with aniline in dilute alcoholic solution, but on heating the diurethane with aniline alone, diphenylcarbamide is formed. On heating the diurethane with phenylthiocarbamide, no change occurs; the addition of dilute alcohol causes a complicated decomposition, the chief product being phenylthiourethane, NHPh·CS·OEt. *Toluylenesemi-*

urethane, $NH_2\cdot C_7H_6\cdot NH\cdot COOEt$, is obtained from the mother liquors (see above) by evaporating to dryness, treating with excess of potassium hydroxide, and recrystallising several times from dilute alcohol, in which it is readily soluble; it forms colourless, flat, interlaced needles melting at 90—91°. The *hydrochloride* is readily soluble in water; the *platinochloride* forms small crystals. *Thiocarbanilotoluyleneurethane*, $COOEt\cdot NH\cdot C_7H_6\cdot NH\cdot CS\cdot NHPh$, is obtained, together with diphenylthiocarbamide, by heating toluylenesemiurethane with phenylthiocarbamide and dilute alcohol; it is very sparingly soluble in alcohol, from which it crystallises in colourless prisms melting at 154—155°. *Amidotoluyloxamic acid*,

$$NH_2\cdot C_7H_6\cdot NH\cdot CO\cdot COOH,$$

is formed by boiling toluyldioxamethane, obtained in the preparation of toluyleneoxamethane, with 90 per cent. alcohol for some time; it forms small, hard crystals melting at 222—224°, and is very sparingly soluble in alcohol.

Thiocarbanilotoluyleneoxamethane,

$$NHPh\cdot CS\cdot NH\cdot C_7H_6\cdot NH\cdot CO\cdot COOEt,$$

is obtained by warming phenylthiocarbamide with toluyleneoxamethane dissolved in dilute alcohol. The compound is purified by repeated recrystallisation from alcohol; it forms small, yellowish crystals melting at 154—155°. Two compounds containing sulphur may be separated from the mother liquor; the one is obtained as a yellow, crystalline powder melting at 198°, it is sparingly soluble in warm alcohol, and has the formula  $C_7H_6<\genfrac{}{}{0pt}{}{NH\cdot C_2O_2}{NH\cdot CS}>NPh$; it is probably formed from the above oxamethane-derivative by elimination of alcohol. The second compound crystallises in lustrous leaves melting at 136—138°, and is only formed in very small quantity.

J. B. T.

Triphenylguanylthiocarbamide and Dicyanodiamide. By B. RATHKE and R. OPPENHEIM (*Ber.*, 23, 1668—1675; compare Rathke, Abstr., 1887, 662).—Dicyanodiamide is formed from guanylthiocarbamide by elimination of the elements of hydrogen sulphide; in a similar manner, *triphenyldicarbimide* is obtained from triphenylguanylthiocarbamide.

Dicyanodiamide may be represented by one or other of the formulæ $NH_2\cdot CNH\cdot NH\cdot CN$;  $NH{:}C<\genfrac{}{}{0pt}{}{NH}{NH}>C{:}NH$. The constitution of the triphenyl-derivative can, however, only be expressed by a ring formula, corresponding with the second of the above; as it differs widely in general properties from dicyanodiamide, the latter would appear to be best represented by the open-chain formula. *Triphenyldicarbimide*, $C_{20}H_{16}N_4$, is obtained by boiling an alcoholic solution of triphenylguanylthiocarbamide,

$$NHPh\cdot CS\cdot NH\cdot C(NPh)\cdot NHPh,$$

with freshly precipitated mercuric oxide; it is most conveniently purified by treating the alcoholic solution with hydrochloric acid, and diluting with water; the crystals of the hydrochloride which separate are then treated with sodium carbonate. The *free base* crystallises with 1 mol. of alcohol, in fine, long, yellowish needles melting at 70—74°. The hydrochloride is very sparingly soluble; it crystallises in slender needles. The platinochloride forms reddish-yellow crystals, containing 1 mol. of water. The sulphate is sparingly soluble. The picrate melts at 53°. The free base may also be prepared by heating diphenylguanidine for an hour at 170—180°; the product is dissolved in alcohol, allowed to stand for 24 hours, filtered, and hydrochloric acid added to the hot solution; the hydrochloride, which separates on cooling, is then treated as above.

Triphenylbiguanide, $C_{20}H_{19}N_5$, is obtained by boiling triphenylguanylthiocarbamide with silver nitrate and ammonia in excess. The silver sulphide is removed, the solution concentrated, and treated with hydrochloric acid; the mixed crystals are separated by recrystallisation from dilute alcohol, in which triphenylbiguanide hydrochloride is readily soluble. The free *base* crystallises from alcohol in colourless prisms melting at 137°. The hydrochloride crystallises from alcohol in thin, pointed prisms. The platinochloride forms reddish-yellow crystals. The nitrate, oxalate, and acetate have also been prepared. The same base may be obtained by treating diphenylguanidine with phenylcyanamide in ethereal solution; after remaining for a week, the ether is evaporated, and the residue treated first with hydrochloric acid, and then with ether; the insoluble portion consists of triphenylbiguanide hydrochloride.

Triphenylthiammeline has already been prepared; it is also formed by boiling the additive compound of diphenplguanidine and phenylthiocarbamide with alcohol and mercuric thiocyanide.

Experiments have shown that ammonia, or thiocyanic acid, only reacts with triphenyldicarbimide at the moment of its formation.

J. B. T.

Action of Hydroxylamine and its Derivatives on the Thiocarbimides. By L. VOLTMER (*Chem. Centr.*, 1890, i, 861—862; from *Inaug. Diss.*, *Berlin*).—Hydroxylamine and phenylthiocarbimide combine together at ordinary temperatures with formation of *phenylhydroxythiocarbamide*, NHPh·CS·NH·OH, which decomposes, when melted, into a gas and an oily product. The alcoholic solution, which is slightly acid, is coloured violet by very dilute ferric chloride. By heating the alcoholic solution, sulphur and phenylcyanamide are formed; the latter melts at 39—40°. If hydroxylamine and the thiocarbimide are heated together, the same reaction seems to occur. Ethoxylamine reacts similarly with phenylthiocarbimide with formation of *phenylethoxythiocarbamide*,

NHPh·CS·NH·OEt,

which melts at 103° without decomposition. It is more stable than the first named; but by boiling its solution sulphur, alcohol, and phenylcyanamide are formed.

Phenylmethoxythiocarbamide melts at 115°. *Phenylbenzyloxythiocarbamide*, NHPh·CS·NH·OC_7H_7, prepared from benzylhydroxylamine and phenylthiocarbimide, melts at 105°. *Orthotolylhydroxythiocarbamide* is obtained at ordinary temperature from the action of orthotolylthiocarbimide in chloroform on hydroxylamine; it melts at 92°. *Orthotolylcyanamide*, obtained from this by warming the solution, melts at 77°. When heated with hydrochloric acid, it is converted into monotolylcarbamide. *Orthotolylbenzyloxythiocarbamide* melts at 125°; *α-naphthylhydroxythiocarbamide*, $C_{10}H_7\cdot NH\cdot CS\cdot NH\cdot OH$, prepared from the thiocarbimide and hydroxylamine, melts at 116°. Ferric chloride colours the alcoholic solution from dark-yellow to green. The α-naphthylcyanamide obtained from it melts at 150°. The corresponding benzyloxycarbamide melts at 132—133°.

Allylthiocarbimide reacts violently with hydroxylamine with separation of sulphur, but the corresponding carbamide could not be obtained.

Carbanil and benzylhydroxylamine react together with formation of *phenylbenzyloxycarbamide*, $NHPh\cdot CO\cdot NH\cdot OC_7H_7$, melting at 106°. It is very stable. J. W. L.

Paramethoxydihydroxydihydroquinoline and a New Case of Stereochemical Isomerism. By A. EICHENGRÜN and A. EINHORN (*Ber.*, **23**, 1489—1494).—*Orthonitrometachlorophenylbromopropionic acid*, prepared by treating orthonitrometachlorocinnamic acid with hydrobromic acid, crystallises from alcohol in needles melting at 142·5—143·5°; when carefully neutralised with concentrated ammonia in the cold, it yields a lactone which crystallises from ethyl acetate in prisms melting at 147°, and shows all the properties of an orthonitro-β-lactone. When this lactone is boiled with alkalis, it is converted into orthonitrometachlorophenyllactic acid; this acid can also be obtained from orthonitrometachlorophenylbromopropionic acid by dissolving it in warm ammonia and heating the resulting *orthonitrometachlorophenyllactamide*, a crystalline substance melting at 148°, with dilute sulphuric acid.

Orthonitrometachlorophenyllactic acid separates from water and ether in crystals and melts at 152°; when heated under pressure with potassium methoxide and methyl alcohol, it is converted into the sparingly soluble potassium salt of orthonitrometamethoxyphenyllactic acid, from which the free acid can be obtained by decomposition with a dilute mineral acid.

Orthonitrometamethoxyphenyllactic acid crystallises from water in colourless plates melting at 106°; on reduction with ferrous sulphate and ammonia, it yields *paramethoxydihydroxydihydroquinoline*,  $OMe\cdot C_6H_4<\begin{matrix}CH(OH)\\N:C(OH)\end{matrix}>CH_2$, and small quantities of paramethoxycarbostyril. Orthonitrometamethoxyphenyllactic acid can also be obtained by warming orthonitrometachlorocinnamic acid with potassium methoxide in methyl alcoholic solution; the *orthonitrometamethoxycinnamic acid* thus produced crystallises from alcohol in long needles, melts at 225°, and combines with hydrogen bromide, yielding *orthonitrometamethoxyphenyl-β-bromopropionic acid*, which crystallises from a mixture of chloroform and light petroleum in needles melting at 162—163°. When this bromo-acid is carefully neutralised with sodium carbonate or alcoholic ammonia in the cold, it is converted into a lactone, which separates from ethyl acetate in prisms melting at 124—125°; but when it is treated with warm ammonia, it dissolves, yielding a reddish solution, from which *orthonitrometamethoxyphenyllactamide* is deposited after some time in small, colourless plates melting at 187—188°. The last-named compound can be converted into orthonitrometamethoxyphenyllactic acid by boiling it with dilute sulphuric acid.

Orthonitrometachlorophenyl-β-lactic acid methyl ketone is obtained, together with the ketones of orthonitrometachlorophenyl-β-lactic acid and orthonitrometachlorocinnamic acid, by the condensation of orthonitrometachlorobenzaldehyde with acetone; it crystallises from alcohol in plates, melts at 106·5—107·5°, and, when heated at 70—80° with a solution of sodium hypochlorite, it is converted into orthonitrometachlorophenyl-β-lactic acid with liberation of chloroform. This acid, the constitution of which is proved by its method of formation, crystallises from dilute alcohol in colourless, hexagonal plates, melts at 156°, and has properties entirely different from those of the orthonitrometachlorophenyllactic acid (m. p. 152°) obtained from orthonitrochlorocinnamic acid as described above. Experiments have shown that the two compounds are stereochemically isomeric, but attempts to convert the one into the other by heating with water, alcohol, or dilute mineral acids under pressure were unsuccessful, the acid prepared from cinnamic acid remaining unchanged under those conditions, that prepared from the ketone being decomposed into cinnamene-like compounds. The isomerism of the two compounds is proved by the following experiments:—When the thick, oily orthonitrometachlorophenyllactic aldehyde, obtained by the condensation of orthonitrometachlorobenzaldehyde with acetaldehyde in presence of 6 per cent. soda, is oxidised with freshly precipitated silver oxide in alcoholic solution, considerable quantities of the more stable acid (m. p. 152°) are obtained; but if the aldehyde is oxidised by warming it with a solution of sodium hypochlorite, the labile acid is formed.

As, therefore, either acid can be obtained at will from one and the same aldehyde simply by varying the oxidising agent, there can be no doubt that they are stereochemically isomeric, the isomerism being due to the presence of an asymmetric carbon-atom. Molecular weight determinations by Raoult's method proved that the two compounds are not polymeric.

Attempts to displace the chlorine-atom by the methoxy-group in the acid (m. p. 156°) prepared from the ketone have hitherto been unsuccessful, and no pure compound has yet been obtained from it by reduction with ferrous sulphate and ammonia; the isomeride, on the other hand, is easily converted into a *chlorodihydroxydihydroquinoline*, melting at 172°. F. S. K.

Phenetoïlphthaloylic Acid. By E. GRANDE (*Chem. Centr.*, 1890, i, 822; from *Ann. Chim. Farm.* [4], **10**).—By means of Friedel and Craft's reaction with aluminium chloride on phthalic anhydride and phenetoïl, *phenetoïlphthaloylic acid*, $COOH\cdot C_6H_4\cdot CO\cdot C_6H_4\cdot OEt$, is obtained. It melts at 135—136°, also in boiling water; it is sparingly soluble in boiling water, but readily in hot alcohol, ether, benzene, carbon bisulphide, and hot toluene. The neutral solution of the ammonium salt gives the following reactions:—With mercuric chloride, a white, crystalline precipitate; with cupric sulphate, a pale-blue, crystalline precipitate; with ferric chloride, a yellow, crystalline precipitate; and with plumbic acetate, a white, crystalline precipitate. The potassium and calcium salts are readily soluble in water and alcohol; the barium salt crystallises with 5 mols. H_2O, is soluble in water and alcohol, and has a sweet taste; the silver salt is sparingly soluble in water, and is stable in daylight. J. W. L.

β- and δ-Benzallevulinic Acid. By H. Erdmann (*Annalen*, **258**, 129—133).—The method described by Erlenmeyer (Abstr., 1890, 495) for the preparation of β-benzallevulinic acid does not yield this compound, but an isomeride which has the constitution $CHPh:CH\cdot CO\cdot CH_2\cdot CH_2\cdot COOH$, and is, therefore, a δ-benzallevulinic acid. This compound melts at 120°, and differs from the β-acid (Abstr., 1890, 375) both in chemical and physical properties; its behaviour with bromine is different from that of the β-acid; it is converted into a neutral compound by acetic anhydride in the cold, and nascent hydrogen transforms it into a δ-benzyllevulinic acid which melts at 87—88°. The δ-benzallevulinic acid combines with hydroxylamine, yielding an *oxime*, $C_{12}H_{13}O_3N$, which crystallises in yellowish prisms, melts at 148—149°, and has a strongly acid reaction; its salts are also totally different from those of the β-acid.

Metachlorobenzaldehyde and levulinic acid condense together in alkaline solution, yielding *metachloro-δ-benzallevulinic acid*, $C_{12}H_{11}ClO_3$, which melts at 128°. β-Benzallevulinic acid and benzaldehyde under the same conditions give *βδ-dibenzallevulinic acid*,

$$CHPh:CH\cdot CO\cdot C(CHPh)\cdot CH_2\cdot COOH$$

(m. p. 146°). Both β- and δ-benzallevulinic acids can be obtained by the condensation of their components in acid solution. The investigation of the δ-acid is being continued. F. S. K.

Synthesis of Homopiperic and Piperic Acids. By S. Gabriel (*Ber.*, **23**, 1767—1773).—1·1 gram of sodium is dissolved in 10 c.c. of absolute alcohol, 15 grams of ethyl malonate, and then 10 grams of bromopropylphthalimide added, the mixture boiled for an hour in a reflux apparatus, and the alcohol and unchanged ethyl malonate driven over with steam. The residue is repeatedly extracted with light petroleum, and the solution on cooling deposits *ethyl γ-phthalimidopropylmalonate*,

$C_6H_4{<}\begin{matrix}CO\\CO\end{matrix}{>}N\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH(COOEt)_2$, in brilliant, colourless, monoclinic crystals, which melt at 46—48°, and dissolve readily in most solvents, sparingly in light petroleum, and not at all in water. When it is heated with hydrochloric acid (sp. gr. 1·13) for 3 hours at 180—190° in a sealed tube, it is decomposed, yielding phthalic acid, carbonic anhydride, ethyl chloride, and δ-amidovaleric (homopiperic) acid, $NH_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH_2\cdot COOH$, which was shown to be identical with that obtained by Schotten from benzoylpiperidine.

Chlorobutyronitrile was prepared by treating trimethylene chlorobromide with potassium cyanide. It was then heated with an equivalent quantity of potassiophthalimide at 150—180°, and the γ-cyanopropylphthalimide formed was heated with dilute sulphuric acid; γ-amidobutyric acid was thus obtained, and found to be identical in its properties with the piperic acid prepared by Schotten's method from piperylurethane.

Schotten had previously shown that neither δ-amidovaleric nor γ-amidobutyric acid is poisonous, whilst the anhydride of the former (piperidone or oxypiperidine) is so. He has lately shown, at the request of the author, that pyrrolidone, the anhydride of γ-amidobutyric acid, is a poison of the same nature as piperidone, acting upon the nervous system, and causing death by tetanic convulsions when administered in sufficiently large quantity. C. F. B.

Oxidation of Gallic Acid, Tannin, and Oak Tannins. By C. BOETTINGER (*Annalen*, **257**, 248—252).—When oak-bark-red or oak-red is treated with cold very dilute nitric acid, carbonic anhydride is evolved, and after some time the reaction becomes so energetic that the mixture must be cooled with water. If the solution thus obtained is evaporated, rapid oxidation ensues, and there remains a mixture of oxalic acid and various other acids, which can be separated by means of their calcium salts. The quantity of the calcium salts (excluding calcium oxalate) thus obtained is only about 6 per cent. of the material employed.

The acetyl-derivative of oak-wood tannin gives identical oxidation-products. Tannin and gallic acid, on oxidation with nitric acid, also yield compounds other than oxalic acid and carbonic anhydride. After removing the oxalic acid as completely as possible and treating the residue with calcium carbonate, a readily soluble and a very sparingly soluble calcium salt are obtained. The latter contains 16·39 per cent. of calcium, and seems to be calcium trihydroxyglutarate ($+ H_2O$): the latter contains 12·4 per cent. of calcium, and is probably calcium trihydroxybutyrate. A calcium salt, which seems to be that of trihydroxybutyric acid, was also isolated from the oxidation-products of oak-bark-red, oak-red, and the acetyl-derivative of oak-bark tannin. F. S. K.

Reduction-products of Terephthalic Acid. By A. BAEYER and J. HERB (*Annalen*, **258**, 1—49).—The authors have prepared and investigated a number of new derivatives of the hydroterephthalic acids (compare Baeyer, Abstr., 1889, 1176); their experiments have shown that the $\Delta^{1:4}$ and $\Delta^{2\cdot5}$ dihydro- acids can be converted into tetrabromides, but that the $\Delta^{1:3}$ and $\Delta^{1\;5}$ dihydro- acids can only combine with two bromine atoms. The dibromides of the four dihydroterephthalic acids ($\Delta^{1\cdot4}$, $\Delta^{2:5}$, $\Delta^{1:3}$, and $\Delta^{1\;5}$) are all converted into terephthalic acid by treatment with alcoholic potash; this behaviour on the part of the $\Delta^{1\cdot3}$ and $\Delta^{1\cdot5}$ acid affords additional evidence of the existence of a para-binding in benzene, as may be seen by studying the constitutional formulæ of the dibromides in question.

A cheaper method for the preparation of terephthalic acid than that described by Baeyer (Abstr., 1888, 1072) is to convert paratoluidine into the nitrite by Sandmeyer's reaction, hydrolyse the product with boiling moderately dilute (3 : 2) sulphuric acid (10 parts), and oxidise the paratoluic acid thus obtained with an alkaline solution of potassium permanganate. The terephthalic acid is separated from small quantities of unchanged paratoluic acid by treating the crude product with phosphoric chloride and methyl alcohol consecutively, recrystallising the methyl salt thus formed from 96 per cent. alcohol, and then hydrolysing the pure compound; the yield of pure acid is 95—98 per cent. of the paratoluidine employed.

Methyl $\Delta^{2\ 5\,\mathrm{cistrans}}$ *dihydroterephthalic acid dibromide* can be obtained by treating methyl $\Delta^{2\cdot 5}$ dihydroterephthalate (8 grams) with bromine (6·5 grams) in chloroform solution; it separates from light petroleum in transparent, monosymmetrical crystals, $a : b : c = 1{\cdot}5055 : 1 : 1{\cdot}2218$, $\beta = 66° 37'$, melts at 110°, and is readily soluble in ether, chloroform, light petroleum, and alcohol. When treated with alcoholic potash, or with a mixture of concentrated sulphuric acid, glacial acetic acid, and water, it is converted into terephthalic acid; on reduction with zinc-dust and glacial acetic acid, it is transformed into methyl $\Delta^{2\cdot 5}$ dihydroterephthalate, a fact which shows that the two bromine-atoms are in combination with adjacent carbon-atoms. Methyl $\Delta^{2\ 5\,\mathrm{cis}}$ dihydroterephthalate does not give a solid dibromide.

Methyl $\Delta^{2\ 5\,\mathrm{cistrans}}$ *dihydroterephthalate tetrabromide*, prepared by treating the methyl salt (10 grams) with bromine (20 grams) in chloroform solution, separates from light petroleum in transparent, monosymmetrical crystals, $a : b : c = 1{\cdot}3412 : 1 : 0{\cdot}59061$, $\beta = 82° 3'$, melts at 98°, and is readily soluble in chloroform, ether, alcohol, and light petroleum. When hydrolysed with alcoholic potash, it yields terephthalic acid and bromoterephthalic acid, and on reduction with zinc-dust and glacial acetic acid, it is converted into methyl $\Delta^{2\ 5}$ dihydroterephthalate (m. p. 77°), a reaction which proves that both pairs of bromine-atoms are combined with adjacent carbon-atoms. It is not changed even on prolonged heating with a mixture of sulphuric acid, glacial acetic acid, and water. Methyl $\Delta^{2\ 5\,\mathrm{cis}}$ dihydroterephthalate does not give a solid tetrabromide.

When methyl $\Delta^{2\ 5\,\mathrm{cistrans}}$ dihydroterephthalate is heated at 100° for three days in a stream of carbonic anhydride, it undergoes no change; the fact, observed by Baeyer, that when heated in the air it is converted into methyl terephthalate is, therefore, due to oxidation.

Diphenyl $\Delta^{2\ 5\,\mathrm{cistrans}}$ *dihydroterephthalate* is obtained when $\Delta^{2\ 5\,\mathrm{cistrans}}$ dihydroterephthalic acid is converted into the chloride by means of phosphoric chloride, and the product warmed with the calculated quantity of phenol. It separates from alcohol in small crystals, melts at 146°, and is only sparingly soluble in ether, alcohol, and light petroleum. The corresponding salt of the $\Delta^{2\cdot 5\,\mathrm{cis}}$ acid is a colourless oil, readily soluble in light petroleum; when the chloride of the $\Delta^{2\cdot 5\,\mathrm{cis}}$ dihydro-acid is warmed with phenol, the larger proportion undergoes intramolecular change, and the principal product is phenyl $\Delta^{2\cdot 5\,\mathrm{cistrans}}$ dihydroterephthalate (m. p. 146°), small quantities of a phenyl salt melting above 150° being also produced.

$\Delta^{1\ 5}$ *Dihydroterephthalic acid dibromide* can be obtained by treating the acid chloride with bromine, and then warming the product with a concentrated solution of formic acid. It separates from glacial acetic acid in the form of a colourless, crystalline powder, and when boiled with soda it is converted into $\Delta^{1:4}$ dihydroterephthalic acid; alcoholic potash transforms it into terephthalic acid, and on reduction with zinc-dust and acetic acid, it is converted into the $\Delta^{1:5}$ dihydro-acid. The tetrabromide could not be obtained.

Barium $\Delta^{1:5}$ *dihydroterephthalate*, $C_8H_6O_4Ba + 4H_2O$ separates from cold water in colourless, rhombic crystals, $a : b : c = 0{\cdot}3191 : 1 : 0{\cdot}3520$, and quickly turns red on exposure to the air.

Methyl $\Delta^{1:3}$ *dihydroterephthalate dibromide* can be obtained by brominating the methyl salt of the dihydro-acid in chloroform solution; it crystallises from cold methyl alcohol in thin, colourless, seemingly monoclinic plates, melts at 64°, and is readily soluble in alcohol, ether, and light petroleum. When warmed with alcoholic potash, it is converted into terephthalic acid, and on reduction with zinc-dust and glacial acetic acid, it yields methyl $\Delta^{1:3}$ dihydroterephthalate and methyl Δ^2 tetrahydroterephthalate, the last-named compound being formed by the reduction of the methyl salt of the $\Delta^{1:3}$ dihydro-acid. Attempts to prepare a tetrabromide were unsuccessful.

Diphenyl $\Delta^{1:3}$ *dihydroterephthalate*, prepared by warming the acid chloride with phenol, crystallises from methyl alcohol in needles, melts at 175°, and is only sparingly soluble in alcohol, ether, light petroleum, and chloroform, but more readily in boiling alcohol.

Methyl $\Delta^{1:3}$ *dihydroterephthalate dihydrobromide*, prepared by treating the acid chloride with methyl alcohol, is an oil; when it is dissolved in methyl alcohol and hydrogen chloride passed into the solution, it is converted into the crystalline modification (m. p. 171°), and on reduction with zinc-dust and glacial acetic acid, it yields methyl Δ^2 tetrahydroterephthalate (m. p. 3°); on hydrolysis with alcoholic potash, it gives the $\Delta^{1:3}$ dihydro-acid.

Barium $\Delta^{1:3}$ *dihydroterephthalate*, $C_8H_6O_4Ba + 4H_2O$, separates from cold water in large, colourless crystals which are identical crystallographically with those of barium $\Delta^{1:5}$ dihydroterephthalate, but which, unlike the latter, do not turn reddish on exposure to the air; the identity of crystalline form is not due to an intramolecular change of one acid into the other, because the barium salts, on decomposition with hydrochloric acid, yield the $\Delta^{1:3}$ and $\Delta^{1:5}$ acid respectively.

Methyl $\Delta^{1:4}$ *dihydroterephthalate tetrabromide* was obtained after many unsuccessful experiments by treating the methyl salt with bromine. It forms transparent, monosymmetrical crystals, $a : b : c = 1{\cdot}2356 : 1 : 0{\cdot}9170$, $\beta = 81° 54'$, melts at about 149°, and is much more readily soluble in most solvents than the lactone of methyl hydrogen tribromohexahydroterephthalic acid (compare Baeyer, Abstr., 1888, 1073). It undergoes no change when it is warmed for five hours with a mixture of glacial acetic acid, concentrated sulphuric acid and water; since methyl $\Delta^{1:4}$ dihydroterephthalate dibromide under these conditions is converted into the methyl hydrogen salt, the methyl-group must be eliminated from that carboxy-group which is not adjacent to a bromine-atom.

Phenyl $\Delta^{1:4}$ *dihydroterephthalate* separates from methyl alcohol in small scales, melts at 191°, and is very sparingly soluble in boiling alcohol, but rather more readily in chloroform. The *barium* salt, $C_8H_6O_4Ba + 4H_2O$, is very sparingly soluble in water, and is identical crystallographically with the barium salt of $\Delta^{1\,5}$ and of $\Delta^{1\,3}$ dihydroterephthalic acid.

Phenyl Δ^1 *tetrahydroterephthalate* separates from alcohol in monosymmetrical crystals, $a : b : c = 2{\cdot}8244 : 1 : 2{\cdot}4702$, $\beta = 82° 33'$, melts at 145°, and is only moderately easily soluble in alcohol, ether, chloroform, and light petroleum, but readily in the warm solvents. The *hydrobromide* of the phenyl salt, prepared from the hydrobromide of the tetrahydro-acid, separates from methyl alcohol in crystals melting at 127° Δ^1 Tetrahydroterephthalic acid hydrobromide forms monosymmetrical crystals, $a : b : c = 0{\cdot}37093 : 1 : 0{\cdot}48370$, $\beta = 72° 31'$, and is identical with Δ^2 tetrahydroterephthalic acid hydrobromide.

Barium Δ^1 *tetrahydroterephthalate*, $C_8H_8O_4 + 3\frac{1}{2}H_2O$, separates from cold water in forms identical crystallographically with those of the barium salt of $\Delta^{1\,5}$ and of $\Delta^{1\,3}$ dihydroterephthalic acid; when an aqueous solution of the barium salt is evaporated on the water-bath, crystals containing $1\frac{1}{2}$ mols. H_2O are obtained.

Three geometrically isomeric methyl salts of $\Delta^{2\,\text{cistrans}}$ tetrahydroterephthalic acid dibromide are formed when methyl Δ^2 tetrahydroterephthalate (m. p. 3°), prepared by saturating a methyl alcoholic solution of the acid with hydrogen chloride, is treated with excess of bromine in chloroform solution. After evaporating the chloroform, the residue is dissolved in ether, the ethereal solution decolorised with sulphurous acid, washed with sodium carbonate, mixed with an equal volume of light petroleum, and dried over calcium chloride; the semi-solid mass which remains on evaporating the filtered solution is dissolved in a little hot methyl alcohol, and the solution allowed to cool slowly, whereon a compound is deposited in long needles melting at 171°. This same substance can be obtained by brominating methyl Δ^2 tetrahydroterephthalate, prepared from the silver salt and methyl iodide; it is soluble in methyl alcohol, ether, acetone, chloroform, and light petroleum. When the methyl alcoholic mother liquors from the compound melting at 171° are carefully evaporated at a low temperature, a second modification is deposited in large, transparent crystals, $a : b : c = 1{\cdot}4638 : 1 : 1{\cdot}9222$, $\beta = 80° 52'$, which melt at 51°; this substance is much more readily soluble than the isomeride melting at 171° and dissolves freely in methyl alcohol, ethyl alcohol, acetone, ethyl acetate, chloroform, light petroleum, &c. The third modification separates in colourless crystals when the freshly prepared crude product is dissolved in acetone (about $1\frac{1}{2}$ vols.), and the solution kept at a low temperature; it melts at 94°, and as regards solubility, it is about intermediate between the two other isomerides. When methyl Δ^2 tetrahydroterephthalate which has been prepared from the acid chloride is treated with bromine, the product is an oil, from which a trace of a crystalline substance melting at about 20° is deposited after some time; owing to its low melting point, this compound could not be isolated, but the oily product, which may be simply a mixture, and the three crystalline modifications described above have the following properties in common: (1.) On reduction with zinc-dust and glacial acetic acid, they are reconverted into methyl Δ^2 tetrahydroterephthalate (m. p. 3°), a reaction which shows that in all the modifications the two bromine-atoms are in the ortho-position to one another. (2.) When treated with alcoholic potash, they yield $\Delta^{1\ 3}$ dihydroterephthalic acid and terephthalic acid.

Phenyl $\Delta^{2\ \mathrm{cistrans}}$ *tetrahydroterephthalate* is obtained, together with a substance which seems to be a mixture of the phenyl salts of terephthalic acid and Δ^1 tetrahydroterephthalic acid, when the Δ^2 tetrahydro-acid is treated with phosphoric chloride, and the acid chloride thus produced is warmed with phenol. It crystallises from a mixture of benzene and light petroleum in plates, melts at 107° (?), and is readily soluble in benzene, ether, and acetone, but only sparingly in light petroleum.

$\Delta^{2\ \mathrm{cistrans}}$ *Tetrahydroterephthalic acid hydriodide*, prepared by treating the acid with hydriodic acid of sp. gr. 1·96 for several days in the cold, and then warming the mixture for a short time, separates from alcohol in colourless plates, and is gradually decomposed by boiling water.

Benzyl $\Delta^{2\ \mathrm{cistrans}}$ *tetrahydroterephthalate*, prepared by warming the silver salt with benzyl chloride, separates from alcohol in crystals, and melts at 48°.

Phenyl $\Delta^{2\ \mathrm{cistrans}}$ *hexahydroterephthalate* crystallises from acetone in large colourless monoclinic needles, $a : b : c = 0{\cdot}48619 : 1 : 0{\cdot}35093$, $\beta = 75°\ 6'$, and is only sparingly soluble in ether, alcohol, and light petroleum.

Phenyl terephthalate melts at 194°, not at 191°.

When Δ^1 tetrahydroterephthalic acid is oxidised with a 5 per cent. alkaline solution of potassium permanganate, it is converted into oxalic acid and oily acids, the nature of which could not be determined. The Δ^2 tetrahydro-acid, under the same conditions is converted into succinic acid, a crystalline acid melting at about 150°, and an amorphous acid, but when treated with an alkaline solution of potassium ferricyanide, it is simply oxidised to terephthalic acid.

F. S. K.

Benzylmethylsuccinic and Benzyldimethylsuccinic Acids. By C. A. Bischoff and A. v. Kuhlberg (*Ber.*, **23**, 1942—1950).—In the description of benzylmethylsuccinic acid (this vol., p. 774) it was stated that the acid was probably a mixture of two geometrical isomerides. The authors have now succeeded in proving this supposition and in separating the two compounds. The first, or meso-acid is prepared by boiling the anhydride with water, and melts at 138°, whilst the second, or para-acid is formed when the mixture of acids is heated with hydrochloric acid at 200—240°, and forms slender needles melting at 159—160°.

The ethyl salt obtained by the action of benzyl chloride on ethyl sodisobutenyltricarboxylate does not, as was expected, yield, on hydrolysis, a mixture of benzylisobutenyltricarboxylic and benzyldimethylsuccinic acids, but gives a product from which the seven following acids have been isolated: *Isobutenyltricarboxylic acid*, $COOH{\cdot}CMe_2{\cdot}CH(COOH)_2$, melting at 147—149°; *asymmetrical dimethylsuccinic acid*, $COOH{\cdot}CH_2{\cdot}CMe_2{\cdot}COOH$, melting at 140°; *dibenzylmalonic acid*, $C(CH_2Ph)_2(COOH_2)$, melting at 171°; *dibenzyl-*

acetic acid, $CH(CH_2Ph)_2{\cdot}COOH$, melting at 85—87°; *benzylmethylcarboxyglutaric acid*, $COOH{\cdot}CHMe{\cdot}CH_2{\cdot}C(CH_2Ph)(COOH)_2$, melting at 178°; *benzylmethylglutaric acid*,

$$COOH{\cdot}CHMe{\cdot}CH_2{\cdot}CH(CH_2Ph){\cdot}COOH,$$

melting at 128—130°; and, lastly, *benzylsuccinic acid*,

$$COOH{\cdot}CH_2{\cdot}CH(CH_2Ph){\cdot}COOH,$$

melting at 153—155°. The formation of the first two acids is readily explained by assuming that the sodium compound is partially reconverted into ethyl isobutenyltricarboxylate, of which these are the normal products of hydrolysis. H. G. C.

Anhydrides of the Diphenylsuccinic Acids. By H. TILLMANNS (*Annalen*, **258**, 87—94).—The anhydride of α-diphenylsuccinic acid (m. p. 183°), prepared by treating the acid with acetic chloride, melts at 111—112°, that of the β-acid (m. p. 229°), prepared in like manner, melts at 112°; by treatment with potash, the anhydrides are reconverted into α- and β-diphenylsuccinic acids respectively. The α-acid melts at 183°, but immediately solidifies again, and does not become permanently liquid until the temperature has risen to 220—222°; if the acid is kept at 220—222° for some time, and then crystallised from chloroform, the anhydride (m. p. 111—112°) is obtained, but if it is simply heated to about 185° for a short time, and then treated with chloroform, the anhydride (m. p. 111—112°) passes into solution whilst β-diphenylsuccinic acid (m. p. 229°) remains undissolved. When the β-acid is heated above its melting point, it is gradually converted into the anhydride of the α-acid. F. S. K.

Phenylmalic Acids. By H. ALEXANDER (*Annalen*, **258**, 67—86).—Ethyl phenylhydroxyacetate crystallises in needles, and melts at 26—27°, not at 75° as stated by Naquet and Longuinine (*Annalen*, **139**, 301). Ethyl phenylbromacetate is a colourless oil boiling at 143—145° (10 mm.) with slight decomposition. Ethyl phenylcarboxysuccinate, $COOEt{\cdot}CHPh{\cdot}CH(COOEt)_2$, prepared by treating ethyl sodiomalonate with ethyl phenylbromacetate, as described by Spiegel (*Annalen*, **219**, 31), crystallises from alcohol in colourless needles, melts at 45—46°, and boils at 202°. The free acid crystallises in plates, and melts at 171°, not at 191° as stated by Spiegel. The *silver* salt, $C_{11}H_7Ag_3O_6$, is crystalline and moderately stable. The potassium and the sodium salts are readily soluble in water, but the barium salt is only sparingly soluble. The *calcium* salt, $(C_{11}H_7O_6)_2Ca_3$, is soluble in cold water, but on boiling the solution it is deposited in needles containing 10 mols. H_2O; the crystals lose 2 mols. H_2O over sulphuric acid. *α-Phenylmalic acid* (*α-phenyl-α-hydroxysuccinic acid*),

$$COOH{\cdot}CH_2{\cdot}CPh(OH){\cdot}COOH,$$

is obtained, together with phenylmaleic anhydride, by brominating phenylsuccinic acid, according to Volhard's method, and decomposing the unstable bromo-acid thus produced with hot water; the products are extracted with ether and separated by means of chloroform, in which phenylmaleic acid is only very sparingly soluble. It crystallises from boiling chloroform in very small prisms, melts at 187—188°, and is readily soluble in ether, and moderately easily in water; alcohol converts it into an oil. The lead, iron, and silver salts are insoluble; the salts of the alkalis and alkaline earths dissolve readily in water. When the acid is heated to its melting point, water-vapour and not inconsiderable quantities of carbonic anhydride are evolved, and a crystalline compound melting at 105—106°—probably atropic acid—sublimes in colourless needles; the resinous residue contains small quantities of a crystalline acid melting at 161—162°, possibly phenylfumaric acid.

Phenylmaleic anhydride, $C_{10}H_6O_3$ (see above), crystallises from boiling carbon bisulphide in colourless needles, melts at 119—119·5°, and is readily soluble in chloroform and ether, but only sparingly in carbon bisulphide and light petroleum, and insoluble in water.

Phenylmaleic acid, $C_{10}H_8O_4$, is obtained when the finely-divided anhydride is left for a long time in contact with water, the clear solution extracted with ether, and the extract evaporated at the ordinary temperature. It melts at a temperature below 100°, is moderately easily soluble in cold water, and is very readily converted into the anhydride.

β-Phenylmaleic acid (*β-phenyl-α-hydroxysuccinic acid*),

$$COOH\cdot CH(OH)\cdot CHPh\cdot COOH,$$

can be obtained, together with the oily ethyl hydrogen salt,

$$COOH\cdot CH(OH)\cdot CHPh\cdot COOEt,$$

by treating ethyl phenylformylacetate, prepared by Wislicenus' method (Abstr., 1888, 129), with hydrochloric acid and boiling the product for a short time with concentrated hydrochloric acid. It separates from ether in colourless crystals, begins to soften at 150°, and melts completely at 160° with elimination of water, yielding a sublimate of phenylmaleic anhydride (m. p. 119°). It is very readily soluble in water, but only sparingly in hot chloroform, and insoluble in light petroleum and carbon bisulphide. The salts of the alkalis and alkaline earths are readily soluble in water. The barium salt crystallises in flat prisms; the lead and the unstable silver salts are sparingly soluble or insoluble in water. When the acid is boiled with potash, it is converted into a crystalline compound—most probably phenylacetic acid—which melts at 74·5—75°. F. S. K.

Diparatoluylene Sulphoxide. By H. C. Parker (*Ber.*, 23, 1844—1846).—*Diparatoluylene sulphoxide*, $SO(C_6H_4Me)_2$ [$Me\cdot SO = 1:4$], is prepared by heating toluene with thionyl chloride and aluminium chloride; when cold the product is poured into water, and the oil which separates is washed with aqueous soda, and dried; after evaporating the excess of toluene, the residue is recrystallised from light petroleum, from which it is deposited in long, white, flat crystals melting at 92°. The compound is readily soluble in the ordinary menstrua. The corresponding sulphide is obtained by reduction, and the sulphone is formed on oxidation.

In addition to the methods already known, diphenyl sulphoxide may be obtained by the action of thionyl chloride on mercurodiphenyl, or by titrating benzenesulphinic acid with phosphoric anhydride.

J. B. T.

Displacement of the Sodium in Ethyl Sodiophenylsulphoneacetate. By R. OTTO and A. RÖSSING (*Ber.*, 23, 1647—1653).—A reply to the paper of A. Michael (compare this vol., p. 781). The authors give details of further experiments which they have made with the object of deciding this question. They find that dry sodium ethyl phenylsulphoneacetate is entirely unacted on by heating in a sealed tube with ethyl bromide at 125°. If heated in the same manner with ethyl iodide at 150°, methylphenylsulphone is formed. The same result is obtained by heating at 100° a mixture of pure dry ethyl phenylsulphone acetate dissolved in alcohol, sodium ethoxide, and ethyl iodide; one portion was heated in a flask, and a second in a sealed tube. A similar experiment with methyl alcohol and ethyl bromide was also made without success.

The alcohol employed had been carefully dehydrated by boiling it with calcium oxide and treatment with sodium. J. B. T.

Displacement of the Amido- by the Sulphonic Acid-group. By L. LANDSBERG (*Ber.*, 23, 1454).—When freshly prepared cuprous hydroxide is warmed with a large quantity of sulphurous acid, and the warm mixture poured into a solution of diazobenzene sulphate, a rapid evolution of gas sets in and benzenesulphonic acid is formed; the yield is about one-fifth of the aniline employed. F. S. K.

Aromatic Sulphonamic Acids. By W. TRAUBE (*Ber.*, 23, 1653—1657; compare Wagner, Abstr., 1886, 708).—Anilinesulphonic acid is formed by heating aniline with chlorosulphonic acid, or sulphuric anhydride; but if the aniline is dissolved in chloroform or benzene, the solution well cooled, and the chlorosulphonic acid added gradually, a hydrogen-atom of the amido-group is replaced, *phenylsulphonamic acid* being obtained. The free acid could not be isolated, as the aqueous solution readily undergoes decomposition on evaporation. The *barium salt*, $Ba(NHPh{\cdot}SO_3)_2$, is prepared by treating aniline (3 mols.) with chlorosulphonic acid (1 mol.) as above; the product is poured into water, and treated with barium hydroxide; on evaporating the clear aqueous solution, the barium salt separates in lustrous plates, or long needles, which do not melt. The compound is unaffected by boiling with water, but the addition of a few drops of acid causes its decomposition into aniline and sulphuric acid. The *potassium* and *sodium salts* are obtained from the barium salt by the action of potassium or sodium sulphate.

Barium orthotoluenesulphonamate is prepared from orthotoluidine by the method described. It crystallises from water in lustrous plates, which have no melting point. The free acid could not be obtained in a crystalline form.

Barium metaxylenesulphonamate is prepared from metaxylidine; its properties are very similar to those of the barium salts described above. J. B. T.

Synthesis of Indene-derivatives. By W. v. MILLER and G. ROHDE (*Ber.*, 23, 1881—1886, and 1887—1902; compare Abstr., 1889, 984).—Ketones, like aldehydes, condense to form indene-derivatives: the only general condition being that the side chain shall not contain a double bond. Metanitroketones of the cinnamic acid series resemble the corresponding aldehydes in their behaviour towards tin and hydrochloric acid. Metanitrobenzalacetone, like metanitrocinnamic aldehyde, yields no indene-derivative, whilst metanitro-orthomethylbenzalacetone gives metamido-βγ-dimethylindene.

γ-Methylindene, $C_6H_4<\begin{matrix}CH_2\\CMe\end{matrix}>CH$, is obtained by treating benzalacetone with 8 times its weight of concentrated sulphuric acid; after 24 hours, it is poured into water, and distilled in a current of steam, the distillate is extracted with ether, and, after evaporation, the oily residue is purified by distillation; the yield is very small. The *picrate*, $C_{10}H_{10},C_6H_2(NO_3)_3{\cdot}OH$, crystallises in long, orange-yellow, radiating needles melting at 75—76°. Methylindene dissolves in concentrated sulphuric acid with a yellowish-brown colour; the solution exhibits an intense green fluorescence; on adding water, the colour changes to dark yellowish-red, and, finally, becomes red.

Orthomethylbenzylacetone, $CH_2Ph{\cdot}CHMe{\cdot}COMe$, is prepared by distilling a mixture of α-methyl-γ-phenylpropionic acid and calcium acetate; it forms an almost colourless oil boiling at 234—241° (corr.); it undergoes a slight decomposition on distillation at ordinary pressure; no indene-derivative could be obtained from it, and it does not appear to combine with hydrogen sodium sulphite.

Metamido-βγ-dimethylindene, $NH_2{\cdot}C_6H_3<\begin{matrix}CH_2\\CMe\end{matrix}>CMe$, is obtained by heating metanitro-α-methylbenzalacetone with tin and alcoholic hydrochloric acid; when the reaction is completed, the alcohol is removed and the residue treated with sodium hydroxide and distilled in a current of steam. The compound crystallises in small, lustrous plates melting at 62—63°; it is very soluble, but cannot be recrystallised without undergoing decomposition; it reduces an ammoniacal silver solution, and is very unstable on exposure to light. The *benzoyl*-derivative is deposited in crystalline nodules melting at 198°. *Metamidobenzalacetone* is obtained by the reduction of metanitrobenzalaniline with ferrous ammonium sulphate; it is an oily liquid; the *benzoyl*-derivative, $NHBz{\cdot}C_6H_4{\cdot}CH{:}CH{\cdot}COMe$, crystallises from benzene in small nodules and melts at 125°. Metamidobenzalacetone yields *metamidobenzylacetone* on treating it with sodium amalgam in acid solution; it is an oily liquid; the *benzoyl* compound,

$$NHBz{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH_2{\cdot}COMe,$$

melts at 94—95°. No indene-derivative could be obtained from metamidobenzylacetone, thus proving that the influence of the substituting-groups in the α-position does not merely consist in rendering the side chain capable of being reduced.

The power of condensing to form indene-derivatives is not confined to meta-substituted acids, as hitherto supposed; both ortho- and para-compounds are capable of reacting in the same manner; but, as in the case of aldehydes, this property is greatly dependent on the character of the substituting-groups; the presence of chlorine, bromine, or methyl in the benzene nucleus facilitates the condensation, whilst the amido-group entirely prevents it; as aldehydes acquire the power of forming indene-derivatives in the first instance from the presence of the amido-group, the contrast is sufficiently striking; the difference may, however, be due to the dehydrating agents employed, which are, for aldehydes, tin and hydrochloric acid; for acids, concentrated sulphuric acid.

β-Methylhydrindone,  $C_6H_4<{CH_2 \atop CO}>CHMe$, is prepared by heating *αβ*-methylphenylpropionic acid with 12 times its weight of concentrated sulphuric acid for a few moments at 150°; the liquid is rapidly cooled, poured into water, and treated with excess of sodium hydroxide; the solution is distilled in a current of steam, and the distillate shaken with ether; the oily residue remaining, after evaporation of the ether, is finally purified by distillation. The hydrindone is a viscid, colourless liquid boiling, with slight decomposition, at 244—246° (corr.) under a pressure of 719 mm., and at 167—170° at 117 mm.; it has a penetrating odour resembling that of peppermint, and is readily soluble in water, but insoluble in alkalis; a bluish-violet fluorescence is produced on shaking with concentrated sulphuric acid: the yield is 60 per cent. of the propionic acid employed. Phthalic acid is obtained by oxidising the hydrindone with dilute nitric acid. *β-Methylhydrindonephenylhydrazone*, $C_{10}H_{10}N_2HPh$, crystallises from alcohol in small, yellow leaves melting at 116°. *Metabromhydrindone*,  $C_6H_3Br<{CH_2 \atop CO}>CH_2$, is prepared by heating metabromophenylpropionic acid with concentrated sulphuric acid at 145°. After purification, it crystallises in white needles melting at 122—123°. The yield is 40—50 per cent. *Parabromhydrindone* is obtained in a similar manner from parabromophenylpropionic acid; it melts at 111—112°, and is identical with a compound obtained by Göring (compare Abstr., 1878, 318). Metachloropropionic acid, prepared by the action of sodium amalgam on metachlorocinnamic acid, readily condenses under the influence of sulphuric acid with formation of *metachlorhydrindone*, $C_6H_3Cl<{CH_2 \atop CO}>CH_2$ [CH_2·CO·Cl=1:2:5], which crystallises from dilute alcohol in white needles melting at 95°, and boiling at 274° without decomposition; it is sparingly soluble in water. The *phenylhydrazone*, $C_9H_7Cl{\cdot}N_2HPh$, is obtained in colourless, lustrous, radiating needles melting at 139°; it readily decomposes on exposure to light. Chlorophthalic acid (m. p. 148°) is the sole oxidation-product of metachlorhydrindone; the *phenylhydrazine salt* of this acid is very sparingly soluble; it crystallises in small, white needles melting at 148°. *Metachloro-α-methylcinnamic acid*, $C_6H_4Cl{\cdot}CH{:}CMe{\cdot}COOH$, is prepared by means of Perkin's reaction; it crystallises from chloroform in thick, colourless prisms melting at 106°. The sodium, copper, and barium salts have been prepared; the last-named crystallises in lustrous scales. On treating the free acid with concentrated sulphuric acid, a substance, which is probably a chlorindone, is obtained in very small quantity. *αβ-Methylmetachlorophenylpropionic acid* is prepared by the action of sodium amalgam on the corresponding cinnamic acid; it is an oily liquid boiling at 292—296°. *β-Methylmetachlorhydrindone*, $C_6H_3Cl<\begin{smallmatrix}CH_2\\CO\end{smallmatrix}>CHMe$, is obtained from the previous compound; it is a colourless, strongly refractive, viscid liquid boiling at 265—268°; its odour resembles that of menthol, and it is very sparingly soluble in water. *Paramethylcinnamic acid* is prepared by Perkin's reaction; it crystallises from benzene in fine needles melting at 195·5°, is readily soluble in water, and yields the corresponding propionic acid on reduction with hydriodic acid and phosphorus. *Paramethylhydrindone*,

$$CH_3{\cdot}Me{\cdot}<\begin{smallmatrix}CH_2\\CO\end{smallmatrix}>CH_2,$$

is obtained from paramethylphenylpropionic acid; it crystallises from light petroleum in white needles melting at 63°. *Metamethylhydrindone*, from metamethylphenylpropionic acid, is deposited from light petroleum in long, white needles melting at 59°. *Metanitro-α-methylcinnamic acid*, $NO_2{\cdot}C_6H_4{\cdot}CH{:}CMe{\cdot}COOH$, is prepared by means of Perkin's reaction; it forms a white powder melting at 197·5°, and is sparingly soluble in light petroleum. *Metamido-orthomethylcinnamic acid* is obtained from the nitro-compound by reduction with ammonium ferrous sulphate; it crystallises in long, light-yellow needles melting at 137°. The *benzoyl-derivative* melts at 190—191°. *αβ-Methylmetamidophenylpropionic acid*, $NH_2{\cdot}C_6H_4{\cdot}CH_2{\cdot}CHMe{\cdot}COOH$, is formed from the amidocinnamic acid by reduction with hydriodic acid and phosphorus; it is a reddish-brown oil. The *benzoyl* compound melts at 147—148°. No indone-derivatives could be obtained from these three acids.

J. B. T.

Bidioxymethyleneindigo. By C. LIEBERMANN and F. HABER (*Ber.*, **23**, 1566—1567).—Piperonal was converted into nitropiperonal by the method of Fittig and Remsen; this was dissolved in acetone, and a slight excess of dilute aqueous soda added, when a violet-red, flocculent precipitate of *bidioxymethyleneindigo*,

$$C_2[<\begin{smallmatrix}CO\\NH\end{smallmatrix}>C_6H_2<\begin{smallmatrix}O\\O\end{smallmatrix}>CH_2]_2,$$

was formed. This may also be obtained by using pyruvic acid instead of acetone. It is a deep-blue substance, less soluble than indigo. It dissolves in concentrated sulphuric acid, giving a bluish-red solution, which exhibits two absorption-bands, the stronger extending from D to Cαβ, the weaker from E to *b*. When water is added to the solution, the substance is precipitated unchanged. When heated, it gives violet-red vapours.

C. F. B.

Condensation of Dichlorether with Cresols. By C. BRÜCKNER (*Annalen*, **257**, 322—330).—Ortho-, meta-, and para-cresol combine with dichlorether, yielding the corresponding *trihydroxytritolylethanes*, $OH{\cdot}C_6H_3Me{\cdot}CH_2{\cdot}CH(C_6H_3Me{\cdot}OH)_2$. The three compounds are all colourless, amorphous powders, turn reddish on exposure to the air in a moist condition, and are readily soluble in ether, alcohol, glacial acetic acid, ethyl acetate, acetone, and benzene, but only sparingly in carbon bisulphide (the *ortho-compound is insoluble*), and insoluble in chloroform, water, and light petroleum. The *triacetyl*-derivatives, $C_{29}H_{30}O_6$, are yellowish, amorphous compounds, soluble in alcohol, ether, glacial acetic acid, ethyl acetate, acetone, carbon bisulphide, and chloroform, but insoluble in water, alkalis, and light petroleum. Brownish-violet dyes of the composition $C_{46}H_{46}O_7$ are formed when the trihydroxytritolylethanes are dissolved in acetic acid, and the solutions boiled with ferric chloride; they are dark powders, which decompose at about 200°, and are readily soluble in alkalis, alcohol, ether, glacial acetic acid, acetone, and ethyl acetate, but insoluble in carbon bisulphide, benzene, chloroform, and light petroleum; when boiled with acetic anhydride and sodium acetate, the ortho- and the para-compound yield *triacetyl*-derivatives of the composition $C_{58}H_{58}O_{13}$, whilst the meta-compound seems to yield a mixture of various substances. F. S. K.

Paramidotriphenyl Carbinol. By A. BAEYER and R. LÖHR (*Ber.*, **23**, 1621—1628; compare Tschacher, Abstr., 1888, 375).—Paramidotriphenyl carbinol, the simplest representative of the rosaniline dyes, has not hitherto been prepared; it has now been obtained and is found to correspond in every way with the di- and tri-amido compounds. Although itself colourless, its salts are red; it is a weak base, and probably for this reason does not dye wool or silk.

Paranitrotriphenylmethane is obtained by treating 1 part of paranitrobenzaldehyde with 4 parts of benzene and 4 parts of sulphuric acid. After remaining for 24 hours, the benzene solution is separated from the acid and purified; on evaporating the benzene, the hydrocarbon forms an oily residue, which quickly solidifies. The compound crystallises from alcohol in white plates melting at 93°; on treatment with fuming nitric acid, it yields paratrinitrotriphenylmethane.

Paranitrotriphenyl carbinol is prepared by oxidising paranitrotriphenylmethane with chromic anhydride; the compound is purified by dissolving it in glacial acetic acid and precipitating with water; it melts at 136°.

Paramidotriphenylmethane is completely analogous to orthamidotriphenylmethane. The *hydrochloride* is obtained by treating an alcoholic solution of the nitro-compound with tin and hydrochloric acid; it crystallises from dilute hydrochloric acid in lustrous plates or needles. The *free base* is liberated on adding sodium hydroxide solution to the hydrochloride; it crystallises from light petroleum in short, lustrous needles melting at 83—84°. The *sulphate* and *nitrate* are sparingly soluble in water.

Acetylparamidotriphenylmethane, $CHPh_2{\cdot}C_6H_4{\cdot}NHAc$, is formed on warming the free base with acetic anhydride. On the addition of water, the compound is deposited from glacial acetic acid in bushy aggregates of needles or prisms, melting at 157°.

Acetylparamidotriphenylcarbinol, $OH{\cdot}CPh_2{\cdot}C_6H_4{\cdot}NHAc$, is obtained by cautiously oxidising the preceding compound with chromic anhydride. On the addition of light petroleum to a benzene solution, it forms slender, lustrous needles melting at 176°. The acetyl compound is best hydrolysed by dissolving it in glacial acetic acid, and pouring the solution into hot dilute sulphuric acid; the mixture is then boiled for some time, and the base precipitated with an alkali.

Paramidotriphenyl carbinol, $OH\cdot CPh_2\cdot C_6H_4\cdot NH_2$, crystallises from toluene, or from a mixture of ether and light petroleum, in small, colourless nodules, melting at 116°. The *sulphate* is *red*, and forms well developed plates, containing 1 mol. H_2O, which it loses at 100°. The *hydrochloride* crystallises from alcohol in long, red needles, which give up 1 mol. H_2O on heating to 120°. The *platinochloride* is red. The *picrate* is sparingly soluble, and crystallises in coloured needles. By the reduction of paranitrotriphenyl carbinol, a base is obtained, which crystallises from ether in long, well-developed, yellowish, lustrous needles melting at 123—124°. This compound appears to be *paramidobenzophenone*. The *hydrochloride* crystallises in tufts of long, golden-coloured needles. J. B. T.

Displacement of the Methylene Hydrogen-atoms in Deoxybenzoïn and Benzyl Cyanide: New Synthesis of Substituted Quinolines. By M. Buddeberg (*Ber.*, 23, 2066—2078).—*Allyldeoxybenzoïn*, $COPh\cdot CHPh\cdot C_3H_5$, is obtained when deoxybenzoïn is treated with sodium ethoxide and allyl iodide. It is a yellowish-brown oil boiling at 335—337°; its benzyl-derivative could not be prepared.

Allylbenzyl cyanide, $CN\cdot CHPh\cdot C_3H_5$, prepared by heating benzyl cyanide at 150—160° with allyl iodide and anhydrous sodium hydrate, is a colourless oil boiling at 260—270°; the yield is very small. When warmed with sodium ethoxide and benzyl chloride in alcoholic solution, it yields small quantities of an oil boiling at 320—330°, which seems to be impure benzylallylbenzyl cyanide,

$$CH_2Ph\cdot CPh(CN)\cdot C_3H_5.$$

Orthonitrobenzyldeoxybenzoïn, $NO_2\cdot C_6H_4\cdot CH_2\cdot CHPh\cdot COPh$, can be obtained by gradually adding a dilute alcoholic solution of sodiodeoxybenzoïn to a cold alcoholic solution of orthonitrobenzyl chloride. It crystallises from alcohol in needles, melts at 100—102°, and is readily soluble in alcohol, ether, glacial acetic acid, &c.; a benzyl-derivative of this compound could not be obtained. The corresponding *para*-compound, prepared in like manner, crystallises from alcohol in needles, melts at 110—112°, and is rather more sparingly soluble in alcohol than the ortho-compound. Orthodinitrostilbene (m. p. 196°), identical with the compound prepared by Bischoff (Abstr., 1888, 1094), is formed when orthonitrobenzyl chloride is added to an alcoholic solution of sodiobenzyl cyanide.

A compound of the composition $C_{21}H_{15}N$, which seems to be *αβ-diphenylquinoline*, is formed when orthonitrobenzyldeoxybenzoïn is reduced with iron powder and hot glacial acetic acid. It separates from alcohol in large, transparent crystals, melts at 95—96°, boils at about 420° without decomposition, and is soluble in most ordinary solvents. Vapour-density determinations gave results in accordance with the molecular formula given above. The *hydrochloride* crystallises in thin plates, and is decomposed by cold water. The *mercurochloride* crystallises from boiling dilute hydrochloric acid in long needles, and turns yellowish on exposure to the air. The *platinochloride*, $(C_{21}H_{15}N)_2,H_2PtCl_6$, is an orange-yellow, crystalline powder very sparingly soluble in water and alcohol.

Paramidobenzyldeoxybenzoïn, $NH_2\cdot C_6H_4\cdot CH_2\cdot CHPh\cdot COPh$, can be obtained by reducing paranitrobenzyldeoxybenzoïn with stannous chloride and hydrochloric acid in boiling alcoholic solution. It crystallises from alcohol in needles, melts at 140—141°, and is readily soluble in the ordinary solvents. The *hydrochloride*, $C_{21}H_{19}N,HCl$, crystallises from dilute alcohol in needles, is very readily soluble in alcohol, and is decomposed by boiling water. F. S. K.

Derivatives of Deoxybenzoïn. By J. EPHRAIM (*Chem. Centr.*, 1890, i, 906; from *Inaug. Diss. Berlin*).—By heating phthalic anhydride with orthocarboxylphenylacetic acid at 190°, *deoxybenzoïnorthodicarboxylic acid*, $COOH\cdot C_6H_4\cdot CH_2\cdot CO\cdot C_6H_4\cdot COOH$, is formed melting at 238—239°. Another substance, melting at 250°, is formed at the same time, and appears to be a double lactone.

Dibenzylorthodicarboxylic acid is obtained from deoxybenzoïnorthodicarboxylic acid by heating the latter with hydrogen iodide and phosphorus. With alcoholic ammonia, *deoxybenzoïnorthoimidodicarboxylic acid*, $C_{16}H_{11}O_3N$, is formed, the constitution of which is not certain. Phosphorus oxychloride abstracts one molecule of water from it, forming the compound $C_{16}H_9O_2N$.

Deoxybenzoïnorthodicarboxylic anhydride is obtained by passing hydrogen chloride into the alcoholic solution of the acid, after which the addition of water causes the formation of a precipitate, which is treated with sodium carbonate. Ethyl iodide, when added to the silver salt suspended in alcohol, causes the formation of the same anhydride. Hydroxylamine reacts with deoxybenzoïnorthodicarboxylic acid, with formation of an *oximidolactone*, $C_{16}H_{11}O_4N$, melting at 229—230°. Sodium amalgam reduces the same acid to the *lactide of hydroxytoluylenorthodicarboxylic acid*, melting at 201°, from which, by the action of barium hydroxide, followed by silver nitrate, the silver salt is obtained. The free acid could not be prepared. The barium salt crystallises with 2 mols. H_2O. J. W. L.

Isomeric Cuminildioximes. By E. HOFFMANN (*Ber.*, **23**, 2064—2066).—*a-Cuminildioxime*, $C_{20}H_{24}N_2O_2$, separates in colourless crystals when cuminil is warmed with hydroxylamine hydrochloride in methyl alcoholic solution; it melts at 249°, and is almost insoluble in alcohol, ether, and benzene, but readily soluble in soda. The *diacetyl*-derivative, $C_{24}H_{28}N_2O_2$, prepared by treating the dioxime with acetic anhydride in the cold, forms colourless crystals, melts at 127°, and is sparingly soluble in alcohol and glacial acetic acid.

β-Cuminildioxime, $C_{20}H_{24}N_2O_2$, is obtained when the *a*-compound is heated with alcohol at 140° for 10 to 12 hours. It crystallises from alcohol in needles, melts at 227°, and is readily soluble in alcohol and soda. The *diacetyl*-derivative is a syrup. F. S. K.

Oximes of Halogen-benzophenones. By K. AUWERS and V. MEYER (*Ber.*, **23**, 2063—2066).—Various compounds are formed when bromobenzophenone is treated with hydroxylamine in alkaline solution, but they have not yet been isolated. Chlorobenzophenone under the same conditions yields at least two isomeric oximes; the one melts at 96—97°, but solidifies again on prolonged heating at 100°, being converted into an isomeride which, after recrystallisation from alcohol, melts at about 155°; the other melts at 155°, and may be identical with the compound (m. p. 148—149°) obtained by Beckmann and Wegerhoff (*Annalen*, **252**, 7). The acetyl- and benzyl-derivatives of these two compounds also differ from one another. F. S. K.

Molecular Weight of the Desaurines. By V. MEYER (*Ber.*, **23**, 1571—1573).—Under the name of "Desaurines," a class of compounds has been described, distinguished by their golden-yellow colour, insolubility, and the formation of a blue-violet solution with concentrated sulphuric acid. They are obtained by the action of thiophosgene, $CSCl_2$, on deoxybenzoïn and analogous compounds, and that obtained from deoxybenzoin itself has the composition $COPh{\cdot}CPh{:}CS$. Its properties seemed to show that its molecular formula must be a multiple of that given above, and at the request of the author experiments were made by Beckmann on the lowering of boiling point caused when it is dissolved in ethylene bromide, as compared with solutions of benzil and phenyl benzoate in the same solvent. The results corresponded with a molecular weight double of that given above; possibly, therefore, the formula of the substance is  $COPh{\cdot}CPh{:}C{<}{}^{S}_{S}{>}CPh{:}C{\cdot}COPh$. C. F. B.

Benzyloxanthranol. By C. BACH (*Ber.*, **23**, 1567—1571).—This substance is obtained as a flocculent precipitate on reducing anthraquinone with zinc-dust, and shaking the filtered alkaline solution in air. Its formula is  $CO{<}{}^{C_6H_4}_{C_6H_4}{>}C(OH){\cdot}CH_2Ph$. When heated in a reflux apparatus with sodium acetate and acetic anhydride, it yields the *acetyl*-derivative, which forms yellowish needles melting at 281°, soluble in strong sulphuric acid with a yellow colour, and decomposed by long boiling with alcohol, benzyloxanthranol being re-formed. By dissolving the latter substance in strong sulphuric acid, *dehydrobenzyloxanthranol*,  $CO{<}{}^{C_6H_4}_{C_6H_4}{>}C{:}CHPh$, is obtained. This forms long, yellow needles, which sublime without decomposition. When allowed to remain for a few hours with the calculated quantity of bromine, it takes up two atoms of it and forms *dehydrobenzyloxanthranol bromide*  $CO{<}{}^{C_6H_4}_{C_6H_4}{>}CBr{\cdot}CHBrPh$, which crystallises from benzene in yellow needles melting at 148°. and soluble in ether, acetic acid, sulphuric acid, and slightly in alcohol, but not in water; its solution

in sulphuric acid is yellowish-red. By boiling it for a long time with alcohol, *bromodehydrobenzyloxanthranol*, $CO<{C_6H_4 \atop C_6H_4}>C{:}CBrPh$, is obtained. This dissolves easily in alcohol, and with sulphuric acid yields a violet-red solution. It crystallises from alcohol in yellow crystals melting at 254°, and forms yellow needles when sublimed. By heating it with red phosphorus and hydriodic acid in a reflux apparatus, *γ-benzylanthracene*,
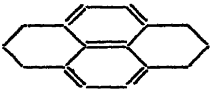
$C_6H_4<{C(CH_2Ph) \atop CH}>C_6H_4$, is formed, and is obtained by extracting the mass with alcohol and precipitating the hydrocarbon by the addition of a little water to the alcoholic extract. It crystallises from alcohol in long, colourless needles which melt at 119°; it dissolves in alcohol, ether, and benzene with a blue fluorescence, whilst its solution in concentrated sulphuric acid is green, and exhibits a red fluorescence. When it is dissolved in carbon bisulphide and treated with bromine (1 mol.), *bromobenzylanthracene*, $C_{21}H_{16}Br$, is formed; on evaporating the solution, this is left as prisms, which are soluble in alcohol, ether, and acetic acid, in benzene with a bluish fluorescence, and in sulphuric acid with a green colour. It crystallises from benzene in yellowish prisms, and decomposes when heated to 113—114°. By dissolving benzylanthracene in sulphuric acid and neutralising with barium carbonate, *barium benzylanthracenemonosulphonate*, $(C_{21}H_{15}SO_3)_2Ba$, is obtained in small, yellowish needles, which in solution exhibit a blue-violet fluorescence. C. F. B.

Action of Methyl Chloride on Naphthalene, and the Constitution of the Hydrocarbon obtained from Carminic Acid. By C. A. Bischoff (*Ber.*, **23**, 1905—1908).—By the action of methyl chloride on naphthalene in presence of aluminium chloride, the author finds, in agreement with Brunel (Abstr., 1884, 1035), that no methylnaphthalene is formed. If the product of the reaction be subjected to distillation, it yields, below 225°, a fraction containing naphthalene; between 225—260°, substances come over which partially solidify, and have melting points varying from 54° to 70°; between 260—325°, small quantities of oily products distil over, which were not further examined. The residue on distillation in a vacuum yielded two chief fractions, the one boiling below 360°, and the other above 360°. The former fraction was solid, but mixed with oil, and was purified by recrystallisation from alcohol. As soon as the melting point became 179—181°, the crystals were united with those obtained from the second fraction, and the whole recrystallised from alcohol until it became white; it was thus obtained in small plates, sparingly soluble in cold alcohol, acetic acid, and light petroleum, readily in the hot liquids. It was not free from ash, but the analyses appear to show that its formula is $C_{16}H_{10}$ or $C_{16}H_{12}$. It forms a *picrate*, crystallising in long, elastic, orange-yellow needles, which become plastic at 162°, and melt at 181°.

In its properties the hydrocarbon strongly resembles the compound $C_{16}H_{12}$ obtained by Liebermann and Dorp from ruficoccin (Abstr., 1872, 706), and by Fürth from carmine (Abstr., 1884, 84), the melting points and behaviour towards chromic and picric acids agreeing almost exactly, so that the two substances are probably identical. The author believes that it is formed from tetramethylnaphthalene (1 . 1′ . 4 . 4′), and that the carbon-atoms are united in the following manner—



an assumption which agrees well with the formula proposed by Liebermann and Dorp for ruficoccin (*loc. cit.*). H. G. C.

Reduction of Naphthalene and Anthracene. By E. BAMBERGER and M. KITSCHELT (*Ber.*, **23**, 1561—1565).—When naphthalene is dissolved in amyl alcohol and treated with sodium, it is almost entirely reduced to *tetrahydronaphthalene*, $C_{10}H_{12}$, which is a colourless, mobile oil boiling at 204·5—205° at 716 mm. pressure, and not solidifying in a freezing mixture. It has an odour like that of naphthalene, its sp. gr. at 17° is 0·978, and it very readily undergoes oxidation. When oxidised at the ordinary temperature with a dilute permanganate solution, it yields orthocarboxyhydrocinnamic acid,

$$COOH{\cdot}C_6H_4{\cdot}CH_2{\cdot}CH_2{\cdot}COOH,$$

and hence must have all its four additional hydrogen-atoms in the same ring [H_4 = 1 : 2 : 3 : 4]. This tetrahydronaphthalene has moreover been obtained from tetrahydroamidonaphthalene [$NH_2 : H_4$ = 1′ : 1 : 2 : 3 : 4] by the diazo-reaction, and probably also in an attempt to displace the amido-group in this substance by the nitro-group by means of Sandmeyer's reaction. It is not, however, identical with the tetrahydronaphthalene obtained by Graebe by treating naphthalene with hydriodic acid and phosphorus, for this yielded phthalic and not orthocarboxyhydrocinnamic acid when oxidised, and when treated with sulphuric acid it yielded a sulphonic acid, the barium salt of which crystallised in tables with 1½ mols. H_2O. The tetrahydronaphthalene obtained by the authors, on the other hand, yielded a *sulphonic acid*, the barium salt of which $(C_{10}H_{11}SO_3)_2Ba$, was anhydrous and crystallised in small, white needles.

Attention is drawn to the fact that naphthalene readily takes up four hydrogen-atoms, whilst anthracene takes up only two, which unite themselves to the middle carbon-atoms. This fact accords best with the hexacentric formulæ for naphthalene and anthracene.

C. F. B.

Action of Chlorine on Quinoneoximes. By T. ZINCKE and L. SCHMUNK (*Annalen*, **257**, 133—155).—Chlorine converts β-naphthaquinone-α-oxime into derivatives strictly analogous to those obtained from β-naphthaquinone (compare Zincke, Abstr., 1888, 158 and 489); its action is quite different from that of bromine, which forms an additive product with the oxime, as has been shown by Brömme (Abstr., 1888, 490).

Chloro-β-naphthaquinone-α-oxime, $C_6H_4{<}{\begin{matrix}C(:NOH)\\CH : CCl\end{matrix}}{>}CO$, is deposited in crystals when the theoretical quantity of chlorine is passed into a well-cooled chloroform solution of β-naphthaquinone-α-oxime, and the solution is then kept for about 12 hours. It crystallises from hot alcohol in yellowish-red needles, melts at 167—168° with decomposition, and is readily soluble in hot alcohol, glacial acetic acid, chloroform, and benzene; it dissolves in cold concentrated sulphuric acid, yielding a red solution from which it is reprecipitated unchanged on the addition of water. The *sodium* salt, $C_{10}H_5ClNO_2Na$, separates in green plates when soda is added to an alcoholic solution of the oxime; it is moderately easily soluble in water and dilute alcohol, and it gives coloured precipitates with solutions of salts of the heavy metals. Chloro-β-naphthaquinone-α-oxime is decomposed when it is boiled with concentrated hydrochloric or sulphuric acid in glacial acetic acid solution, and, on cooling, chlorhydroxynaphthaquinone (m. p. 214—215°) is deposited; when oxidised with nitric acid in warm acetic acid solution, it yields chloro-β-naphthaquinone and resinous products.

Chlorhydroxynapthaquinoneimide, $C_{10}H_6ClNO_2$, is formed when chloro-β-naphthaquinoneoxime is heated with sulphuric acid (1 vol.) and acetic acid (3 vols.) at a temperature below 80—90°. It crystallises from hot alcohol or hot acetic acid in brownish-red needles, melts at 179—180° with decomposition, and is only sparingly soluble in ether and light petroleum, but more readily in benzene; it dissolves unchanged in cold sodium carbonate, yielding a brownish-red solution, but on warming it is converted into chlorhydroxynaphthaquinone, with evolution of ammonia; soda and acids cause the same decomposition. These reactions show that the compound is not an oxime, and its constitution may therefore be expressed by the formula

$$C_6H_4<\begin{matrix}C(NH)\\CO\cdot CCl\end{matrix}>C\cdot OH.$$

Dichloro-β-naphthaquinone-α-oxime,  $C_6H_4<\begin{matrix}C(:NOH)\\CCl:CCl\end{matrix}>CO$, is deposited in green needles, in the form of the potassium salt, when the trichloronaphthaquinoneoxime described below is dissolved in chloroform, and a slight excess of concentrated potash added to the well-cooled solution; the crystals are separated by filtration and decomposed with dilute hydrochloric acid. It crystallises from hot glacial acetic acid in golden needles, melts at 165—166° with decomposition, and is moderately easily soluble in hot glacial acetic acid, hot alcohol, benzene, and chloroform; it dissolves unchanged in cold concentrated sulphuric acid yielding a red solution, but on warming it is converted into β-chlorhydroxy-α-naphthaquinoneoxime (see below); when warmed with nitric acid in acetic acid solution, it is converted into dichloro-β-naphthaquinone (m. p. 184—185°), identical with the compound obtained from α-amido-β-naphthol.

β-Chlorhydroxy-α-naphthaquinoneoxime,  $C_6H_4<\begin{matrix}C(:NOH)\\CO\text{—}CCl\end{matrix}>C\cdot OH$, is best obtained by warming the dichloroxime with concentrated sulphuric acid as long as hydrogen chloride is evolved, and then pouring the cold solution into water. It crystallises from hot dilute alcohol in long, golden needles, melts at 187—188° with decomposition, and is readily soluble in alcohol, ether, and glacial acetic acid, but m sparingly in light petroleum; it is soluble in boiling water, and it dissolves in sodium carbonate yielding a reddish-brown solution. This oxime can also be prepared by treating β-chlorhydroxy-α-naphthaquinone with excess of hydroxylamine hydrochloride in alkaline solution, as has lately been shown by Kostanecki (Abstr., 1889, 887), who named the product chloronitrosonaphtharesorcinol.

Trichloro-β-ketohydronaphthalene-α-oxime,

$C_6H_4<\begin{matrix}C(:NOH)\\CHCl\cdot CCl_2\end{matrix}>CO$, is deposited in crystals when excess of chlorine is passed into a well-cooled chloroform solution of β-naphthaquinone-α-oxime. It crystallises from a mixture of benzene and light petroleum in colourless needles, melts at 185—186° with decomposition, and is moderately easily soluble in alcohol, chloroform, and glacial acetic acid; it turns reddish on long exposure to the air, but it is very stable towards acids.

When the bromo- or the dibromo-β-naphthaquinone-α-oxime described by Brömme (*loc. cit.*) is heated with concentrated hydrochloric acid in acetic acid solution, it is converted into chlorhydroxynaphthaquinone (m. p. 214—215°), and not into bromonaphthaquinone, as stated by him; if sulphuric acid is used in the place of hydrochloric acid, the product is bromhydroxynaphthaquinone (m. p. 196—197°). When β-naphthaquinone-α-oxime is treated with bromine in glacial acetic acid solution, it is converted into bromhydroxynaphthaquinone; Brömme states that bromonaphthaquinone is formed under these conditions.

F. S. K.

Azo-colours from α-Naphthylamine, Dimethylaniline, and α-Hydroxynaphthoic Acid. By C. A. Bischoff (*Ber.*, 23, 1908—1911).—In order to characterise the shade of the colouring matter obtained from dimethylpiperazine and sulphanilic acid (Abstr., 1889, 1010), the author has prepared the following naphthalene azo-colouring matters.

Dimethylamidobenzene-α-azonaphthalene, $Me_2N\cdot C_6H_4\cdot N_2\cdot C_{10}H_7$, is prepared by diazotising a solution of an α-naphthylamine salt in the usual manner, and mixing it with an alcoholic solution of dimethylaniline, the crude colouring matter being purified by alternate treatment with hydrochloric acid and ammonia. It is insoluble in cold water, sparingly soluble in alcohol and ether, readily by chloroform, crystallising from the latter in prisms, which appear black by reflected light, and ruby-red by transmitted light. Its hot aqueous solution becomes wine-red on the addition of hydrochloric acid, yellow with acetic acid, and lemon-yellow with soda. It dissolves in concentrated sulphuric acid, forming a violet-coloured solution, and decomposes about 100°.

By the action of sulphuric acid containing 20·5 per cent. of anhydride, it yields, according to the duration of the reaction and the temperature, three sulphonic acids, the sodium salts of which are readily soluble in water. The first, obtained by heating for 10 minutes at 110—112°, has a yellow colour; the second, which is formed at 116—120°, has an orange colour; and the third, obtained by heating for an hour at 125°, a pure brown.

α-Naphthylazo-α-hydroxynaphthoic acid, $C_{10}H_7\cdot N_2\cdot C_{10}H_5(OH)\cdot COOH$, is best prepared by pouring a cold solution of diazonaphthalene chloride in a thin stream into a well-cooled solution of hydroxynaphthoic acid in sodium carbonate. The colouring matter is recrystallised from acetic acid. This reaction has also been carried out by Nietzki and Guitermann (Abstr., 1887, 732), but they were unable to get any concordant analyses of the compound. The same difficulty was also experienced in this case, but, finally, by very careful combustion, numbers were obtained agreeing closely with the above formula. It forms golden-yellow plates, which melt at 198° with decomposition, and are insoluble in cold water, sparingly soluble in ether, benzene, and chloroform, readily in acetic acid and acetone. It is not decomposed by boiling dilute acids, and dissolves in concentrated sulphuric acid, forming a deep blue solution from which water precipitates it in green floccules. The neutral salts have a deep red colour, and are readily soluble in water, whilst the acid salts are yellow, and less soluble in cold water. The acid sodium salt does not colour unmordanted cotton, but in an alkaline bath dyes wool a fiery orange-yellow. H. G. C.

Sulphonation of Aniline and Naphthylamine with Potassium Hydrogen Sulphate. By C. A. BISCHOFF, A. SIENUCKI, and H. BRODSKY (*Ber.*, **23**, 1912—1914).—When aniline is heated with potassium hydrogen sulphate (2 mols.) at 200—240°, sulphanilic acid is formed in quantities varying from 8 to 19 per cent., the latter yield being obtained at 200—220°. α-Naphthylamine yields from 15—18 per cent. of the monosulphonic acid, the most favourable temperature being 230°, whilst with β-naphthylamine 60 per cent. of the monosulphonic acid may be thus obtained.

If a mixture of powdered α-naphthylamine (1 part) and potassium hydrogen sulphate (3 parts) be made into thin cakes, then heated to 60—80°, and pressed between hot plates, and the cakes heated for 3 hours at 200°, 50 per cent. of the α-monosulphonic acid may be obtained. According to Bayer and Duisberg, the product from α-naphthylamine is ordinary α-naphthionic acid, and that from β-naphthylamine, β_1-β_4-naphthionic acid mixed with traces of β-naphthylamine-δ-sulphonic acid. H. G. C.

Diazosulphonic Acids. By G. TOBIAS (*Ber.*, **23**, 1628—1634).—The conversion of diazosulphonic acids into the corresponding chlorosulphonic acids, by the action of cuprous chloride on a hydrochloric acid solution (Sandmeyer's reaction) is frequently incomplete on account of the sparing solubility of the chlorinated compounds in concentrated hydrochloric acid. The addition of water causes the reaction to proceed until the diazo-compound is entirely decomposed; it is also found that a mere trace of cuprous chloride is sufficient to bring about the change.

Tarnished copper foil has the same effect. An evolution of nitrogen takes place if a little *cuprous oxide* is added to the diazo-compound dissolved in any one of the following acids, namely, nitric, sulphuric, acetic, formic, or in ethyl or methyl alcohol, or even in pure water.

In the case of water, the reaction proceeds at the ordinary temperature, but the actual change which occurs has not been ascertained.

Under certain conditions, if the solvent is 50 per cent. formic acid, hydrogen is substituted for the diazo-group—hydrogen sodium diazonaphthalenedisulphonate, for example, yields the corresponding naphthalenedisulphonic acid; a considerable quantity of carbonic anhydride is evolved during the experiment, showing that part of the reduction is effected at the cost of the formic acid.

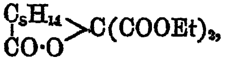
The action of ethyl alcohol is similar to that of formic acid; the diazo-compound is reduced, and a portion of the alcohol oxidised to aldehyde. Cuprous chloride acts like cuprous oxide, if the solvent is water, alcohol, or formic acid. J. B. T.

Nutmeg Oil and Mace Oil. By F. W. SEMMLER (*Ber.*, **23**, 1803—1810).—A sample of commercial nutmeg oil examined was found to contain nothing but a mixture of terpenes, and its study was abandoned, as these substances are now being investigated by several chemists. It was colourless, and had a sp. gr. of 0·8611 at 15°.

A sample of mace oil was then examined, of sp. gr. 0·9309 at 14°. It had a yellow colour, and contained a considerable quantity of oxygen. With alcoholic ferric chloride, it gave a green colour. It was fractionated under 10 mm. pressure. 53 per cent. passed over below 70°, and was a mixture of the same terpenes as are contained in nutmeg oil. 15 per cent. more came over between 70° and 114°, and doubtless contained myristicol; this fraction is to be examined later. The portion boiling above 114° was practically identical with an oil bought under the name of "high-boiling portions of mace oil." By treating this cautiously with sodium in a vacuum, and distilling the product, a clear homogeneous oil was obtained, boiling at 142—149° under 10 mm. pressure, and of sp. gr. 1·1501 at 25°. When cooled, it forms white needles which melt at 30·25°. Analysis and vapour density point to the formula $C_{12}H_{14}O_3$. It has been named *myristicin*, and it is present as such in the commercial oil. When carefully treated with bromine, it takes up two atoms, yielding *dibromomyristicin*, $C_{12}H_{14}Br_2O_3$, which forms white aggregates of needles melting at 105°. It also takes up chlorine and iodine. Hence, it probably contains a radical of the allyl series. When heated with zinc-dust, it yields benzene, and as it is not acted on by sodium, it is probably an ether, the oxygen-atoms being united both to the benzene ring and to fatty radicals.

Beside myristicin, the crude oil also contains a phenol-like substance, which causes a green colour with ferric chloride, and which oxidises readily in the air, turning dark green. C. F. B.

Ethyl Camphorylmalonate. By J. WISLICENUS and H. WINZER (*Annalen*, **257**, 298—321).—*Ethyl camphorylmalonate*,



$$\begin{matrix} C_8H_{14} \\ | \\ CO\cdot O \end{matrix}\!\!>\!C(COOEt)_2,$$

is obtained when camphoric anhydride (1 mol.) or camphoryl dichloride (1 mol.) is treated with ethyl sodiomalonate (2 mols.), and the mixture heated for a long time to complete the reaction; the whole is then treated with water, and the insoluble oil separated and kept for some time, whereon the new compound is deposited in crystals. It separates from ether in well-defined crystals, melts at 82°, boils at 284° (corr.) under a pressure of 40 mm. without decomposition, and at about 360° under the ordinary pressure with slight decomposition; it is readily soluble in ether, alcohol, chloroform, acetone, carbon bisulphide, and glacial acetic acid, but only sparingly in hot light petroleum, and is insoluble in water. Compounds analogous to ethyl phthalyldimalonate and ethyl phthaloxydimalonate (compare Wislicenus, Abstr., 1888, 149) are not obtained by the action of ethyl sodiomalonate on camphoryl dichloride.

Hydrocamphorylmalonic acid, $COOH\cdot C_8H_{14}\cdot CH_2\cdot CH(COOH)_2$, is formed when the preceding compound is dissolved in aqueous alcohol and sodium added to the well-cooled solution, which is kept slightly acid by the frequent addition of dilute sulphuric acid. The decanted alcoholic solution is then evaporated, the precipitated oil redissolved by adding soda, the solution mixed with copper sulphate, and the precipitate, which seems to consist of a mixture of the copper salts of ethyl dihydrogen and diethyl hydrogen hydrocamphorylmalonate, separated by filtration; the filtrate is acidified, the precipitated hydrocamphorylmalonic acid separated and recrystallised from a mixture of hot alcohol and benzene. It melts at 178°, and is soluble in ether, alcohol, and hot water, but only very sparingly in cold water and benzene; silver, lead, ferric, and mercurous salts produce precipitates in its neutral aqueous solution, but the copper, ferrous, zinc, and barium salts are readily soluble in water.

Hydrocamphorylacetic acid, $COOH\cdot C_8H_{14}\cdot CH_2\cdot CH_2\cdot COOH$, is obtained by heating the malonic acid derivative until the evolution of carbonic anhydride is at an end; it crystallises from hot water in colourless plates, melts at 141—142°, and is readily soluble in ether, alcohol, and benzene.

Ethyl hydrocamphorylmalonate, $C_{19}H_{32}O_6$, is obtained when the mixture of insoluble copper salts referred to above is decomposed with hydrochloric acid, the oily acids converted into their silver salts, the latter heated with ethyl iodide, and the product fractionated under reduced pressure in order to separate it from a compound of lower boiling point (see below). It is a colourless oil boiling at 253—255° (80 mm.), and is insoluble in water.

Ethyl dihydrogen hydrocamphorylmalonate, $C_{15}H_{24}O_6$, can be prepared by treating the ethyl salt just described with excess of sodium ethoxide in alcoholic solution, and decomposing the crystalline salt which is deposited with hydrochloric acid. It crystallises from hot water in colourless needles, melts at 136—138°, and decomposes at a higher temperature with evolution of carbonic anhydride.

Camphoryldiamide,  $C_8H_{14}<\begin{matrix}C(NH_2)_2\\CO—O\end{matrix}>$, is gradually deposited in colourless crystals when an ethereal solution of ethyl camphorylmalonate is saturated with ammonia, and then kept for some time. It crystallises from a mixture of alcohol and light petroleum in large prisms, melts at 192—193°, and is readily soluble in alcohol, but insoluble in ether, chloroform, benzene, and light petroleum; it dissolves freely in water, and on evaporating the solution at 100°, it separates again unchanged. The camphoryldiamide described by Moitessier (*Annalen*, **120**, 253) must have been a very impure substance.

Camphorylimide, $C_6H_{14}<\substack{C(NH)\\COO}>$, is precipitated when the diamide is boiled with soda, and the solution acidified; it can also be obtained by heating camphoric anhydride with a saturated alcoholic solution of ammonia at 160°. It crystallises in plates, sublimes at 120°, melts at 241—242°, and is readily soluble in ether, alcohol, and hot water, but only sparingly in light petroleum and cold water. This compound has been previously prepared by Laurent (*Annalen*, **60**, 329), and by Ballo (*ibid.*, **197**, 332), but only in an impure condition.

An *acid* of the composition $C_{11}H_{18}O_3$, probably *acetocamphenylcarboxylic acid*, $COMe\cdot C_8H_{14}\cdot COOH$, is formed, together with camphoric acid, malonic acid, and carbonic anhydride, when ethyl camphorylmalonate is boiled with a concentrated solution of barium hydroxide. The whole is boiled with water, the solution filtered from barium carbonate, and concentrated by evaporation to precipitate the barium malonate; the filtrate is then further evaporated, mixed with alcohol, and ether gradually added to the solution, whereon the barium camphorate is first precipitated in crystals, and, finally, the barium salt of the new acid is deposited as a colourless syrup, which, however, gradually solidifies. The free acid crystallises from a mixture of benzene and light petroleum in rhombic prisms, melts at 95°, and is soluble in hot water, ether, alcohol, and benzene, but almost insoluble in cold water and light petroleum; it separates from hot water in the form of an oil, which gradually solidifies to a mass of plates melting at 68—69°. The *ethyl* salt, $C_{11}H_{17}EtO_3$, is produced, together with carbonic anhydride, malonic acid, and ethyl hydrogen camphorate, when an alcoholic solution of ethyl camphorylmalonate is mixed with sodium ethoxide, and kept for about eight days; the solution is then neutralised with dilute hydrochloric acid, the precipitated oil extracted with ether, mixed with a little dilute soda, distilled with steam, dried, and fractionated. It can also be obtained by treating the silver salt of the acid (m. p. 95°) described above with ethyl iodide. It boils at 270—271°, has a slight odour of camphor, and is identical with the low-boiling compound obtained in fractionating ethyl hydrocamphorylmalonate (see above). The *silver* salt, $C_{11}H_{17}AgO_3$, was prepared from this low-boiling compound. The *oxime*,

$$COOH\cdot C_{10}H_7{:}N\cdot OH,$$

obtained by treating the acid with hydroxylamine hydrochloride and sodium carbonate in dilute alcoholic solution, crystallises in colourless needles, melts at 166°, and is soluble in ether, alcohol, and hot water, but only sparingly in cold water.

A dicarboxylic *acid* of the composition $C_{21}H_{32}O_4$, is formed with evolution of carbonic anhydride when ethyl camphorylmalonate is heated with concentrated sulphuric acid, and on the addition of water it is precipitated in colourless crystals; it is also obtained in the form of the sodium salt when ethyl acetocamphenylcarboxylate is boiled for several hours with an alcoholic solution of sodium ethoxide. It crystallises from ether in prisms, melts at 224°, and is readily soluble in alcohol, benzene, and hot water, but more sparingly in light petroleum and ether; it sublimes readily under reduced pressure, and in its neutral aqueous solutions silver, copper, ferric, and mercury salts produce a precipitation. F. S. K.

Amethylcamphophenosulphone and a Nitro-colouring Matter derived from it. By P. Cazeneuve (*Compt. rend.*, **110**, 961—964).—*Amethylcamphophenolsulphone*, $C_9H_{12}O(SO_2)\cdot(OH)_2$, obtained in the manner already described (this vol., p. 791), forms large, white plates which resemble cholesterin. It dissolves in water, but is less soluble in alcohol, and is insoluble in benzene, ether, chloroform, and carbon bisulphide. It does not melt, is optically inactive, is neutral to litmus and methyl-orange, and does not decompose carbonates It has a phenolic function, and with ferric chloride gives a deep blue coloration which is destroyed by acids and alkalis. With 1 mol. of potassium hydroxide, it develops 7 Cals., but there is no further thermal disturbance on adding more alkali, although the compound contains two hydroxyl-groups, and one of them must therefore have a secondary alcoholic function. Barium hydroxide yields a precipitate of the composition $C_9H_{12}O(SO_2)\colon O_2Ba$, but no precipitate is formed with lime-water, starch-paste, gelatin, albumin, tartar emetic, or salts of mercury, zinc, or copper. The compound precipitates salts of lead, quinine, cinchonine, aconitine, strychnine, and brucine, but does not precipitate morphine or theine. It reduces boiling solutions of gold chloride or ammonio-silver nitrate, but not platinic chloride. When fused with potash at 300°, it loses its sulphur and yields a phenol.

Acetic anhydride yields a monacetic derivative of the composition $C_9H_{12}O(SO_2)(OH)\cdot OAc + 2H_2O$, very soluble in water and alcohol. It does not melt without decomposition, gives no coloration with ferric chloride, and no precipitate with barium hydroxide, and is easily saponified. A di-acetic derivative with similar properties is obtained by boiling the compound with acetic anhydride and sodium acetate.

When the compound is heated for a long time on the water-bath with phenylhydrazine, it yields a liquid which is difficult to purify, but the formation of which proves that the compound retains the ketonic group of the camphor.

If 1 part of the compound is added gradually to 5 parts of fuming nitric acid cooled to 0—10°, it dissolves without evolution of gas, and on mixing with ice-cold water, the compound

$$C_9H_8(NO_2)_3O(SO_2)(OH)\cdot ONO_2$$

is precipitated. It crystallises from alcohol in beautiful, yellow needles which melt at 87°, solidify at 80°, and boil above 200° with partial decomposition. It is only slightly soluble in water, but more soluble in alcohol, has a slightly piquant but not bitter taste, detonates when thrown into a red-hot crucible. It is bibasic, and yields orange-yellow crystallisable salts, all of which are soluble. The barium salt crystallises with 2 mols. H_2O, which it loses in a vacuum or at 100°, and acquires a red colour, but absorbs water again on exposure to air.

The nitro-compound and all its salts dye wool and silk a magnificent yellow or orange-yellow without any mordant. It is the first nitro-colouring matter of the terebene group. C. H. B.

Distillation of Rosin in a Vacuum. By C. A. Bischoff and O. Nastvogel (*Ber.*, **23**, 1919—1924).—If rosin be distilled under diminished pressure, the products obtained are less numerous and more readily separated than when the distillation is carried out at the ordinary pressure. By repeated fractionation of the distillate under 30 mm. pressure, two chief fractions were obtained, that formed in larger quantity boiling at 248—250°; this, on remaining for a short time, solidifies to a colourless, brittle, microcrystalline mass, which is insoluble in water, but dissolves readily in ether and alcohol. It has the composition $C_{40}H_{58}O_3$, rotates the plane of polarisation in alcoholic solution to the right ($[\alpha]_D = 63°$), and behaves in all respects as an anhydride. It dissolves on warming with caustic potash, the solution on acidification with acetic acid yielding the corresponding acid, which melts at 60·5—62·5°, and has the composition $C_{20}H_{30}O_2$. It is, therefore, isomeric with sylvic acid, and may be termed isosylvic acid, the above compound, $C_{40}H_{58}O_3$, becoming then isosylvic anhydride. The second fraction boils at 218—220° under 30 mm. pressure, and appears to be a diterpene having the composition $C_{20}H_{32}$. It is probably identical with Deville and Riban's colophene. H. G. C.

Peucedanin. By A. Jassoy (*Chem. Centr.*, 1890, i, 766; from *Apoth. Zeit.*, 5, 150).—This bitter is *oreoselon methyl ether*, $C_{14}H_{11}O_3{\cdot}OMe$. Bromine combines with oreoselon, forming bromoreoselon, and in the same manner it reacts with peucedanin, forming the same compound, the methyl-group being eliminated. Nitric acid forms *nitrooreoselon*, $C_{14}H_{11}(NO_2)O_4$, with both oreoselon and with peucedanin; styphnic acid is formed at the same time. Organic acid anhydrides do not react with peucedanin as they do with oreoselon, but acid chlorides form with peucedanin the same compounds that they do with oreoselon, methyl chloride being separated. J. W. L.

Ostruthin. By A. Jassoy (*Chem. Centr.*, 1890, i, 766; from *Apoth. Zeit.*, 5, 150).—The bitter, ostruthin, noticed by Gorup-Besanez in the young rhizome of *Imperatoria ostruthium*, has the formula $C_{18}H_{20}O_3$, according to the author's researches, and he finds that it does not contain any methoxyl-group, but a hydroxyl-group of the nature of a phenol. Acid radicles can be readily introduced into this group, and the acetyl-, propionyl-, butyryl-, and benzoyl-ostruthins were prepared. Acid chlorides decompose ostruthin. The author could not find peucedanin in the roots of *Imperatoria ostruthium*. J. W. L.

New Method of Formation of Pyrroline-derivatives. By A. HANTZSCH (*Ber.*, 23, 1474—1476).—Ethyl 2 : 5-dimethylpyrrolinecarboxylate (m. p. 116—117°), identical with the compound described by Knorr (*Ber.*, 15, 1558), is formed when concentrated ammonia is gradually added to a mixture of chloracetone (1 mol.) and ethyl acetoacetate (1 mol.); the yield is very small. F. S. K.

Action of Hydroxylamine on Pyrroline-derivatives. By G. CIAMICIAN and C. U. ZANETTI (*Ber.*, 23, 1787—1793).—When an alcoholic solution of 1-ethylpyrrol and hydroxylamine hydrochloride is boiled with sodium carbonate, succinaldoxime, $C_2H_4(CH\colon N\cdot OH)_2$, is formed, together with ethylamine. This shows that in this and similar reactions it is the imido-group of the pyrroline, substituted or otherwise, which goes to form ammonia or an amine.

By treating 2 : 4-dimethylpyrroline with hydroxylamine, *α-methyllevulindioxime*, $OH\cdot N\colon CH\cdot CHMe\cdot CH_2\cdot CMe\colon N\cdot OH$, was obtained. This substance forms yellowish needles or prisms which melt at 87—90° to a liquid of the same colour. It dissolves easily in alcohol and water, sparingly in ether. It reduces Fehling's solution and ammoniacal silver nitrate. When treated with sodium ethylate, it yields a *disodium compound*, $ONa\cdot N\colon CH\cdot CHMe\cdot CH_2\cdot CMe\colon N\cdot ONa$, which is an easily decomposable, yellowish-white powder little soluble in alcohol or ether. When reduced with sodium and alcohol, it yields *αβ′-dimethyltetramethylenediamine*, $NH_2\cdot CHMe\cdot CH_2\cdot CHMe\cdot CH_2\cdot NH_2$. This is a clear, colourless liquid boiling at 175°, fuming in the air, and having a penetrating, ammoniacal odour. It forms a normal *oxalate*, $C_4H_6Me_2(NH_2)_2,C_2H_2O_4$, in fine, white needles melting at 244° and sparingly soluble in alcohol. The *platinochloride*, $C_6H_{16}N_2,H_2PtCl_6$, forms orange-yellow crystals moderately soluble in water; the *aurochloride* forms yellow needles easily soluble in water.

When 2 : 5-methylphenylpyrroline was treated with hydroxylamine hydrochloride and potassium carbonate in alcoholic solution, *acetophenoneacetonedioxime*, $OH\cdot N\colon CPh\cdot CH_2\cdot CH_2\cdot CMe\colon N\cdot OH$, melting at 108°, was obtained in small needles, and was identified with the substance formed when acetophenone is treated with hydroxylamine. It dissolves easily in alcohol, acetic acid, and ether, very sparingly in water and light petroleum; it dissolves in caustic alkalis, but is reprecipitated on the addition of acids.

The following table gives the results of experiments hitherto made on the action of hydroxylamine on pyrroline-derivatives. It will be seen that the ease with which these yield oximido-derivatives depends both on the nature and on the position of the substituting radicles:—

Pyrroline. Yield of succinaldoxime, 35 per cent.

2 : 5-*Dimethylpyrroline.* Yield of acetonylacetonedioxime, 90 per cent.

2 : 4-*Dimethylpyrroline.* Yield of α-methyllevulindioxime, 55 per cent.

2 : 5-*Methylphenylpyrroline.* Yield of acetophenoneacetonedioxime, 25 per cent.

1-*Ethylpyrroline.* Yield of succinaldioxime, 20 per cent.

1-*Phenylpyrroline*, 2 : 5-*diphenylpyrroline*, *tetraphenylpyrroline*, *methyl 2-pyrrolinecarboxylate*, *ethyl* 2 : 4-*pyrrolinedicarboxylate*, and also *indole*, *thiophen*, and 2 : 5-*dimethylthiophen* are not acted on by hydroxylamine. C. F. B.

Action of Ethyl Oxalate on Pyrroyl Methyl Ketone. By A. Angeli (*Ber.*, 23, 1793—1797).—When a cooled alcoholic solution of 2-acetylpyrroline (1 mol.) is treated with ethyl oxalate (1 mol.) in the presence of sodium ethoxide, *ethyl pyrroylpyrotartrate*, $C_4NH_4\cdot CO\cdot CH_2\cdot CO\cdot COOEt$, is formed. It is obtained by saturating the cooled mixture with carbonic anhydride and recrystallising the crystalline precipitate from boiling benzene. It forms brilliant, pale-yellow plates, melting at 123°, and dissolving easily in alcohol and benzene, sparingly in water, and hardly at all in light petroleum. It has feebly acid properties, and gives a green, crystalline precipitate with copper acetate and a green colour with ferric chloride; its benzene solution has a faint green fluorescence. The free acid cannot be obtained from it, as it is decomposed by caustic alkalis.

When treated with alkaline carbonates, or ammonia, it yields the *imineanhydride* of *pyrroylpyrotartaric acid*,  $CH\!\begin{array}{l}\diagup CH{:}C\cdot CO\cdot CH_2\\ \diagdown\!\!\diagdown CH\cdot N\cdot CO\cdot CO\end{array}$, which was also formed in the original reaction, in addition to ethyl pyrroylpyrotartrate, and could be obtained from the mother liquor of the latter by acidifying it with hydrochloric acid. A molecular weight determination by Raoult's method corresponded with the above formula. When crystallised from benzene, it forms yellow needles which decompose at 250° without melting. It dissolves easily in alcohol and acetic acid, sparingly in benzene, and not at all in light petroleum. With water, it gives an unstable solution which is coloured reddish-brown by ferric chloride. It has acid properties, and decomposes solutions of alkaline carbonates, giving orange-yellow solutions.

When ethyl pyrroylpyrotartrate is treated with excess of hydroxylamine hydrochloride, an *anhydride* of *ethylpyrroylisonitrosopropionate*  $CH\!\begin{array}{l}\diagup CH{:}C\ CO\cdot CH_2\\ \diagdown\!\!\diagdown CH\cdot N\cdot N{=}C\cdot COOEt\end{array}$, is obtained, which when purified, crystallises from alcohol in white needles melting at 123—124°. When treated with aqueous alkalis, it readily yields the corresponding *acid*, which, when purified, crystallises from alcohol in brilliant, white needles melting with decomposition at 179°. It dissolves easily in alcohol, sparingly in benzene and chloroform, and not at all in water. With strong nitric acid, it gives a green colour; with sulphuric acid and dichromate, a red colour. A solution of its ammonium salt gives, with mercuric chloride, zinc chloride, and lead acetate, white precipitates, soluble in the case of the last two salts on warming the solution; with ferric chloride, a yellow precipitate turning brown when warmed; with silver nitrate, a yellow; with copper sulphate, a green precipitate; and with nickel sulphate, no precipitate. C. F. B.

Compounds of Tertiary Amines with Acetic Acid and its Homologues. By J. A. Gardner (*Ber.*, 23, 1587—1594).—Mixtures were made of various tertiary bases with acids of the acetic acid series, and the mixture in each case subjected to distillation. In several cases it was found that the greater part of the mixture distils at an approximately constant temperature, higher than the boiling point of either of its constituents, and that this fraction has a constant composition. These liquids of constant boiling point have an acid reaction, mix with water in all proportions, and are decomposed by caustic alkalis with liberation of the base; they are not simple acetates, but have a more or less complex composition. They cannot be obtained absolutely pure, as they always decompose somewhat when distilled. Indeed, it was found in most cases, by vapour-density experiments, that the liquid is completely dissociated into base and acid when it passes into the state of vapour. Below are given the boiling points and composition (ratio of mols. of base to mols. of acid) of the fractions of constant boiling point in the case of the mixtures experimented with.

Mixture.	Boiling point.	Composition.		
		Mols. base.		Mols. acid.
Pyridine and acetic acid......	139—140°	2	:	3
Picoline and acetic acid... ..	145—148	2	:	3
Triethylamine and acetic acid .	162°	1	:	4
Pyridine and formic acid	148—150	1	:	3
Picoline and formic acid......	156—159	1	:	3
Pyridine and propionic acid...	148—150	1	:	3

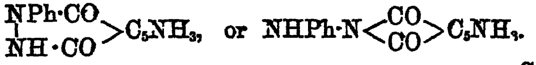
Quinoline, dimethylaniline, and aniline were also experimented with, but on distilling mixtures of either of these substances with an acid, decomposition took place, and no fraction of constant boiling point was obtained. C. F. B.

Pyridineorthocarboxylic Acids. By H. STRACHE (*Monatsh.*, 11, 133—148; compare Abstr., 1889, 1016).—When a solution of the anhydride of cinchomeronic acid ($\beta\gamma$-pyridinedicarboxylic acid) in benzene is treated with a large excess of dry gaseous ammonia, a voluminous white precipitate of the ammonium salt of cinchomeronamic acid, $CONH_2\cdot C_5NH_3\cdot COONH_4$, is formed. It is exceedingly soluble in water, commences to sinter at 50—60°, and melts at 228—229°; the corresponding silver salt crystallises from hot water, in which it is only slightly soluble, in microscopic needles; the free acid is obtained by the action of hydrogen sulphide on a solution of the silver salt, and, on evaporating its aqueous solution, first forms hydrogen ammonium cinchomeronate, which decomposes into cinchomeronic acid and ammonia.

Cinchomeronimide, $C_5NH_3<{CO \atop CO}>NH$, is obtained by heating the ammonium salt of cinchomeronamic acid at 120°, in an air-bath, or by heating neutral ammonium cinchomeronate. It melts at 229—230°, sublimes readily, forming dendritic masses of long needles, and crystallises from alcohol in felted masses of microscopic needles. It is only slightly soluble in ether and chloroform, but dissolves readily in water, with partial decomposition, forming cinchomeronamic acid, hydrogen ammonium cinchomeronate, and free cinchomeronic acid, and yields a sodium-derivative when treated with sodium ethylate.

Cinchomerondianilide, $C_5NH_3(CO{\cdot}NHPh)_2$, is obtained by gradually dissolving cinchomeronic acid in four times its weight of aniline; on crystallisation from dilute alcohol, it forms small, pale-yellow needles melting at 199—206°. It is insoluble in water, but dissolves readily in benzene and chloroform, with difficulty in ether and in water containing hydrochloric acid. When heated above its melting point, aniline escapes with formation of *cinchomeronphenylimide*, $C_5NH_3{<}{\substack{CO\\CO}}{>}NPh$, a substance which crystallises in long, yellow needles, melts at 212—215·5°, is very soluble in hot alcohol, benzene, and chloroform, scarcely soluble in hot water, cold alcohol, and ether, and insoluble in dilute hydrochloric acid and aqueous potash.

Cinchomeronic acid dissolves readily in boiling phenylhydrazine, yielding a diphenylhydrazine compond, $C_5NH_3(CON_2H_2Ph)_2$, which forms yellow, crystalline flocks, soluble in dilute acids and alkalis, and crystallising from alcohol in masses of slender needles. When heated, it loses a molecule of phenylhydrazine with formation of a monophenylhydrazine compound, which melts at above 260°, sublimes readily, is sparingly soluble in water, ether, benzene, and chloroform, dissolves readily in alcohol and dilute acids and alkalis, and has the constitution



$$\begin{matrix}NPh{\cdot}CO\\ | \\ NH{\cdot}CO\end{matrix}{>}C_5NH_3, \quad \text{or} \quad NHPh{\cdot}N{<}{\substack{CO\\CO}}{>}C_5NH_3.$$

G. T. M.

Orthoparadimethylquinoline-α-Aldehyde. By G. Panajotow, (*Ber.*, **23**, 1471).—Orthoparadimethylquinoline-α-aldehyde

$$[COH : N : Me_2 = 3 : 4 : 2' : 4']$$

is formed when orthoparadimethylquinoline-α-acrylic acid hydrochloride (5 grams) is dissolved in sodium carbonate, the solution diluted with water (250 grams), covered with a layer of benzene (125 grams), cooled to 0°, and a solution of potassium permanganate (5 grams) gradually added with constant shaking; the yield is 10 per cent. of the theoretical. It crystallises from light petroleum in yellowish plates, melts at 107°, and is readily soluble in alcohol, ether, and acids, but only sparingly in water and light petroleum.

F. S. K.

Polymerisation of Nitriles: Cyanalkines (Metadiazines). By R. Schwarze (*J pr. Chem.* [2], **42**, 1—18; compare Abstr., 1889, 114, 360, 577, 683, 685) —When sodium ethoxide (1 mol.) and ethyl cyanide (3 mols.) are heated together at 130° for 3—4 hours, amidomethyldiethylmetadiazine (cyanethine) is obtained, the yield being about 66 per cent. In the same way, amidodimethylmetadiazine (cyanomethine) is obtained from methyl cyanide and sodium ethoxide; in this case the yield is 35 per cent. When isopropyl cyanide (3 mols.) and sodium ethoxide were heated together at 160—170°, the mass became solid, and an uninvestigated nitrogenous substance was obtained, but no cyanalkine was formed. When propyl cyanide (15 grams) and sodium ethoxide (7 grams) are heated together at 170°, amidomethyldipropylmetadiazine (cyanopropine, Abstr., 1888, 800; 1889, 684) is obtained.

Amidodimethylmetadiazine is also formed (62 per cent.) when sodium methoxide (5·5 grams) and methyl cyanide (15 grams) are heated together at 130°, and amidomethyldiethylmetadiazine when sodium methoxide and ethyl cyanide are similarly treated at 160° Sodium isobutoxide (7 grams) and ethyl cyanide (12 grams), heated together at 190°, yielded amidomethyldiethylmetadiazine (21 per cent.) and an *isomeride* of the same; this was a colourless oil, which had a characteristic odour, and solidified after a time; the *platinochloride* from this oil crystallised in yellowish-red needles. No change occurred when sodium phenoxide and ethyl cyanide were heated together.

Amidomethyldiphenylmetadiazine (Abstr., 1889, 578; this vol., p. 68) is obtained when sodium ethoxide (4 grams), ethyl cyanide (4·8 grams), and phenyl cyanide (9 grams) are heated together at 180°. The same substance is produced when sodium, ethyl cyanide, and phenyl cyanide (equal mols.) are mixed together in a reflux apparatus; the *hydrochloride*, *sulphate*, two *chromates* $(C_{17}H_{15}N_3)_2,H_2Cr_2O_7$ and $(C_{17}H_{15}N_3)_4,(H_2Cr_2O_7)_3$, and the *platinochloride* of this base have been obtained.

Hydroxymethyldiphenylmetadiazine has been obtained by E. v. Meyer (*loc. cit.*); it is formed from the amido-compound by dissolving the latter in glacial acetic acid, and decomposing it with nitrous acid, or by heating it with dilute hydrochloric acid in a sealed tube at 180°; it melts at 250°, and dissolves in 1183·5 parts of absolute alcohol at 20°. The amido-compound dissolves in 51·3 parts of absolute alcohol at 20°.

Amidodiphenylmetadiazine (m. p. 120—121°) can be obtained when methyl cyanide (8·2 grams), phenyl cyanide (20·5 grams), and sodium (4·5 grams) are mixed together in a reflux apparatus, sealed from the air by mercury. It yields hydroxydiphenylmetadiazine (m. p. 281°, this vol., p. 68; Abstr., 1889, 1008) when heated with strong hydrochloric acid at 180° in a sealed tube.

The constitution of hydroxymethyldiphenylmetadiazine is settled by the fact that it can be obtained by the interaction of benzamidine hydrochloride, ethyl benzoylmethylacetate, and potassium hydroxide at 50—60°. By substituting acetamidine and propionamidine respectively for benzamidine, and allowing the reaction to go on for a long time, hydroxymethylphenylmethylmetadiazine (m. p. 175·5°) and hydroxymethylphenylethylmetadiazine (m. p. 180—181°) are obtained respectively. When a mixture of acetamidine and ethyl propionylpropionate is similarly treated with potassium hydroxide, hydroxymethylethylmethylmetadiazine (m. p. 167·5°, this vol., p. 68; Abstr., 1889, 685) is obtained; its constitution is thereby settled.

A. G. B.

Anilidopropionic Acid and α-Anilidobutyric Acid. By O. Nastvogel (*Ber.*, 23, 2009—2015; compare Abstr., 1889, 1012).—

α-Acetanilidopropionic acid, NAcPh·CHMe·COOH, is formed, together with the two isomeric diphenyl-αγ-dimethyl-βδ-diketopiperazines previously described (*loc. cit.*), when α-anilidopropionic acid is heated with acetic anhydride at 160—180° for two hours. It crystallises from hot water in prisms, and from benzene in plates, melts at 143°, and is readily soluble in most ordinary solvents, but only sparingly in cold benzene, carbon bisulphide, and cold water.

A compound which melts at 163°, and seems to have the composition $C_{20}H_{22}N_2O_2$, is obtained, together with diphenyl-αγ-diethyl-βδ-diketopiperazine (m. p. 260°), when α-anilidobutyric acid is heated with acetic anhydride; it crystallises in colourless needles, and is readily soluble in most ordinary solvents, except ether and hot water.

F. S. K.

Isomerism of the Diphenyl-αγ-dimethyl-βδ-diketopiperazines.

By O. Nastvogel (*Ber.*, **23**, 2016—2022; compare preceding abstract).—An acid (m. p. 78—80°) of the composition $C_{18}H_{20}N_2O_3$, which is probably anilidopropionylanilidopropionic acid, is formed, together with resinous products and an acid melting at 96°, when diphenyl-αγ-dimethyl-βδ-diketopiperazine (m. p. 183·5°) is heated with potash. It melts at 78—80°, with partial decomposition, and is readily soluble in all solvents except water and light petroleum; when heated, it is converted principally into the piperazine (m. p. 144—146°). Diphenyl-αγ-dimethyl-βδ-diketopiperazine (m. p. 144—146°), when treated in like manner, yields the same acid, melting at 78—80°.

A crystalline acid melting above 90° is obtained when the fractions of low melting point, obtained in separating the two isomeric diphenyldimethyldiketopiperazines (Abstr., 1889, 1012), are boiled with potash; when this acid, or the acid melting at 96° (see above) is heated at 120°, it is converted into a third isomeric diphenyldimethyldiketopiperazine, which crystallises from dilute alcohol in prisms, and melts at 172—173°.

F. S. K.

Diphenyl-αγ-diethyl-βδ-diketopiperazines.

By O. Nastvogel (*Ber.*, **23**, 2022—2025).—Diphenyldiethyldiketopiperazine (m. p. 145°) is formed when diphenyl-αγ-diethyl-βδ-diketopiperazine (m. p. 260°; compare Abstr., 1889, 1012) is boiled with alcoholic potash, and the mixture of acids thus obtained heated at 120°. It crystallises from dilute alcohol in long, colourless needles, melts at 145°, and is readily soluble in most ordinary solvents, but only moderately in hot light petroleum and hot ether, and very sparingly in hot water; when heated for a short time with alcoholic potash, it is reconverted into the isomeride (m. p. 260°).

F. S. K.

Diphenylketopiperazine and Diphenyl-αβ-diketopiperazine.

By C. A. Bischoff and O. Nastvogel (*Ber.*, **23**, 2026—2030).—*Anilidoethylenephenylamidoacetic acid*,

$$NHPh·CH_2·CH_2·NPh·CH·COOH,$$

is formed when diphenylketopiperazine (Abstr., 1889, 1009) is boiled with alcoholic potash; it crystallises from a mixture of ether and light petroleum in colourless prisms, melts at 116° with decomposition, and is reconverted into the piperazine by boiling alcohol, hot water, or cold dilute acids.

Diphenylnitrosoketopiperazine, $C_{16}H_{15}N_3O_3$, is obtained when diphenylketopiperazine is treated with sodium nitrite in glacial acetic acid solution; it is a yellow, amorphous powder, decomposes at 220—235°, and is readily soluble in glacial acetic acid, chloroform, aniline, and nitrobenzene, but only sparingly in benzene, xylene, and acetone, and insoluble in ether, alcohol, and light petroleum.

When diphenylketopiperazine is oxidised with chromic acid in cold glacial acetic acid solution, it is converted into diphenyl-αβ-diketopiperazine (Abstr., 1889, 1015); this diketo-derivative, on oxidation with chromic acid in acetic anhydride solution, is converted into tetraketopiperazine, and when treated with nitrous acid in concentrated sulphuric acid solution, it yields a yellow, crystalline compound, of the composition $C_{16}H_{10}N_6O_9$, which melts at 290°, and does not give Liebermann's reaction. Boiling potash decomposes diphenyl-αβ-diketopiperazine into ethylenediphenyldiamine and oxalic acid.

Diparethoxydiphenyldiketopiperazine,

$$\mathrm{OEt\cdot C_6H_4\cdot N}<\begin{matrix}\mathrm{CH_2\cdot CH_2}\\ \mathrm{CH_2\cdot CO}\end{matrix}>\mathrm{N\cdot C_6H_4\cdot OEt},$$

prepared by heating ethylenediethoxydiphenyldiamine with chloracetic acid and sodium acetate at 140—150°, separates from alcoholic ether in almost colourless crystals, melts at 162°, and is readily soluble in hot benzene and hot alcohol, but only sparingly in ether.

F. S. K.

Action of Chloracetic Acid and Oxalic Acid on Ethyleneorthoditolyldiamine. By C. A. Bischoff and O. Nastvogel (*Ber.*, **23**, 2031—2035).—A *ditolylpiperazine*, melting at 153·5—154·5°, is obtained when ethyleneorthoditolyldiamine is heated with chloracetic acid and sodium acetate. It crystallises in slender needles, and is isomeric with the compound obtained from orthotoluidine and ethylene bromide (compare Bischoff, Abstr., 1889, 1010).

A colourless, crystalline compound, which has the composition of a *dichloracetylditolyldiamidoethane*,

$$\mathrm{CH_2Cl\cdot CO\cdot N(C_6H_4Me)\cdot CH_2\cdot CH_2\cdot N(C_6H_4Me)\cdot CO\cdot CH_2Cl},$$

is formed, when chloracetic chloride is added to a benzene solution of ethyleneditolyldiamine; it melts at 211—212°, and is readily soluble in alcohol, but only sparingly in cold water, and almost insoluble in ether.

Glycollic acid orthotoluidide, $C_6H_4Me\cdot NH\cdot CO\cdot CH_2\cdot OH$, is obtained when the preceding compound is heated with orthotoluidine and sodium acetate; it separates from alcohol in colourless crystals melting at 188—189°. When diorthotolyl-αβ-diketopiperazine is boiled with alcoholic potash, it is converted into a crystalline acid, which melts at about 100° with decomposition, and is very unstable, being reconverted into the diketopiperazine when it is kept over sulphuric acid; its *barium* salt, $(C_{18}H_{19}N_2O_3)_2Ba$, crystallises with 10 mols. H_2O.

F. S. K.

Action of Chloracetic Acid and Oxalic Acid on Ethyleneparaditolyl- and Ethylene-α-dinaphthyl-diamine. By C. A. Bischoff and O. Nastvogel (*Ber.*, **23**, 2035—2040).—Diparatolylketopiperazine (Abstr., 1890, 1009) is gradually decomposed by boiling alcoholic potash yielding an unstable acid, which is readily reconverted into the ketopiperazine; the *barium* salt of this acid has the composition $(C_{18}H_{22}N_2O_2)_2Ba + 4H_2O$. When diparatolylketopiperazine is treated with sodium nitrite in glacial acetic acid solution, it yields small quantities of a reddish, crystalline compound, which melts at 171—174°, and gives Liebermann's reaction, but the principal product is *diparatolyl-αβ-diketopiperazine*, $C_{18}H_{18}N_2O_2$. The last-named compound can also be obtained by oxidising diparatolylketopiperazine with chromic acid in glacial acetic acid solution; it crystallises from hot alcohol in colourless plates, melts at 263°, and is readily soluble in aniline, glacial acetic acid, acetone, chloroform, alcohol, concentrated nitric acid, and hydrochloric acid, but only sparingly in xylene, carbon bisulphide, ether, and hot water, and insoluble in cold water and light petroleum. On oxidation with chromic acid in acetic anhydride solution, it seems to be converted into diparatolyltetraketopiperazine, and when boiled with alcoholic potash, it is converted into ethyleneditolyldiamine, oxalic acid, and an acid which seems to have the constitution $C_6H_4Me\cdot NH\cdot CH_2\cdot CH_2\cdot N(C_6H_4Me)\cdot CO\cdot COOH$. This acid decomposes at 135°, but does not melt completely until the temperature rises to 197°, and its salts are not easily obtained in crystals; when boiled with glacial acetic acid, it is reconverted into diparatolyldiketopiperazine.

A green, crystalline substance, which seems to be *ethylenedinaphthyldiamine hydrochloride*, $C_{22}H_{20}N_2,HCl$, is obtained when ethylene-α-dinaphthyldiamine is heated at 165° for half an hour with chloracetic acid and sodium acetate; it melts at 221—223°, and is readily soluble in glacial acetic acid and aniline, but only sparingly in most other solvents. F. S. K.

Action of Acetic Anhydride on the Anilides, Toluidides, and Naphthalides of Malic Acid. By C. A. Bischoff and O. Nastvogel (*Ber.* **23**, 2040—2047).—A colourless, crystalline compound of the composition $C_{32}H_{28}N_4O_4$ is formed when malic dianilide (m. p. 197°, not 175° as stated by Arppe, *Annalen*, **96**, 106) is heated with acetic anhydride at 145—150°; it softens at 290°, melts at 300° with decomposition, and is only sparingly soluble in hot alcohol, but more readily in glacial acetic acid and concentrated sulphuric acid. It is possibly a mixture of two geometrically isomeric anilides of the acid described below.

Diphenyl-αγ-diketopiperazine-βδ-homocarboxylic acid,

$$\mathrm{COOH\cdot CH_2\cdot CH}\!<\!\begin{matrix}\mathrm{NPh\cdot CO}\\ \mathrm{CO\cdot NPh}\end{matrix}\!>\!\mathrm{CH\cdot CH_2\cdot COOH},$$

is obtained, together with aniline and small quantities of a substance of low melting point, when the preceding compound is boiled with alcoholic potash; it separates from hot water in crystals, melts at 226—228°, and is readily soluble in alcohol, ether, glacial acetic acid, and acetone, but only sparingly in benzene, chloroform, and light petroleum.

Malic acid orthotoluidide, $C_6H_4Me\cdot NH\cdot CO\cdot CH(OH)\cdot CH_2\cdot COOH$, is obtained when malic acid (1 mol.) is heated at 140—150° with orthotoluidine (2 mols.); it crystallises from alcohol in colourless needles, melts at 178°, and is soluble in hot water, but only sparingly in ether.

Orthotoluidine malate, $C_7H_9N,C_4H_6O_5$, is formed when the base is treated with malic acid in ethereal solution; it melts at 122—125°, and is soluble in water, alcohol, benzene, xylene, and acetone; when heated with acetic anhydride at 130—140°, it yields malic acid and acetotoluidide.

Malic diorthotoluidide, $C_6H_4Me\cdot NH\cdot CO\cdot CH(OH)\cdot CH_2\cdot CO\cdot NH\cdot C_6H_4Me$, is obtained, together with malic toluidide (see below), when orthotoluidine is melted with malic acid (1 mol.); it crystallises from alcohol in colourless plates, melts at 180·5—181·5°, and is readily soluble in alcohol, acetone, and glacial acetic acid, but only sparingly in chloroform, light petroleum, and ether; its solutions give an orange-red coloration with ferric chloride.

Malic orthotoluidide,  $CO<\begin{array}{l}N(C_7H_7)\cdot CO\\ CH(OH)\cdot CH_2\end{array}$, separates from a mixture of benzene and ether in crystals, melts at 114·5—116°, and is soluble in most ordinary solvents, but only sparingly in ether and light petroleum; its solutions give an orange-red coloration with ferric chloride.

Malic diparatoluidide, $C_{18}H_{20}N_2O_3$, prepared by heating paratoluidine with malic acid at 150—160°, crystallises from glacial acetic acid, melts at 205—208°, and is only sparingly soluble in benzene, acetone, and xylene, very sparingly in alcohol and ether, and insoluble in water, alkalis, chloroform, and light petroleum.

Fumaric diparatoluidide, $C_{18}H_{18}N_2O_2$, is formed when the preceding compound is heated with acetic anhydride at 160°. It crystallises in needles, turns brown at 289—292°, does not melt below 360°, and is insoluble in almost all ordinary solvents; when boiled with alcoholic potash, it yields fumaric acid.

Malic α-dinaphthalide, $C_{24}H_{20}N_2O_3$, prepared by heating malic acid (1 mol.) with α-naphthylamine (2 mols.) at 150—160°, separates from alcohol in crystals, melts at 205° and is readily soluble in glacial acetic acid, chloroform, benzene, aniline and ethylene bromide, but only sparingly in alcohol and insoluble in water, ether, alkalis, and acids; when heated with acetic anhydride, it yields a crystalline substance melting at 223—224°, which seems to be the acetyl-derivative, $C_{26}H_{22}N_2O_4$.

Malic β-dinaphthalide, $C_{24}H_{20}N_2O_3$, is formed, together with malic β-naphthalide, when malic acid is heated with β-naphthylamine; separates from aniline in crystals, melts at 260—263° with decomposition, and is almost insoluble in all ordinary solvents except aniline.

Malic β-naphthalide,  $CO<\begin{array}{l}N(C_{10}H_7)\cdot CO\\ CH(OH)\cdot CH_2\end{array}$, separates from hot water and alcohol in crystals, and melts at 193°.

F. S. K.

Attempts to prepare Aromatic Tetra- and Tri-ketopiperazines. By C. A. Bischoff and O. Nastvogel (*Ber.*, 23, 2051—2055).—The author's attempts to synthesise diphenyltetra- and diphenyltriketopiperazine were unsuccessful. Isoamyl oxanilate, prepared by treating isoamyl chloroxalate with aniline in ethereal solution, is decomposed on heating into oxanilide and isoamyl oxalate; when saturated with hydrogen chloride in the cold and then distilled, it yields oxanilide, carbonic anhydride, carbonic oxide, and isoamyl chloride.

When ethyl phenyloxamate is distilled, it is decomposed into alcohol, carbonic anhydride, carbonic oxide, oxanilide, and phenylcarbylamine; when treated with sodium ethoxide, it yields sodium oxanilate.

Diphenyl-αγ-diketopiperazine and oxanilide are formed when phenylamidacetanilide is heated with oxalic acid at 140—145°, but the two compounds cannot easily be separated.

Monophenyloxamide (m. p. 224°) and chloracetanilide (m. p. 134·5°) are formed when chloracetamide is heated with oxanilide at 230°; the two products can be separated by treatment with light petroleum, in which chloracetanilide is readily soluble. F. S. K.

Attempts to prepare Closed Chains containing two Nitrogen-atoms and two, three, and six Carbon-atoms. By C. A. Bischoff and O. Nastvogel (*Ber.*, 23, 2055—2060).—Methylene iodide and aniline react at 105—110° yielding a vitreous product which seems to consist of the two compounds $CH_2(NHPh)_2$ and

$NPh<\genfrac{}{}{0pt}{}{CH_2}{CH_2}>NPh$.

Trimethylene bromide and aniline, in presence of sodium carbonate, combine together at 140° yielding a grey powder, the hydrochloride of which separates from hot alcohol in crystals, and melts at 221—224°.

Diphenylpiperazine (m. p. 163°) and aniline are obtained when ethylenediphenyldiamine is heated with succinic acid at 175—180°; when succinic anhydride is employed in place of the acid, diphenylpiperazine and a new crystalline acid are formed. This acid seems to have the constitution $NHPh{\cdot}CH_2{\cdot}CH_2{\cdot}NPh{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$; it melts at 76—80° with decomposition, and forms a sparingly soluble barium salt.

Ethenyldiphenylamidine (m. p. 132°) is formed, together with some compounds which contain chlorine, when carbonyl chloride is passed into phenylamidacetanilide heated at 140°. F. S. K.

Derivatives of 1-Phenylpyrazole. By L. Balbiano (*Ber.*, 23, 1448—1453).—*Phenylpyrazoledicarboxylic acid* (1, 3, 5) is obtained when phenyldimethylpyrazole, prepared by treating acetylacetone with phenylhydrazine, is oxidised with an alkaline solution of potassium permanganate. It crystallises from alcohol in small, colourless plates, melts at 255—256° with decomposition, and is only very sparingly soluble in chloroform, benzene, warm light petroleum, and cold water, but more readily in ether and hot water. The *am-*

monium salt, $C_3N_2HPh(COONH_4)_2$, crystallises in plates, melts at 210—212° with decomposition, and is very readily soluble in water. The *lead* salt, $C_3N_2HPh(COO)_2Pb$, and the *silver* salt, $C_3N_2HPh(COOAg)_2$, are crystalline and almost insoluble in water. The *barium* salt is deliquescent.

Phenylbromopyrazoledicarboxylic acid (1, 4, 3, 5) prepared by treating the preceding compound with bromine (1 mol.) in cold glacial acetic acid solution, separates from hot dilute acetic acid in colourless, nodular crystals, melts at 244° with decomposition, and is only sparingly soluble in hot water, but more readily in warm alcohol and glacial acetic acid. The *ammonium* salt, $C_3N_2BrPh(COONH_4)_2$, crystallises in needles and melts at 190—192° with decomposition. The *lead* salt, $C_3N_2BrPh(COO)_2Pb$, is almost insoluble in boiling water. The *silver* salt is precipitated in a gelatinous condition, but becomes crystalline on boiling. The *barium* salt is deliquescent. When phenylbromopyrazoledicarboxylic acid is heated at 240—250°, it is converted into phenylbromopyrazole (1, 4), melting at 81°, identical with the bromo-derivative obtained by brominating 1-phenylpyrazole (this vol., 797).

Phenyldimethylbromopyrazole (1, 3, 5, 4) is formed when phenyldimethylpyrazole (1, 3, 5) is treated with bromine in glacial acetic acid solution. It is a yellow, pleasant smelling liquid, soluble in alcohol but insoluble in, and heavier than, water; when oxidised with potassium permanganate in alkaline solution, it is converted into phenylbromopyrazoledicarboxylic acid (m. p. 244°). F. S. K.

Diazothiazoles and their Decompositions. By A. HANTZSCH (*Ber.*, 23, 1436—1478). The hydrate of ethyl diazomethylthiazolecarboxylate can be isolated in a solid condition by treating ethyl amidomethylthiazolecarboxylate in a suitable manner. This hydrate has probably the constitution  $\begin{array}{l}\mathrm{COOEt{\cdot}C{-\!\!-}S}\\ \quad\quad\quad\;\|\\ \quad\quad\;\mathrm{CMe{\cdot}N}\end{array}\!\!>\mathrm{C{\cdot}N{:}N{\cdot}OH}$; the hydroxyl-group in this compound can be easily displaced by a halogen-atom. Analogous halogen-derivatives can be obtained in like manner from amidothiazole, and the compounds thus produced can be easily converted into thiazoles by reducing agents, and into hydroxy-thiazoles by treatment with alkalis.

When ethyl diazomethylthiazolecarboxylate is treated with alcohol, nitrous acid is eliminated, and a peculiar azimido-derivative is formed.

A full account of these experiments will be published in the *Annalen*. F. S. K.

Oxidation of Phenylmethyltriazolecarboxylic Acid. By J. A. BLADIN (*Ber.*, 23, 1810—1815).—When the above acid is heated for several days on the water-bath with alkaline permanganate, the ring is not broken down, but the side chain is oxidised, and *phenyltriazoledicarboxylic acid*,  $\begin{array}{l}\mathrm{C(COOH){:}N}\\ |\\ \mathrm{N{:}C(COOH)}\end{array}\!\!>\mathrm{NPh}$ is formed, and may be obtained as a white, amorphous mass by cautiously adding hydrochloric acid and cooling the solution.

But if the solution is not kept cool, this compound rapidly loses carbonic anhydride, and *phenyltriazolecarboxylic acid*, $C_2N_3HPh{\cdot}COOH$, is obtained. This crystallises from water in brilliant plates which melt with decomposition at 184°, probably forming phenyltriazol. It dissolves easily in alcohol and acetic acid, sparingly in water, and hardly at all in benzene. The position of the carboxyl-group is not yet determined. The *alkali salts* are very soluble. The *silver salt*, $C_9H_6N_3O_2Ag + 1\frac{1}{2}H_2O$, forms a sparingly soluble, white, amorphous precipitate, easily convertible into fine needles. The *copper salt*, $(C_9H_6N_3O_2)_2Cu$, is a blue, insoluble, crystalline precipitate. The *hydrochloride*, $C_9H_7N_3O_2,HCl$, forms small plates. The *methyl salt*, $C_9H_6MeN_3O_2$, crystallises in small, colourless prisms melting at 116·5—117°, and soluble in alcohol and ether. The *ethyl salt*, $C_9H_6EtN_3O_2$, forms colourless prisms melting at 72°, very soluble in alcohol, ether, and benzole, but not in light petroleum. The amide,

$$Ph{\cdot}C_2N_3H{\cdot}CONH_2 + \frac{1}{2}H_2O,$$

forms asbestos-like needles melting at 194°, and dissolving in water and alcohol. C. F. B.

Ethoxycaffeïne. By H. THOMS (*Chem. Centr.*, 1890, i, 865; from *Pharm. Centralhalle*, 31, 207—208).—Ethoxycaffeïne is prepared by dissolving bromocaffeïne in alcohol, introducing the necessary amount of sodium, and then boiling. It dissolves less readily in water than caffeïne, is readily soluble in hot alcohol, and melts at 138—138·5°. When boiled with hydrochloric acid, the ethyl-group is eliminated; by evaporating with chlorine, amalic acid is formed, which dissolves in ammonia with red colour. Ethoxycaffeïne differs from caffeïne in its behaviour towards alkalis; sodium or potassium hydroxide does not precipitate caffeïne, even when the solution is 1 gram in 10 grams of water, whilst ethoxycaffeïne is precipitated, although not quantitatively. For the identification of ethoxycaffeïne, the murexide test, its behaviour towards aqueous potash, and the melting point will serve. The author ascribes to it the formula

$$CO{<}\begin{matrix} NMe{\cdot}C(OEt){:}C{\cdot}NMe \\ NMe{-\!-\!-\!-}C{=\!=}N \end{matrix}{>}O.$$

J. W. L.

Quinine, Cinchonidine, and their Isomerides. By O. HESSE (*Annalen*, 258, 133—144).—Anhydrous quinine (quinine anhydride) which the author proposes to name "homoquinine," melts at 174·4—175°; the substance obtained by crystallising the trihydrate from alcohol or ether, and drying first in a desiccator and then at 120°, melts at 171·2—172°; the powder obtained by heating the compound $C_{20}H_{24}N_2O_2,C_6H_6$ at 120° melts at 171·5—172°.

Cinchonidine melts at 202·4°, homocinchonidine at 207·6°; the latter can be converted into the former by treatment with warm 25 per cent. sulphuric acid.

The melting points given above were very carefully determined in Roth's apparatus. F. S. K.

Conversion of Tropidine into Tropine. By A. LADENBURG (*Ber.*, **23**, 1780—1781).—When tropidine is treated with hydrobromic acid, a small quantity of a base is obtained which is not volatile with steam, and may thus be separated from tropidine. When distilled, it was found not to boil at a constant temperature; the distillate seemed still to contain bromine, which was removed by treatment with silver oxide. In this way a strong base was obtained, which, when treated with tropaic acid and hydrochloric acid, yielded a substance that reacted like atropine; the base was thus probably either tropine or metatropine.

The author still adheres to the formula $NMe\vdots C_5H_7\cdot CH_2\cdot CH_2\cdot OH$, but thinks it may possibly belong to metatropine, whilst tropine itself has the formula $NMe\vdots C_5H_7\cdot CHMe\cdot OH$. C. F. B.

Alkyl-hydrastines and their Derivatives. By E. and F. SCHMIDT (*Arch. Pharm.* [3], **28**, 221—257).—The hydrastine employed was freed from its yellow colour by crystallisation from alcohol. *Hydrastine methiodide*, $C_{21}H_{21}NO_6,MeI$, formed by heating hydrastine with methyl iodide is obtained in tufts of prismatic or needle-shaped crystals, slightly soluble in water, more easily in alcohol. These crystals are anhydrous, sinter about 197°, and melt at 202° to 205°. By treating the aqueous solution with excess of silver chloride, hydrastine methochloride was produced, but could not be obtained in a crystalline state. The corresponding aurochloride, $C_{21}H_{21}NO_6,MeCl,AuCl_3$, was then formed by precipitation, and on recrystallisation from an acidified aqueous solution, appeared as fine, yellowish-red, anhydrous needles, melting at 183° to 184°. The platinochloride, also anhydrous, could only be obtained as an amorphous, yellow precipitate melting at 204° to 205°. *Hydrastine methylammonium hydroxide*, $C_{21}H_{21}NO_6,MeOH + H_2O$, is obtained by treating an aqueous solution of hydrastine methiodide with moist silver oxide. The compact, yellowish crystals become colourless when recrystallised from an aqueous solution, and melt at 214° to 215°. The compound when dissolved in boiling water, or heated at 100°, is converted into methylhydrastine hydroxide.

Methylhydrastine, $C_{21}H_{20}MeNO_6$, is obtained on treating a hot aqueous solution of hydrastine methiodide with normal potash. It is easily soluble in alcohol, ethyl acetate, and methyl alcohol, with splendid green fluorescence. Recrystallised from alcohol, it forms yellow needles showing green fluorescence, whilst the ethyl acetate solution yields beautiful, lustrous, compact, yellow needles, which are anhydrous and melt at 156° to 157°. *Methylhydrastine platinochloride*, $(C_{21}H_{20}MeNO_6)_2,H_2PtCl_6 + 2H_2O$, is obtained as a yellow, flocculent precipitate, which melts at 199° to 200°. The water found was a little higher than is indicated by the formula. The aurochloride, $(C_{21}H_{20}MeNO_6)_2,HAuCl_4$, formed as a dirty-yellow, flocculent precipitate, recrystallised from dilute acidified alcohol as brownish-red needles melting at 205° to 206°. *Methylhydrastine hydrogen sulphate*, $C_{21}H_{20}MeNO_6,H_2SO_4$, occurs as a yellow, crystalline powder, when the base is dissolved in absolute alcohol and sulphuric acid diluted with alcohol is added. The normal sulphate, $(C_{21}H_{20}MeNO_6)_2,H_2SO_4$, is formed when the base is dissolved in the least possible amount of dilute sulphuric acid. On evaporating the solution to dryness and crystallising from hot alcohol, beautiful, yellow laminæ are obtained which in alcohol show a fine, green fluorescence. *Methylhydrastine hydrochloride*, $C_{21}H_{20}MeNO_6,HCl + H_2O$, is obtained, like the sulphate, as slender, yellow needles, easily soluble in water, somewhat difficultly soluble in alcohol with green fluorescence, melting at 233° to 234°. The corresponding *nitrate*, $C_{21}H_{20}MeNO_6,HNO_3$, was similarly obtained. The salts of methylhydrastine are yellow, and their solutions are strongly fluorescent, whilst hydrastine salts as described by Kerstein (this vol., p. 648—649) are colourless, and exhibit little or no fluorescence. *Methylhydrastine methiodide*, $C_{21}H_{20}MeNO_6,MeI$, results from the action of methyl iodide on the base. Recrystallised from dilute alcohol, it forms well-shaped, greenish-yellow, prismatic crystals melting at 250° to 251°. From this reaction it is inferred that methylhydrastine, like hydrastine, is a tertiary base. Methylhydrastine is partially oxidised by sulphuric acid and manganese dioxide, only hemipinic acid and a volatile base being detected among the products. Oxidation with nitric acid is also somewhat incomplete; the chief product is again hemipinic acid with probably dimethylamine, carbonic anhydride, and oxalic acid. Methylhydrastine methiodide, when acted on by potassium hydrate, yields trimethylamine and a non-nitrogenous compound, $C_{20}H_{18}O_7$, which occurs as small, colourless, four-sided plates melting at 168° to 169°. This compound, when oxidised by potassium permanganate, yields hemipinic acid and an acid which has not yet been fully examined.

Methylhydrastine alcoholate, $C_{21}H_{20}MeNO_6,EtOH$, is obtained in minute, light-yellow crystals, when methylhydrastine is dissolved in alcohol, water added until turbidity appears, the precipitate redissolved by heating, and the solution finally allowed to cool. The crystals melt at 95° to 96°, so that the compound analysed was only dried at 90°. Their aqueous and alcoholic solutions exhibit only a relatively slight fluorescence. The platinochloride,

$$[C_{21}H_{20}MeNO_6,EtOH]_2,H_2PtCl_6,$$

is obtained as a light-yellow powder melting at 163° to 164°. When methylhydrastine alcoholate is dissolved in as little alcohol as possible, and excess of nitric acid is added, a little methylhydrastine nitrate (?) separates as a yellow, crystalline powder; on adding ether to the filtrate, almost colourless, needle-shaped crystals of methylhydrastine alcoholate nitrate, $C_{21}H_{20}MeNO_6,EtOH,HNO_3$, gradually form, which melt at 145° to 146°. Corresponding hydrochlorides and sulphates were obtained. The alcoholate, heated with sulphuric or hydrochloric acid, is decomposed yielding the salt of methylhydrastine. The mother liquor from methylhydrastine alcoholate completely loses its green fluorescence on evaporation, and yields drusy groups of small, brownish crystals on cooling, which become colourless when recrystallised from dilute alcohol. *Methylhydrastine hydroxide*, $C_{21}H_{22}MeNO_7 + 2H_2O$, thus formed melts at 151° to 152°, and dissolves in alcohol without fluorescence. Of the three mols. H_2O contained in this base, one enters directly into the molecule; the other two are combined as water of crystallisation. The production of this compound from hydrastine methylammonium hydroxide has already been mentioned; the same product is obtained by dissolving methylhydrastine in boiling water and allowing the solution to cool. The hydroxide evaporated with sulphuric or hydrochloric acid gives a salt of methylhydrastine. *Methylhydrastine hydroxide platinochloride*,

$$(C_{21}H_{22}MeNO_7)_2,H_2PtCl_6,$$

is obtained by dissolving the hydroxide in acidified water and precipitating in the cold with platinic chloride. The yellow, amorphous flocks become crystalline after a time. The yellow, crystalline powder melts at 208°. *Methylhydrastine hydroxide hydrochloride*,

$$C_{21}H_{22}MeNO_7,HCl,$$

is prepared by dissolving the base in absolute alcohol, adding excess of fuming hydrochloric acid, and then ether; on dissolving it in alcohol and reprecipitating by ether, small, colourless needles are obtained which melt at 182° to 183°. A corresponding sulphate can be similarly prepared, and other salts of the same base. Methyl iodide produces a greenish, resinous mass with the base; the chloride, formed by dissolving this compound in alcohol and treating with silver chloride, is a similar resinous mass. The chloride dissolved in water and precipitated with platinum chloride gives a yellow, flocculent platinochloride, $[C_{21}H_{22}MeNO_7,MeCl]_2PtCl_4$. This composition confirms the supposition that 1 mol. of water in the base is more intimately combined than the other two. *Ethylhydrastine hydroxide*, $C_{21}H_{22}EtNO_7 + 2H_2O$, prepared from ethylhydrastine, like the corresponding methyl compound, forms colourless needles which, heated in a capillary tube, melt at 130°, but solidify to a yellow mass at a somewhat higher temperature, and then melt again at 206—207°. As in the case of the methyl compound, 2 of the 3 mols. of water contained in the ethyl hydroxide are easily removed over sulphuric acid, whilst the third mol. is more intimately combined—as the composition of the platinochloride also shows. By evaporation with dilute mineral acids, the colourless ethylhydrastine hydroxide becomes converted into the yellow, strongly fluorescent hydrastine salt. Ethylhydrastine hydroxide platinochloride, $[C_{21}H_{22}EtNO_7]_2,H_2PtCl_6 + 4H_2O$, was obtained as a yellow, flocculent precipitate which melts at 137° to 138°. Owing to the close relationship existing between hydrastine and narcotine, the former containing two methyl-groups, and the latter three similar groups, it is probable that narcotine, or one of its isomerides, may be prepared from hydrastine. This investigation is still in progress. J. T.

Lobeline. By H. Paschkis and A. Smita (*Monatsh.*, 11, 131—132). —In order to extract the alkaloïd from *Lobelia inflata*, the plant was exhausted with dilute acetic acid, and the filtered extract made alkaline and exhausted with ether. On evaporating the ethereal solution, the alkaloïd remained as a viscid, honey-yellow mass having an odour resembling that of honey and tobacco. The alkaloïd was purified by dissolving it in ether, shaking the ether with an excess of water containing hydrochloric acid, treating this with an alkali, and again exhausting with ether. After repeating this process three times, the ethereal solution was dried with potash, and the ether distilled off in an atmosphere of hydrogen.

When lobeline (1 gram) is suspended in a solution of 10 per cent. potash (300—400 c.c.) and treated with 4 per cent. potassium permanganate, added in small quantities, until the greenish colour of the solution only disappears after remaining some time, benzoic acid is formed. G. T. M.

Ptomaïnes. By O. DE CONINCK (*Compt. rend.*, **110**, 1339—1341). —The ptomaïne $C_{10}H_{15}N$ (Abstr., 1888, 730) is a yellowish, viscous liquid with an agreeable odour; it is heavier than, and only slightly soluble in water, but dissolves readily in ether, absolute alcohol, acetone, and light petroleum. After being dried over fused potash, it boils at about 230° with partial decomposition. It oxidises rapidly in presence of oxygen or air, becomes brown, and forms a thick resin soluble in acids. The *hydrochloride* is obtained by saturating the base with hydrochloric acid and concentrating rapidly in a vacuum. It forms yellowish needles which are highly deliquescent and very soluble in water. In presence of a very small quantity of air, the crystals acquire a rose colour, and with larger quantities of air they become brown and form a resinous product identical with that obtained by direct oxidation of the base. The *platinochloride* is a deep-red solid insoluble in cold water, very soluble in warm water, and decomposed by boiling water. It is permanent in dry air, but in moist air loses hydrogen chloride, and is partially oxidised. C. H. B.

Physiological Chemistry.

Respiration in the Horse during Rest and Work. By N. ZUNTZ and C. LEHMANN (*J. Physiol.*, **11**, 396—398).—The authors defend their method of experimentation recently criticised by F. Smith (this vol., p. 392), and in turn pass unfavourable remarks on the methods adopted by Smith. According to them the chief fallacies of Smith's method consist in using a mask of too great capacity, and in determining the amount of gaseous interchange immediately after instead of during work. Their own values are in general far greater than those of Smith's, and they compare the two sets of results in the following table:—

		Litres per minute.			Resp. quot.
		Air expired.	CO_2 expired.	O_2 absorbed.	
Rest..	S	35	0·534	0·772	0·69
	L and Z. Respiration through a mask	69	1·570	1·722	0·92
	L and Z. Respiration through a cannula in the trachea	44	1·478	1·601	0·92
Walk.	S	63	0·509	0·962	0·53
	L and Z	177	4·342	4·766	0·90

W. D. H.

Absorption of Fat. By O. Minkowski (*Practitioner*, 45, 139—140; from *Berlin klin. Wochensch*, 1890, No. 13).—From an examination of the fæces, it was found that after extirpation of the pancreas the fat of the food is no longer absorbed. An exception to this was milk, whose fatty constituents were more or less taken up. If the fresh pancreas of the pig were mixed with the food, then the greater part of the fat was absorbed. To the view that the pancreatic juice breaks up fat into fatty acid and glycerol, the results lend no support; on the contrary, although the pancreas was altogether absent, the fatty matter in the fæces was for the most part found split up; this likewise renders untenable the theory that fat is largely absorbed in the form of soaps. That the action of the juice is not a special one upon the absorbent elements of the intestine is evident from the fatty matter of milk being ingested in the absence of the gland, and this also shows that what is important is the form in which the fat comes into contact with the intestinal mucous membrane. Milk is a fine emulsion, differing much from the saponified emulsion of alkaline carbonates. Bernard showed that whilst ordinary alkaline emulsions are destroyed by acidulation, the fat running into large drops, a pancreatic emulsion remains unchanged by this treatment; the same property is possessed by the emulsified fat of the chyle and of milk. Kühne suggested that the fat globules of a pancreatic emulsion possess an albuminous membrane which facilitates their adhesion to the protoplasm of the epithelial cells of the intestine. This, however, is questionable.

The further observation was made that an action of the pancreas on fatty matters takes place, although there is no direct flow of the pancreatic secretion into the intestinal canal, provided a part of the pancreatic tissue capable of performing its functions remains in the organism. Thus, after partial extirpation of the gland, fat absorption, though impaired, was not altogether prevented.

The fact is also established, that in dogs complete removal of the pancreas leads to diabetes; and Hirschfeld has shown that in diabetic patients the absorption of proteïd and fat is much impaired. This is perhaps an indication that the cause of diabetes in some cases is disease of the pancreas. W. D. H.

Destruction of Glucose by Blood and Chyle. By R. LEPINE and BARRAL (*Compt. rend.*, **110**, 1314—1316).—The authors have made further experiments, which confirm the existence in the blood, and especially in the chyle, of a ferment which destroys glucose (this vol., p. 810). This ferment disappears in cases of acute diabetes. The action of the ferment is greatly accelerated by rise of temperature, but is retarded by the presence of carbonic anhydride. The destructive action exerted by living tissues is much greater in presence of this ferment than when it is absent. All the experiments were made with a dog. The authors term the ferment the *glycolytic* ferment. C. H. B.

Cattle Marrow. By K. THÜMMEL (*Arch. Pharm.*, **228**, 280—290). —Fresh marrow contains 7·62 per cent. water, and 0·39 to 0·48 per cent. membrane; its melting point varies from 37° to 46°, and solidifying point varies from 30° to 38°, depending on the varying amounts of trioleïn present, which may be 43 to 62·9 per cent., as deduced from the iodine number for various samples. Hehner's number, which gives the percentage of insoluble fixed fatty acid in the fat, is 93·4 for old animals, and 93 for young ones. Köttstorf's saponifying process gives 191·3 alkali for young cattle, and 204·7 for old cattle, per 1000 of glyceride. The corresponding numbers are. according to Benedikt, for tallow, 196·5; olive oil, 191·8 to 203; and butter, 227. The amount of glycerol, calculated from the foregoing, is for old cattle 10·56 per cent., and for young ones 11·18. The fatty acids were found to consist approximately of oleic, 40 per cent.; stearic, 35; and palmitinic, 25. In the marrow of young cattle, the oleic acid amounts to 60 per cent. Volatile fatty acids are present in small quantity only. Medullic acid, described by Eylert as existing in marrow, could not be found. J. T.

Pigments of the Peridinia. By F. SCHÜTT (*Chem. Centr.*, 1890, **1**, 767—768; *Ber. deut. bot. Gess.*, **8**, 9—32).—The pigment of a large number of sea-water *Peridinia* becomes separated at their death into two pigments, the one of which is red, soluble in water, and diffuses itself therein, whilst the other is yellowish-green and remains in the chromatophores. The former has been named "phykopyrrin" by the author, and is obtained in concentrated solution by extracting the *Peridinia* with a little water. If this brownish-red solution is treated with alcohol, no change is perceptible; if shaken with benzene, the pigment passes into the latter, but appears to suffer change thereby, the extract having a yellow colour.

The extracted peridinia are next boiled with water, and eventually all the soluble pigment passes into solution, leaving the peridinia greenish-yellow coloured. The extract obtained with boiling water is yellowish-brown, and has not the same appearance as that obtained with cold water. The author names that obtained with cold water α-phykopyrrin, and that obtained by boiling water β-phykopyrrin. Both pigments seem to have the same physical properties.

If the peridinia, after extraction with cold and hot water, are treated with successive portions of alcohol, extracts varying in colour from port-wine-red to chlorophyll-green are obtained, which the author names peridinin- and peridinia-chlorophyllin.

The physical properties of these several pigments are—

(1.) *Phykopyrrin*, brownish-red in aqueous solution, yellow in alcohol, ether, benzene, carbon bisulphide, and glacial acetic acid. It has a strong absorption band in the red λ 65—68, corresponding with the chlorophyll band I, and another at λ 60—62, corresponding with the chlorophyll band II. *Peridinin*, insoluble in water, readily soluble in alcohol, benzene, ether, carbon bisulphide, glacial acetic acid, little soluble in light petroleum. Weak absorption band in the orange λ 64. *Peridinia-chlorophyllin*, insoluble in water, soluble in alcohol, ether, benzene, carbon bisulphide, glacial acetic acid; little soluble in light petroleum. It shows a strong absorption band in the red, corresponding with the chlorophyll band I, and a minor band in the green. J. W. L.

Pathological Effusions. By W. D. HALLIBURTON (*Brit. Med. Journ.*, 2, 1890, 193—196).—In this research, analyses were made of a number of dropsical effusions into the serous sacs. The word serous used in this connection is an unfortunate one, as the fluid in them is not serum, but very nearly resembles plasma in its composition. The proteïds present are fibrinogen, serum-globulin, and serum-albumin, and the analyses chiefly relate to the quantities of these which are present. They illustrate the following points:—

1. That when simultaneous dropsies occur in various parts, those in the pleura, pericardium, and peritoneum have, so far as the amount of their albuminous constituents is concerned, different compositions, and are all much richer in proteïd matter than the fluid of subcutaneous œdema. This is probably due to the varying conditions of vascular pressure in the different situations.

2. That in successive tappings the fluid removed from a serous sac remains remarkably constant in composition.

3. That the total proteïd, the yield of fibrin, and the specific gravity are all much higher in exudations, that is, inflammatory effusions, than in transudations, that is, simple effusions due to derangements of vascular pressure. This may be illustrated by the following table of average results of analyses of fluid removed from the pleural cavity:—

	Specific gravity.	Total proteïd per cent.	Fibrin per cent.
From cases of inflammation (pleurisy)	1021	4·5903	0·0473
From cases of simple dropsy (hydrothorax)	1014	1·7748	0·0086

4. That in cases of simple dropsy, the fluid obtained from cases of heart disease is richer in total proteïds than in that due to liver or kidney disease. This may be illustrated by the following table:—

	Average percentage of proteïds in acetic fluid.
Cases of liver disease	1·760
Cases of kidney disease	2·209
Cases of heart disease	4·589

This appears to confirm a view urged by Wooldridge (*Proc. Roy. Soc.*, **45**, 309), that in heart disease there is also a change in the blood which leads to increased exudation through the vascular walls.

5. That the proteïd quotient (that is, relation of albumin to globulin) varies considerably, but the variations show no fixed relation to the cause of the effusion. The proteïd quotient of effusions varies directly as that of the blood (Salvioli, *Du Bois Reymond's Archiv*, 1881, 269; F. Hoffman, *Arch. exp. Path. Pharm.*, **16**, 133; Pigeaud, *Maly's Jahresb.*, **16**, 474), and observations are still wanting to enable us to state under what conditions the proteïd quotient of the blood rises and falls. This is of some interest, for seemingly diffusion through living membranes differs from that through dead membranes; in the latter case globulin diffuses more slowly than albumin (Gottwalt, *Zeit. physiol. Chem.*, **4**, 423).

6. That aqueous humour resembles the so-called serous effusion in its composition and reactions.

Analyses of pericardial, hydrocele, and œdema fluids are given, but present no points of particular interest. Peptones and albumoses are absent in all these fluids, so differing from cerebro-spinal fluid, (Abstr., 1887, 514; 1889, 793). In those cases where a reducing substance is present, it appears to be sugar; this is another point in which serous effusions differ from cerebro-spinal fluid.

The analysis of one specimen of ovarian fluid showed that in addition to the ordinary proteïds, true mucin was present. Pseudomucin or paralbumin, which often occurs in ovarian fluid, was absent.

W. D. H.

Proteïds in Urine. By D. NOEL PATON (*Brit. Med. Journ.*, **2**, 1890, 196—201).—It was Senator (*Virchow's Arch.*, **60**, 476) who first stated that in all cases of albuminuria both of the chief proteïds of the blood-plasma (serum-globulin and serum-albumin) are present. The proteïd quotient (that is, the ratio of albumin to globulin) may, however, vary within wide limits; in the present observations between 0·6 and 39. In acute nephritis, when blood is absent, the quotient is high. When hæmoglobin is present, the globulin is of course in excess. As the disease becomes more chronic, the quotient sinks. This alteration depends probably on the condition of the patient, and is probably related to a similar change in the blood-plasma. Waxy degeneration of the kidneys cannot be distinguished from the ordinary forms of nephritis by the high proportion of serum-globulin as was formerly maintained by Senator; Maguire's suggestion (*Lancet*, **1**, 1886, 1062), that functional albuminuria is characterised by a high proportion of serum-globulin, is also incorrect. In every case the quotient varies much in the course of the day, the proportion of globulin being always highest in the night; its greatest fall is after breakfast, and in most cases it rises again in the evening. Milk diet, as observed by Lecorché and Telamon (*Traité de l'Albuminurie*, Paris, 1888), has a peculiar effect in increasing the proportion of serum-albumin. The amount of proteïds passed appears to bear a direct proportion to the amount of proteids ingested, and, excluding milk diet, the increase of the proteids in the urine on a diet rich in those substances, appears to be chiefly due to an increase in the serum-albumin. The variation in the proportion of the albumin to the globulin in the urine is frequently so great that it can hardly be believed that it is connected with a similar change in the plasma. The experiments performed would, however, suggest that a high pressure favours the transudation of serum-albumin, whilst a low pressure increases the proportion of serum-globulin transuded.

W. D. H.

Action of Rennin and Fibrin-ferment. By A. S. Lea and W. L. Dickinson (*J. Physiol.*, **11**, 307—311).—The term *rennin* is suggested in place of that of rennet-ferment. Fick (*Pflüger's Arch.*, **45**, 293) has recently stated that the mode of action of the clotting ferments is fundamentally different from that of the ordinary digestive enzymes, inasmuch as the molecules of the former do not require to come into close relationship with the molecules of the substance acted on, but that when once the change has been set up by the ferment in any one portion of the substance, this change is propagated from particle to particle without the further necessary intervention of the ferment. In the present experiments, measured quantities of milk were introduced into tubes of different sizes, and warmed to 40°. Rennin solution, also warmed to 40°, was then placed in the bottom of the tubes by means of a long pipette with capillary ending, so as to form a clear layer beneath the milk. The tubes were then kept at 40°. In about 20 minutes a clot at the junction of the two fluids had formed; the supernatant milk was completely fluid, and remained so for from five hours in the narrow tubes to seven hours in the wider ones. Control tubes, in which the rennin was mixed with the milk, showed complete coagulation in three minutes. Precisely similar results were obtained with fibrin-ferment solution and dilute salted plasma. The ultimate coagulation that occurs is explicable on the ground that there is a gradual dissemination of the ferment by convection currents. This view is supported by the fact that the final clotting occurs sooner in the narrow than in the wide tubes; in the latter case, convection currents would not be so active.

Milk placed in a porous battery cell, the cell being immersed in a beaker of rennin solution, did not clot for over 24 hours, when the observation was suspended.

From these experiments the conclusion is drawn that Fick is in error, and that the mode of action of the clotting ferments is essentially similar to that of other well-characterised enzymes, as far as contact between the ferment and the alterable substance is concerned. W. D. H.

Influence of Salts on Clotting. By S. RINGER and H. SAINSBURY (*J. Physiol.*, **11**, 369—383).—Previous experiments have shown that minute quantities of various salts of the alkalis and alkaline earths, such as occur normally in the blood, have very distinct actions on the contraction of the heart-muscle and voluntary muscle. Some favour, others hinder, the contraction, and the two sets of salts are antagonistic to one another. The formation of myosin, causing *rigor mortis* in dead muscle, is a process completely analogous to the formation of fibrin in dead blood, and both are similar in many respects to the formation of casein in milk by the activity of rennet. Hermann's view of the phenomena of muscular contraction is, that it is essentially the same thing as the death of a muscle, the difference being one of degree only. Dead muscle and contracted muscle are similar in electrical potential, and in the fact that they have an acid reaction due to sarcolactic acid. The formation of a clot of myosin during contraction has, however, never been proved, and in the present research it was thought that the question might be further elucidated by a study of the action of various salts on the coagulation process (in blood, milk, and pathological effusions); it was found that these salts act as favouring or hindering agents on the act of coagulation, precisely in the same way as they do on the contraction of muscle. The main result of the research is therefore that the experiments afford a confirmation of Hermann's theory that contraction and coagulation are analogous phenomena.

The individual conclusions respecting the salts investigated are as follows:—

Calcium is an essential to the act of clotting. This was previously shown by Green (Abstr., 1888, 306) to be true for calcium sulphate and blood clotting. Hammarsten long ago pointed out the necessity of calcium phosphate for the efficient action of rennet, and Freund (*Centr. Med. Wiss.*, Oct., 1889) believes this salt plays also an important part in fibrin-formation. In the present research the chloride was found to be a very efficient salt in favouring coagulation, and the opinion is expressed that the effect of calcium is a generic effect belonging to all its salts. Strontium and barium act like calcium, but are less powerful. The action of all three metals is largely controlled by the solubilities of their salts. Potassium and sodium salts, on the other hand, have a restraining influence on coagulation, the latter metal being the more powerful in this direction. There is antagonism between the salts of the alkaline earths on the one hand, and those of the alkaline metals on the other. W. D. H.

Osmosis with Living and Dead Membranes. By E. W. REID (*Journ. Physiol.*, **11**, 312—351).—A full account, with diagrams, tracings, and figures of apparatus used, of experiments of which a preliminary account has already appeared (this vol., p. 277).

W. D. H.

Pernicious Anæmia. By F. W. Mott (*Practitioner*, **45**, 81—93).—The case published is similar in essential points to two already described (Abstr., 1888, 1324, and this vol., p. 1017). The present case is remarkable as occurring in a young subject (æt. 11 years), in the fact that the urine, though loaded with uric acid crystals, was not highly coloured, and in the presence of more iron in the spleen than has been previously noted. The following table gives the amount of iron found in various organs:—

Organ.	Wt. in grams.	Total iron as ferric oxide.
Liver..............	900	1·33 grams.
Spleen..............	100	0·17 ,,
Pancreas..........	50	0·01 ,,
Kidneys............	100	0·01 ,,

In connection with Delépine's work (see next abstract), it is suggested that pernicious anæmia is an exaggeration of a normal physiological process. When the absorption of the products of digestion occurs, the blood is replenished by new materials, and plethora would occur if there were not a proportional destruction of the plasma and corpuscles to form urea and pigments which leave the body by the natural channels. Whether the excessive destruction that occurs in pernicious anæmia is due to a poison, the result of bacterial activity derived from the alimentary canal, must for the present be considered unproved, for it does not seem that there is always a relation between the pyrexia, the anæmia, and the colour of the urine. Moreover, severe putrefactive processes may occur in the intestine without any pernicious anæmia being brought about.

It is known that peptone has a very marked influence upon the blood, and it is possible to suppose that this substance, if not reconverted into albumin during absorption, might be the poison in question. The liver and spleen of a dog, into whose circulation peptone solution had been injected, yielded the iron reaction very markedly; but this may have been accidental, and further experiments are promised on this subject. W. D. H.

Normal Storage of Iron in the Liver. By S. Delépine (*Practitioner*, **45**, 94—98).—Pigment is constantly found in liver cells and in some of the endothelial cells of the intralobular capillaries; it may be particulate, or diffused through the cell in a state of solution. It gives the reactions of ferric salts, and these are more intense between 8 and 12 hours after food, and reach a minimum immediately after the ingestion of food. The pigment is, as a rule, most abundant in the portal zone. The liver has thus a ferrogenic function, which probably consists of a separation of iron from effete iron-containing pigment, a storage of that iron in the form of a loose compound, and the gradual formation of a more stable albumino-ferruginous compound analogous if not identical with hæmoglobin, and ready for assimilation by the young red blood-corpuscles. Pernicious anæmia is probably an exaggeration of this normal process.

W. D. H.

Physiological Action of Morphine and its Derivatives. By R. STOCKMAN and D. B. DOTT (*Brit. Med. Journ.*, 2, 1896, 189—192).—A medium dose of morphine first depresses the spinal cord, and this is followed by tetanus. When a minimum narcotic dose is given, the narcosis is not deep, and no tetanic symptoms follow. When the dose is sufficient to produce both sets of symptoms, the morphine is slowly absorbed, and only a small portion reaches the cord at first; hence the depression; as more is absorbed, more comes into contact with the nerve cells, and then tetanus occurs. Tetanus can, however, be induced at once without any preliminary depression if the morphine be thrown directly into the circulation so as to reach the cord in sufficient quantity. The usual sequence of depression and stimulation is thus entirely a matter of dosage.

Methylmorphine, ethylmorphine, and amylmorphine have identical physiological actions, the narcotic action of morphine being diminished and its tetanic action increased.

Acetyl-, diacetyl-, benzoyl-, and dibenzoyl-morphine have a much greater depressant action in small doses on the cord and on the respiratory centre than morphine; their narcotic action is not nearly so profound. Increase of dose, instead of deepening the narcosis, brings on tetanic symptoms which are much more marked than those produced by morphine.

Morphine Sulphuric Ether and Nitrosomorphine.—In these two substances, the introduction of the radicles HSO_3 and NO modifies the action of morphine much in the same way as the introduction of alcoholic and other acid radicles.

Methylmorphium Chloride and Methylcodeïum Sulphate.—From experiments with these two additive products, the conclusion is drawn that the actions of morphine or of codeine are not very profoundly altered by the chemical change. The paralysing action on the motor nerves is considerably increased, and the narcotic action is lessened.

Chlorine-derivatives (chlorocodide and trichloromorphine) have the characteristic actions of the morphine-group on the central nervous system. In addition, they act energetically as muscle poisons, soon destroying the contractile power of the voluntary muscles with which they first come in contact at the place of injection, and more gradually affecting the other muscles of the body. Chlorine is well known to be a powerful muscle poison.

Methocodeine.—In this substance, two methyl molecules are introduced into morphine, one replacing a hydroxyl hydrogen-atom, whilst the other is introduced into the body of the morphine molecule, $C_{17}H_{17}MeNO(OH)\cdot OMe$. Here the distinguishing features of morphine poisoning are wholly absent, the chief symptom observed being gradual poisoning of the voluntary muscles.

The experiments carried out in this research were performed on frogs and rabbits.

W. D. H.

Physiological Action of Pituri and Nicotine. By J. N. LANGLEY and W. L. DICKINSON (*Jour. Physiol.*, 11, 265—306).—Pituri is an alkaloid extracted from the leaves of a shrub (*Duboisia Hopwoodii*) which grows in Australia. The Australian blacks make with the leaves a quid for chewing. The main result of the present experiments is to show that the physiological action of pituri is identical with that of nicotine. It is possible that pituri leaves, like tobacco leaves, may contain more than one alkaloid, but that pituri leaves contain nicotine does not admit of doubt unless it be supposed that different chemical substances have the same physiological action.

The bulk of the paper is taken up with a very complete account of the physiological action of the two drugs on both frogs and mammals. A complete bibliography of the subject is also given.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Preparation of Wine Yeasts. By A. Rommier (*Compt. rend.*, **110**, 1341—1343).—In order to obtain pure wine yeast, the juice of carefully selected grapes is allowed to ferment, and small quantities of the fermented liquid are added to filtered and sterilised grape juice. A number of successive cultivations in grape juice are then made with intervals of one to four days, and the final cultivations are made in a solution of sugar mixed with the necessary inorganic salts. In this way the less energetic yeasts are eliminated, and only *Saccharomyces ellipsoideus* remains. C. H. B.

Alcoholic Fermentation and Conversion of Alcohol into Aldehyde by Champignons du Muguet. By G. Linossier and G. Roux (*Compt. rend.*, **110**, 868—870).—Existing statements as to the fermentative power of champignons du muguet (the fungus of the lily of the valley) are very contradictory. The authors find that when carefully sterilised liquids are inoculated with a pure cultivation of the fungus with all the usual precautions, quantities of alcohol were obtained varying from 2·7 per cent. in the case of a sugar solution containing inorganic salts, to 5·5 per cent. in the case of wort from dried raisins. The fungus ferments levulose and maltose as well as glucose. It develops at the expense of saccharose, but neither inverts it nor ferments it. It cannot assimilate lactose. In a mixture of levulose and dextrose, both sugars are attacked, but the latter disappears the more rapidly. In addition to alcohol, glycerol, succinic acid, a notable quantity of acetic acid, a little butyric acid, and a somewhat large quantity of aldehyde are formed. A small quantity of the aldehyde may be a product of excretion of the ferment, but the greater part is formed by the oxidation of alcohol in presence of air and under the influence of the ferment. The ferment, in fact, develops readily in very dilute alcohol mixed with inorganic salts, a mixture of aldehyde and acetic acid being formed. The acetic acid, on the other hand, is probably formed by the direct oxidation of the aldehyde by the oxygen of the air, without intervention of any life process. The ferment, in fact, cannot develop at the expense of aldehyde even in presence of suitable salts.

This is the first instance in which aldehyde has been found to be the chief product of fermentation by a low organism. The general behaviour of champignons du muguet, the maximum quantity of alcohol produced, the rate of fermentation, &c., show that it is more nearly related to the *Mucorinæ* than to *Saccharomyces*, and this result agrees with the authors' deduction on morphological grounds that this fungus did not belong to the group of *Saccharomyces*.

C. H. B.

The "Bouquet" of Fermented Liquids. By G. JACQUEMIN (*Compt. rend.*, **110**, 1140—1142).—The characteristic bouquets of wines from various districts are due to the special characters of the yeast used in each district. One and the same must fermented with the yeast obtained from several different districts gave wines having the bouquet characteristic of the district from which the particular yeast producing them had come. Even in a 10 per cent. solution of sugar, the cultivated yeasts, although producing very little alcohol, will develop their characteristic bouquet in a very remarkable and intensified degree.

C. H. B.

The Nitrifying Organism. By WINOGRADSKI (*Ann. Agron.*, **16**, 273—274; from *Ann. de l'Institut Pasteur*, 4, 213, 261).—After trying several nutritive media, the author found that the organic matter generally introduced is prejudicial to nitrification, and he therefore employed river water (Lake of Zurich) with the addition of 1 gram per litre each of ammonium sulphate and potassium phosphate. A little magnesium or calcium carbonate is added, and the liquid sterilised by ebullition and then fertilised with a few drops from a previous operation. Five organisms were recognised in the light surface deposit formed on the liquid, but these had no nitrifying power. The body of the liquid is generally perfectly clear, but when the nitrification is very active the liquid becomes slightly clouded about the fifth or sixth day by oval, slightly fusiform organisms, moving with great agility. These disappear after some time, but the layer of magnesium or calcium carbonate at the bottom becomes entangled in a gelatinous, greyish deposit of thick groups of a fine, oval bacterium. It is impossible to grow this bacterium on the gelatin plates commonly used, and the author takes advantage of this fact to isolate it. Some drops of the deposit are removed by a capillary tube and placed in a flask of sterilised water, and drops of this attenuated liquid are cultivated on separate plates of gelatin; after some days, the plates are examined, and those showing no growths are selected as containing the nitrifying organism alone. Fragments of these sown in the ammoniacal liquid employed give rise to nitrates in measurable quantities. The author goes on to infer that as the nitrifying bacterium lives, develops, and carries out its functions in a medium containing minerals only, it must derive the carbon necessary to its structure from the carbonic anhydride of carbonates, the energy necessary to reduce the carbonic anhydride being derived from the heat disengaged by the oxidation of ammonia into nitric acid. It, therefore, furnishes us with an example of a non-chlorophyllous cell able to effect the decomposition of carbonic anhydride.

J. M. H. M.

Note by Abstractor.—On March 13, 1890, Dr. P. F. and Mrs. Frankland communicated to the Royal Society an account, with drawings, of the nitrifying bacillo-coccus, isolated by a process of dilution, and refusing to grow in gelatin peptone. Warington, commenting (*Chem. News*, **61**, 135) on their experiments and his own, remarks that "the medium they made use of was an ammoniacal solution containing no organic matter." He also appears to have isolated the same organism from cultures in "weak solutions of ammonium salts containing the necessary nutritive salts but no organic matter." In connection with this point in the investigations of Frankland, Warington, and Winogradski, I may be permitted to point out that in a paper published in this Journal (Trans., 1886, 632—681), and afterwards translated in full in the *Ann. Agronom.*, I showed that "the merest traces of organic matter," if any, "such as may be furnished accidentally by occasional exposure to the dust of the air, are sufficient for complete nitrous fermentation of the quantities of ammonia used in these experiments" (*loc. cit.*, p. 654), and that in general "the presence of a tartrate or any similar organic body is distinctly prejudicial to nitrification" (p. 654). On this account, I adopted boiled well or river water with added ammoniacal salt as a suitable nitrifying medium, and remarked (p. 667), "In the purest well waters, there is a very slight flocculent deposit during nitrification; there is more deposit in the rapidly nitrifying waters. Nitrification in filtered well water, or in boiled well water seeded with a nitrifying solution free from fermentable organic matter, would probably furnish a deposit well suited for microscopic observation of the nitrifying organism, called by Schloësing and Muntz *Micrococcus nitrificans*" (p. 667). Using a solution almost identical with that since adopted by Winogradski, namely, plain water with the addition of an ammoniacal salt and a little potassium phosphate (p. 680), I also succeeded in suppressing the so-called incubating period of the nitrifying organism, and starting nitrification in a fresh solution in less than seven hours. But Winogradski's inference as to the decomposition of carbonic anhydride by this organism appears to me open to grave doubt.

J. M. H. M.

Action of Light on Acetic Fermentation. By M. GIUNTI (*Bied. Centr.*, 19, 490—491; from *Staz. Sper. Agr. Ital.*, 18, 171—183). —White wine was diluted with water, treated with acetic acid, sterilised, and inoculated with *Mycoderma aceti*, which had been cultivated in the same wine diluted. The liquid contained alcohol (4·51 vols. per cent.) and acetic acid (3·03 grams per litre). Two series of experiments were made under equal conditions, except that one was exposed to light, and the other kept in the dark, whilst a third experiment was made without the organism, the object of which was to correct errors in reading the volumes of gas. After three or four weeks the solutions were analysed. The results showed that direct sunlight hinders the development of the *Mycoderma aceti*, and consequently the acetic fermentation; even diffused daylight hinders the development if the surface of the liquid is not shaded. Prolonged sunlight did not, however, sterilise the liquid inoculated with *Myco-*

derma, but it might be possible to hinder the formation of acid in wines in this way. N. H. M.

Elaboration of Nitrates in the Plant. By O. LOEW (*Ann. Agron.*, 16, 279—280).—On heating 3 grams of glucose and 1 gram of potassium nitrate at 60—70° for six hours with 200 c.c. of water and 110 grams of spongy platinum, 45·6 per cent. of the nitrogen was found transformed into ammonia, which was combined with acids formed by oxidation of the glucose. A rancid odour resembling caproic acid, valerian root, or rancid butter was at the same time developed. The author believes the vegetable cell may exercise a similar "catalytic" reducing action on nitrates previous to the elaboration of the nitrogen into protoplasmic compounds.

J. M. H. M.

Calcium Oxalate Crystals. By G. ACQUA (*Ann. Agron.*, 16, 275).—The raphides so common in *Phytolacca dioica* are most numerous in the neighbourhood of the young shoots. There are no crystals in the embryo, but soon after germination they appear in the root cap, afterwards in the cotyledons; before their formation, the cells in which they are to appear are filled with gelatinous contents. If the young plants are grown in a nutritive solution containing no calcium, fresh crystals do not appear, but those already formed do not dissolve. Oxalic acid is formed in all the turgescent cells of the bark and pith; it unites with potash, and passes in solution through the intercellular spaces; in certain cells, distinguished by the nature of their contents, the calcium salts everywhere present precipitate the oxalate. Similar observations were made with *Mesembryanthemum acinaciforme* and *Euonymus japonicus.* The oxalate always remains where it is formed.

J. M. H. M.

Importance of Chlorine in the Plant. By C. ASCHOFF (*Ann. Agron.*, 16, 275—277).—Knop concluded from his water-culture experiments that chlorine is not essential to the growth of plants; Beyer, Leydhecker, Nobbe, Siegert, and Wagner hold the contrary opinion. The author has experimented with common haricots, Spanish haricots, and maize, growing them in a nutritive solution containing magnesium sulphate, 0·1002 gram; potassium chloride, 0·1215 gram; calcium nitrate, 0·2674 gram; potassium phosphate, 0·1019 gram; and a trace of ferric chloride, per litre; also in the same solution, with the potassium chloride omitted and the ferric chloride replaced by ferric pyrophosphate; and in pure water. In the pure water, no growth took place; in the complete solution, the growth was normal, and the plants flowered and seeded, whether the cotyledons were removed from the seeds or not; in the solution deprived of chlorine, growth soon stopped, the roots aborted, the terminal buds dried up, and the leaves fell. The Spanish haricots when deprived of chlorine formed no tannin, but the common haricot did in both solutions. Chlorine may be considered necessary to the three plants experimented with. J. M. H. M.

Solanidine in Potato Shoots. By JORISSEN and GROSJEAN (*Ann. Agron.*, 16 284—285).—The shoots thrown out by potato tubers kept in the dark contain solanidine, which can be extracted by ether, treated with potash to remove oily matter, and purified by crystallisation from alcohol; 1·5 grams was obtained from 1 kilo. of the fresh shoots containing 90 per cent. of water. On analysis, the formula $C_{26}H_{41}NO_2$ was obtained. J. M. H. M.

Nitrogenous Constituents of the Tubercles of Stachys tuberifera. By A. v. Planta (*Ber.*, 23, 1699—1700).—In addition to stachyose (this vol., p. 1088), various nitrogenous compounds also occur in the tubercles of *Stachys tuberifera*. Of these, glutamine and tyrosine have been identified, and a base has also been obtained which is precipitated by phosphotungstic acid, and forms a hydrochloride and aurochloride somewhat resembling those of betaine. Its exact nature has not yet been determined. H. G. C.

Yields and Composition of a Variety of Red Clover. By P. Baessler (*Bied. Centr.*, 19, 478—479).—The experiments were made with a Norwegian variety of red clover ("Totenklee"), distinguished by its hardiness and its producing large crops, in a humous, sandy soil containing, nitrogen, 0·2; lime, 1·2; potash, 0·1; phosphoric acid, 0·3 per cent. The manuring was superphosphate and sodium nitrate, and half of the experimented land had besides a top-dressing of a bye-product from the manufacture of potassium salts, containing about 50 per cent. of gypsum, 28 per cent. of calcium carbonate, 5 per cent. of lime, and 7·5 per cent. of potassium sulphate. The first crop gave, per acre, 132 cwt. of green fodder and 42·7 cwt. of hay without, and 168 cwt. of green fodder and 53·5 cwt. of hay with, the top-dressing of calcium and potassium salts.

The following numbers show the mean percentage composition of the air-dried hay of the two plots:—

Water.	Ash.	Crude fat.	Crude protein.	Crude fibre.	Non-nitrogenous extract.
14·55	6·33	2·09	14·00	22·40	40·63

Nitrogen.	Albuminoïd nitrogen.	Nitrogen as amides, &c.
2·24	1·84	0·40

The differences in composition of the produce from the two plots were only slight. N. H. M.

Decomposition of Rocks and Formation of Arable Soils. By A. Muntz (*Compt. rend.*, 110, 1370—1372).—A summary of the causes which are active in producing the disintegration of rocks. The author lays special stress on the importance of the part played by the nitric ferment and other low organisms (compare Abstr., 1887, 1135). C. H. B.

Decomposition of Organic Manures in Soils. By A. Muntz (*Compt. rend.*, 110, 1206—1209).—In soils in which, from their nature (*e.g.*, acid soils), nitrification cannot take place, the nitrogen of the organic matter is converted into ammonia. In strong clay soils also the nitrogen is almost completely converted into ammonia, very little nitrification taking place. The same result is observed with nitrifiable soils in which the nitric ferment has been killed by exposure to a temperature of 90°. Even with arable soils in which nitrification takes place rapidly, part of the organic nitrogen is converted into ammonia. If the soil has been heated to 120°, the formation of ammonia is, as a rule, prevented, but takes place if a small quantity of non-sterilised soil is added.

It follows from these results that the ammonia ferment exists in soils simultaneously with the nitric ferment, and produces a preparatory change, which is useful, if not essential, in the process of nitrification, and which accelerates the conversion of organic nitrogen into nitrates. C. H. B.

Green Manures as Suppliers of Nitrogen. By A. MUNTZ (*Compt. rend.*, **110**, 972—975).—Soil was mixed with green manure (lupin), dried blood, and ammonium sulphate respectively in such quantity that the proportion of nitrogen was 1 gram per kilo. The first soil, I, was light, and contained 2 per cent. of calcium carbonate; the second, II, was a strong, clay soil, containing but little lime; the time in both cases was three months, and the figures give the quantity of nitric nitrogen in milligrams per kilo.

	Green manure.	Dried blood.	Ammonium sulphate.
I..........	183	161	268
II..........	88	3·6	5·1

The relatively rapid nitrification with the bulky green manure in II is due to its effect in making the soil more pervious to the air.

An experimental plot at Vincennes was divided into four parts. which were treated with different manures, so that 100 kilos. of nitrogen was present per hectare. Eighteen days after spreading the manures, the milligrams of nitric nitrogen per kilo. were as follow:—

Green manure (lucerne).	Dried blood.	Ammonium sulphate.	No manure.
86·0	72·2	121·4	14·5

The weight of the crop of maize, cut in September, was as follows:—With green manure, 78,000 kilos.; with dried blood, 71,500 kilos.; with ammonium sulphate, 66,000 kilos.; with sodium nitrate, 78,500 kilos.; and with no manure, 39,500 kilos.

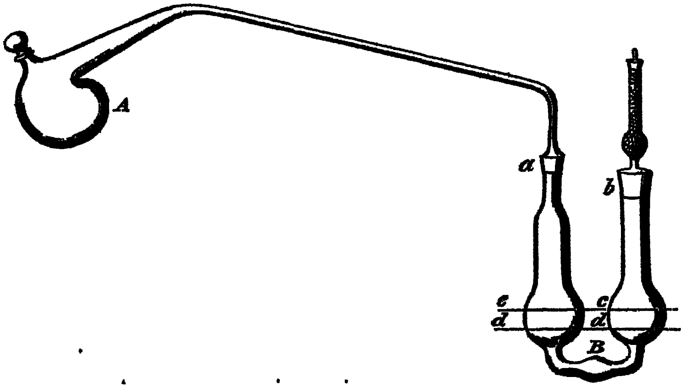
It follows that the efficiency of green manures is due to the ease with which their proteïd constituents are nitrified, and to the favourable influence which the manure exerts on the physical properties of the soil. C. H. B.

Analytical Chemistry.

Apparatus for Drying Substances under Diminished Pressure. By D. Sidersky (*Zeit. anal. Chem.*, **29**, 280—282).—The apparatus is essentially a water-oven, with a door which can be closed air-tight, and stop-cock connections by which the interior chamber can be exhausted by an air-pump, or refilled with dry air. In form it is a double-walled cylinder of copper, of about 30 cm. high and 26 cm. diameter, with conical ends; the annular space is filled with water which is kept boiling. Owing to the reduced pressure in the interior, substances dry with great rapidity, and with less tendency to decompose than in an ordinary water-oven. M. J. S.

Characteristic Reaction of Hydrogen Peroxide. By G. Denigès (*Compt. rend.*, **110**, 1007).—A 10 per cent. aqueous solution of ammonium molybdate, mixed with its own volume of strong sulphuric acid, gives with a few drops of hydrogen peroxide a deep-yellow coloration. When more water is added, the intensity of the colour decreases more rapidly than the degree of dilution increases; but it is not affected by heating the liquid. The reaction will detect 0·0001 gram of hydrogen peroxide. A permolybdic acid seems to be formed; sodium molybdate may be used instead of the ammonium salt. C. H. B.

Estimation of Iodine. By W. Stortenbeker (*Zeit. anal. Chem.*, **29**, 272—280; see Abstr., 1889, 185).—For processes involving the distillation of iodine, the author, whilst fully endorsing the statements of Topf (*Zeit. anal. Chem.*, **26**, 277), suggests the subjoined apparatus as simpler. The retort A has a capacity of 250 c.c.; the neck is 40 cm. long, and serves as a condenser; it is connected at *a* with the U-tube by grinding, and the joint is wetted (Topf, however,



states that ground joints are to be avoided, as iodine adheres with peculiar tenacity to ground surfaces). The U-tube is filled to *dd* with potassium iodide solution, with which also the beads in the small tube are moistened. It is plunged into cold water up to the level *cc*. The joint *b* may be of caoutchouc. No stream of gas is required, the steam being sufficient for the complete expulsion of the iodine.
M. J. S.

Estimation of Iodine in Haloïd Salts. By F. A. Gooch and P. E. Browning (*Amer. J. Sci.* [3], **39**, 188—201).—The method proposed consists in boiling the solution of the iodide with sulphuric and arsenic acids; the iodide is oxidised by the latter, and arsenious acid is formed, together with free iodine, which volatilises with the steam. The arsenious acid in the residual solution is titrated with standard iodine. There must be at least 25 per cent. by volume of strong sulphuric acid in the solution when the boiling is finished. The presence of considerable quantities of chlorides makes the result too low, owing to volatilisation of arsenious chloride; bromides are slightly oxidised by arsenic acid, and consequently make the result too high. It was found that in the case of the solutions experimented with, these errors might be corrected; the correction to be applied to the weight of iodine found being (weight of sodium chloride × weight of potassium iodide × 0·004) — (weight of potassium bromide × 0·0016).

The mode of proceeding in the analysis of a mixture of alkaline chlorides, bromides, and iodides may be summarised as follows:—

The substance (which should not contain more chloride than corresponds with 0·5 gram of sodium chloride, or of bromide more than corresponds with 0·5 gram of potassium bromide, or of iodide much more than the equivalent of 0·5 gram of potassium iodide) is dissolved in water in an Erlenmeyer beaker of 300 c.c. capacity, and to the solution are added 2 grams of dihydrogen potassium arsenate dissolved in water, 20 c.c. of a mixture of sulphuric acid and water in equal volumes, and enough water to increase the total volume to 100 c.c., or a little more. A platinum spiral is introduced, a trap, made of a straight two-bulb drying-tube, cut off short, is hung with the larger end downwards in the neck of the flask, and the liquid is boiled until the level reaches the mark put upon the flask to indicate a volume of 35 c.c. Great care should be taken not to press the concentration beyond this point on account of the double danger of losing arsenious chloride and setting up reduction of the arsenate by the bromide. On the other hand, although 35 c.c. is the ideal volume to be attained, failure to concentrate below 40 c.c. introduces no appreciable error. The liquid remaining is cooled and nearly neutralised with sodium hydroxide (ammonia is not equally good), neutralisation is completed by hydrogen potassium carbonate, an excess of 20 c.c. of the saturated solution of the latter is added, and the arsenious acid in solution is titrated by standard iodine in the presence of starch.

With ordinary care, the method is rapid, trustworthy, and easily executed, and the error is small. In analyses requiring extreme accuracy, all but accidental errors may be eliminated from the results by applying the corrections indicated. C. F. B.

New Method of Estimating Sulphur in Inorganic Sulphides. By P. Jannasch (*J. pr. Chem.* [2], **41**, 566—574).—The author has improved the absorption apparatus which he uses for his method of determining sulphur in inorganic sulphides by combustion in oxygen (compare Abstr., 1889, 1244). Instead of cylinders with corks, to which he objects as being likely to retain splashings in their pores, he now uses cylinders with glass stoppers which have tubes sealed through them. The tube which dips under the liquid in the first cylinder is widened at the top to admit of a cork through which the drawn-out and downward-bent end of the combustion-tube is thrust. The tube which does not dip under the liquid in the second cylinder is bent twice at right angles, and its other end dips into bromine-water in an Erlenmeyer flask. The operation is conducted as previously described (*loc. cit.*). When it is concluded (after about $\frac{3}{4}$ hour), all the absorbent is transferred to a beaker, strong hydrochloric acid (1 c.c.) added, and heated until all bromine is expelled; the sulphuric acid is then precipitated as barium sulphate, with all the usual precautions.

The author gives examples of analyses of blende, copper pyrites, and antimonite by this method, for which he claims rapidity, accuracy, and freedom from interference by other substances.

A. G. B.

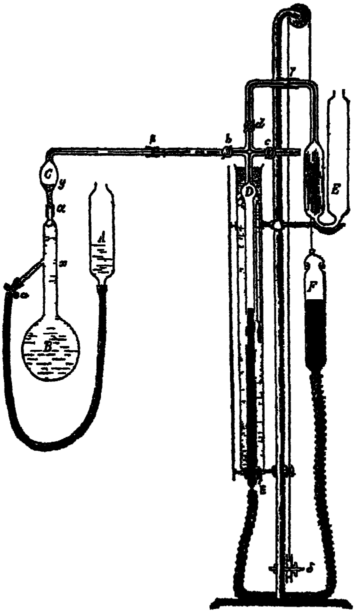
Estimation of Arsenic by Marsh's Method. By B. Kühn and O. Saeger (*Ber.*, **23**, 1798—1803).—About 150 grams of pure zinc (sufficient for the decomposition of about 0·11 gram of arsenious acid) is placed in an Erlenmeyer flask, which is also provided with an india-rubber stopper through which pass a funnel, 50 cm. long, reaching to the bottom of the flask, and a delivery-tube bent at right angles. The latter is connected to a wash-bottle containing 50 c.c. of a 5 per cent. lead acetate solution, this to a drying-tube containing at least 100 grams of calcium chloride, and this, finally, to the shorter drawn-out end of the combustion-tube. The latter is made of hard glass tubing, of 10—12 mm. internal diameter; 80 cm. of it lie in a combustion-furnace, heated by 24 burners, and it is drawn out at both ends to a tube of about 5 mm. internal diameter for a length of 25 cm. at one end and 60 cm. at the other. Over the funnel, above mentioned, are two burettes, one containing the arsenic solution, the other dilute sulphuric acid (1 part by vol. of acid (sp. gr. 1·84) to 3 of water). The combustion-tube is heated to a dull-red heat, and sulphuric acid run into the flask, so as to sweep out the apparatus with a current of hydrogen. The acid is then arranged so as to drop in at about $\frac{3}{4}$ c.c. per minute, 25 c.c. of the arsenic solution is run in at about $\frac{1}{2}$ c.c. per minute, and the shorter, contracted limb of the combustion-tube is heated at three separate places with bunsen burners; if any arsenic is deposited here, it is a sign that the current of hydrogen is too slow. The current must not be so fast that the bubbles in the lead acetate bottle cannot be counted, and in order to see that no arsenic has escaped, a wash-bottle containing a little silver nitrate should be connected with the further end of the combustion-tube. The arsenic is deposited as a mirror in the longer limb of the combustion-tube; it is brought as much as possible into one part of this by warming it, and sending a reversed current of hydrogen through if necessary. The piece of tubing is cut off, weighed, the arsenic dissolved in strong nitric acid, and the tube weighed again. Or if, as may happen in toxicological cases, it is desired to preserve the arsenic, the little piece of tubing should be placed inside a larger piece, drawn out at one end, and the arsenic sublimed into this end in a current of hydrogen. More than 0·1 gram of arsenic cannot be easily estimated, and, in any case, the results are not very exact, but the method is expeditious, and, for some purposes, may be useful.

It has also been found that, contrary to the statement of the text-books, arseniuretted hydrogen is decomposed to a considerable extent when it is passed over solid caustic potash, though not so easily as antimoniuretted hydrogen. C. F. B.

Estimation of Moisture and Carbonic Anhydride in Air. By J. S. Haldane and M. S. Pembrey (*Phil. Mag.* [5], 29, 306—331).—The authors have improved the absorption method for determining the amount of water-vapour in the atmosphere. The absorption apparatus employed by them consists of a pair of test-tubes, 4 × 1 inch, filled with pumice soaked in sulphuric acid, and connected up in the ordinary way with well paraffined corks and glass tubing. When charged, the pair weighs about 80 grams. A counterpoise, in every respect similar to this apparatus, and exposed to the same conditions, should always be used to diminish the error in weighing. Experiment showed that air could be aspirated through such absorption-tubes at the rate of 7 litres a minute without appreciable quantities of moisture (less than 0·1 per cent.) escaping. A comparison with the psychrometric method showed errors in the latter ranging from +30 to −7 per cent.

The apparatus for absorbing carbonic anhydride was formed of another such pair of tubes, the first containing soda-lime, and the second pumice and sulphuric acid. The air must be perfectly dry before reaching the soda-lime tube, so that a simultaneous determination of moisture and carbonic anhydride was usually made, the rate of aspiration being in general 1 litre per minute. Here again the mean error is only about 0·1 per cent. Pettenkofer's method gave results 8 to 27 per cent. higher than those obtained by direct weighing. J. W.

Estimation of Carbonic Anhydride. By O. Pettersson (*Ber.*, 23, 1402—1406).—The carbonic anhydride in all solid or liquid substances can be estimated by means of the following apparatus, which is more especially suitable for the determination of the gas when in a dissolved or partially combined state, as, for example, in natural spring or sea water. The substance containing the carbonic anhydride is boiled with dilute acid in the flask B under reduced pressure, and a slow stream of hydrogen, obtained from a small piece of iron or aluminium wire enclosed in a long capillary tube, introduced into B, is passed through the liquid during the operation; in this way the whole of the carbonic anhydride is expelled, and bumping is avoided. If nitric acid has to be employed (compare this vol., p. 1027), the necessary quantity of hydrogen is obtained from a piece of aluminium wire, bound round with platinum wire.



The evolved gases are measured over mercury in a moist condition in the burette D, the carbonic anhydride being then absorbed with potash in the Orsat's tube E; the residual air can then be expelled through *c*, either partially or entirely, and the space C above the liquid exhausted at will, so that the boiling always takes place under greatly reduced pressure. The horizontal tube in connection with C is capillary; the others are narrow, but not capillary. As a rule, a small quantity (0·3—0·5 c.c.) of water collects on the surface of the mercury in D; this is removed, before the boiling is completed, by opening *b* and raising F.

The details of the operation are as follow:—The liquid to be analysed is introduced into B up to the mark *x*, the metal wire is thrown in, and the bulb-shaped tube C is securely connected at *α* with B and at *β* with the horizontal tube of the burette by means of india-rubber tubing. A sufficient quantity of dilute hydrochloric acid, or nitric acid, is then poured into A, the cocks *a* and *b* are opened (*c* and *d* being closed), and F is lowered by turning the roller *δ*; when the acid has risen to *y*, *a* is closed, and C is exhausted.

The stopcock *b* is then shut, F is raised until the level of the mercury in D and F is the same, and *d* is opened; a few large bubbles of air are then blown into *e* to equalise the temperature of the water in the tube surrounding D, and the level of the soda in E is brought to the mark on the capillary tube. The volume of the air in D, the temperature, and the barometric pressure are noted, and the air is then passed into E; after about two minutes, it is brought back into the burette, and its volume again measured. The air which remains in D, after exhausting, contains very little carbonic anhydride, and, except when the liquid in B is very rich in this gas, the quantity does not exceed 0·03 cm.

Before commencing to heat the liquid in B, the volume of air in D is reduced to about 13 c.c. by opening *c* and raising F; about half the residual air is then passed into E, *d* is closed, and F is lowered until the pressure in D is reduced to about 110—130 mm. On heating the liquid in B (by means of a rose-burner) and opening *b*, ebullition quickly commences, and the evolved gas collects in D without carrying over any appreciable quantity of water; small drops, which collect in the capillary tube, can be driven back into C by quickly raising F, and, in order to further prevent water from distilling over, the stopcock *b* can be kept closed, except when transferring the liberated gas to D. As soon as the burette is filled with gas, under a pressure of one-sixth to one-seventh of an atmosphere, *b* is closed, and the carbonic anhydride in the gaseous mixture is determined as before, the bunsen flame being meanwhile simply lowered. As a rule, this operation must be repeated two or three times in order to expel the whole of the carbonic anhydride; but, when after 10—15 minutes boiling only 0·02—0·03 c.c. of the gas is obtained, the boiling can be discontinued.

Quantitative experiments gave very good results. In estimating the carbonic anhydride in solid substances, the quantity of this gas present in the distilled water used must be determined separately.

The above diagram shows the apparatus one-twelfth its actual size.

F. S. K.

Valuation of Zinc-dust. By G. Klemp (*Zeit. anal. Chem.*, **29**, 253—266).—The methods of Fresenius (Abstr., 1879, 400), Beilstein and Jawein (1880, 826), Barnes (1887, 80), and Morse (1885, 1012) depend on the treatment of the zinc with an acid and estimation of the hydrogen evolved: that of Drewsen (*Zeit. anal. Chem.*, **19**, 50), on the reducing action of the zinc on acidified potassium chromate. Topf (Abstr., 1887, 997) adds the zinc-dust to an excess of iodine and estimates the iodine left uncombined. Weil (Abstr., 1887, 301, 1000) treats the zinc-dust with a known quantity of cupric chloride, and titrates the excess by stannous chloride. The results of Drewsen's method are irregular, and also low, compared with those of Topf and Fresenius. On the other hand, in the methods involving treatment with an acid, iron, and to some extent lead, which are often present as impurities, are estimated as zinc, although they are valueless when the zinc is used for reductions in alkaline solution, which is frequently the case. On this account, the author prefers to estimate the metallic zinc by its reducing action on potassium iodate in alkaline solution. In concentrated solutions, containing a sufficient excess of iodate, zinc reduces the iodate to iodide, without any evolution of hydrogen, and on the subsequent addition of an acid, the iodide reacts with the excess of iodate setting free iodine in the proportion of 0·7799 part of iodine for 1 part of zinc (there are misprints in the numbers in the original). The iodine can now be distilled out, condensed in potassium iodide, and titrated with thiosulphate. The conditions for success are as follows:—There must be a certain excess of iodate and alkali, and the liquids should be as concentrated as is possible without precipitation of the iodate by the alkali. The zinc-dust must be very intimately mixed with the liquid, but it must not be wetted with water before adding the reagent.

For each 0·1 gram of zinc there should be used 0·1525 gram of potassium iodate in 3 c.c., and 3 grams of sodium hydroxide or 3·7 grams of potassium hydroxide in 10 c.c. The zinc (0·5—1 gram) is weighed into a dry stoppered bottle of about 200 c.c. capacity, some glass beads are added, and then the two reagents, previously mixed, and the bottle is vigorously shaken for five minutes. Warming is unnecessary. The contents of the bottle are now made up to 250 or 500 c.c. and 100 c.c. taken for distillation. The apparatus of Topf (*loc. cit.*) is the most convenient for the purpose. The condensing tubes may contain about 4 grams of iodide in 20 c.c. The liquid placed in the retort is acidified with dilute sulphuric acid, a slow stream of carbonic anhydride is passed through, and the contents of the retort are boiled until colourless. The iodine is then titrated with a thiosulphate solution containing about 7 grams per litre. Finely divided lead treated as above reduces iodate corresponding with about 3 per cent. of zinc, but when lead is mixed with zinc it slightly lowers the results. Iron has a similar effect, in consequence of the escape of a little hydrogen when the mixture is treated with the alkaline iodate. M. J. S.

Volumetric Estimation of Zinc. By L. Blum (*Zeit. anal. Chem.*, 29, 271—272).—Donath and Hattensaur have published (*Chem. Zeit.*, 1890, 323) a method for the titration of zinc in presence of iron in an ammoniacal tartrate solution by potassium ferrocyanide, the end being ascertained by mixing a drop with acetic acid. In presence of manganese, a frequent impurity in zinc ores, the results are too high, so that in most cases the method is useless. M. J. S.

Estimation of Zinc in its Ores. By D. Coda (*Zeit. anal. Chem.*, 29, 266—271).—In the ordinary method, after removal of copper, &c., by hydrogen sulphide, the iron is precipitated from the hydrochloric acid solution by a mixture of ammonia and ammonium carbonate, and the zinc in the filtrate is titrated by sodium sulphide. The iron precipitate always carries down with it a portion of the zinc, which cannot be completely detached either by long standing, by boiling, or by a second precipitation. But in a sulphuric acid solution, containing ammonium sulphate, the latter salt adheres to the ferric precipitate in place of the zinc, and the whole of the zinc is obtained in the filtrate.

About 2·5 grams of the zinc ore is dissolved in 15—20 c.c. of nitrohydrochloric acid and the solution evaporated to dryness; 15—20 c.c. of sulphuric acid is then added, and the whole heated until fumes of sulphuric acid escape. If metals precipitable by hydrogen sulphide are present, they must be removed, and the filtrate boiled to expel hydrogen sulphide. The filtrate is neutralised with ammonia, and then 40 c.c. more ammonia, containing one-fourth of ammonium carbonate, is added. The cooled mixture is made up to 500 c.c. and filtered, and 100 c.c. is taken for titration. The standard solution used is a 2 per cent. solution of crystallised sodium sulphide, the strength of which must be ascertained by an experiment with a quantity of pure zinc approximately equal to that in half a gram of the ore. This quantity is dissolved in 4 c.c. of hydrochloric acid, diluted, and made alkaline with 20 c.c. of ammonia. Each liquid is then diluted to about 250 c.c., and the sodium sulphide is run in till the zinc is nearly all precipitated. The precipitate is allowed to settle, and a little of the clear liquid removed and added to a drop of an 8 per cent. solution of sodium nitroprusside, further quantities of sulphide being added until the colour appears of equal intensity in the two test mixtures when enough of the supernatant liquid is used to make a pool on the porcelain slab of 30 mm. diameter.

M. J. S.

Estimation of Zinc in Iron Ores. By B. PLATZ (*Zeit. anal. Chem.*, 29, 342—345; from *Stahl und Eisen*, 9, 494).—The old method of precipitating the zinc by hydrogen sulphide from an acetic acid solution only gives good results when the amount of zinc is considerable; if the amount is small, iron always precipitates at the same time. The following method achieves the separation completely. Five grams of the ore is dissolved in concentrated hydrochloric acid, and the solution is evaporated with 2 or 3 c.c. of nitric acid and filtered. The strongly acid solution (200 c.c.) is heated to 80—100° and saturated with hydrogen sulphide. If copper is to be estimated, any precipitate obtained may be filtered off. Acetic acid and ammonium acetate are added, and ammonia is run in from a burette, the point of which dips into the liquid, until the precipitate becomes permanently greyish. The grey colour is removed by cautious addition of hydrochloric acid (1 : 50) and then again very dilute ammonia added until the very faintest permanent grey is obtained. At the right point for stopping the addition of ammonia, the precipitate aggregates and begins to subside. It is filtered off and washed with water containing acetic and hydrosulphuric acids. The filtrate should remain clear on further addition of ammonia. The precipitate is dissolved in hydrochloric acid (1 : 6) and the solution filtered. The hydrogen sulphide is expelled by heating, and to the cold solution sodium carbonate is added in slight excess. The mixture is then heated to boiling and filtered. The precipitate obstinately retains alkaline salts, but as, when thrown down in this way, it subsides and filters well, it can be completely washed in an hour. When copper, cobalt, and nickel are absent, the zinc sulphide may at once be ignited with sulphur in hydrogen.

M. J. S.

Estimation of Zinc in presence of Iron and Manganese. By RIBAN (*Compt. rend.*, **110**, 1196—1199).—The liquid is diluted so that it contains not more than 0·1 gram of zinc in 100 c.c. and sodium carbonate is added until a slight precipitate persists, the precipitate being then dissolved by the addition of a few drops of dilute hydrochloric acid. A current of hydrogen sulphide is passed into the cold liquid until the greater part of the zinc is precipitated together with sulphur separated by the action of the ferric salt. A large excess of a solution of sodium dithionate is then added, and the passage of the gas is continued; the zinc is completely precipitated and the iron remains in solution. If the iron is subsequently to be precipitated by ammonia, it is better to use ammonium dithionate, since the ferric hydroxide is very apt to retain alkaline salts. For the same reason, the solution should be neutralised with ammonium carbonate, which should be added until the yellow colour of the liquid begins to change to orange.

After washing with water containing hydrogen sulphide, the precipitate is dried, heated with sulphur in a current of hydrogen, and weighed. It is then dissolved in hydrochloric acid, mixed with a few drops of nitric acid, a large quantity of ammonium chloride added, and then an excess of ammonia. The minute quantity of iron carried down by the zinc is thus precipitated; its weight rarely amounts to 0·002 gram. The examples given are very satisfactory. The method is applicable in presence of calcium salts, since calcium dithionate is soluble.

In order to estimate the iron in the filtrate, it is peroxidised with nitric acid, which has little action on the dithionate, and is precipitated in the usual way. C. H. B.

Detection and Estimation of Antimony and Arsenic. By J. THIELE (*Chem. Centr.*, 1890, i, 877—878; from *Apoth. Zeit.*, 5, 86—87).—According to the author's experiments, metallic antimony is so far soluble in water that a serious error is caused if washed with hot water previously to weighing it as metal; a partial oxidation also takes place. If the washing is conducted in an atmosphere of hydrogen in presence of electrolytically deposited iron, the solution of the metal is prevented, but this takes from the method its great recommendation, namely, that the antimony is in a directly weighable condition, and necessitates the separation of the iron from the antimony.

As a reagent for the detection of arsenic, hypophosphorous acid will detect 0·05 milligram of arsenious anhydride in 5—10 c.c. of solution. If a small crystal of potassium iodide is added, the reaction becomes still more delicate, 0·025 milligram being detectable. Copper interferes with the reaction. In presence of bismuth and antimony, the precipitate is brought into solution by hydrochloric acid and bromine, omitting the potassium iodide from the reaction. In presence of iron, the solution must be excluded from the air.

In applying Marsh's apparatus to the detection of arsenic in presence of antimony, the author finds that if electrolytically deposited iron is used, no antimony hydride is formed, and this enables small quantities of arsenic to be detected in the presence of antimony, 0·015 milligram having been detected. If arsenic acid is precipitated in a slow current of hydrogen sulphide in the cold, arsenic trisulphide is formed; if the solution is hot, and the current of hydrogen sulphide is rapid, arsenic pentasulphide is precipitated

J. W. L.

Loss of Nitrogen in the Analysis of Guanidine and Biguanidine Compounds by Will and Varrentrapp's Method. By J. Freydl (*Monatsh.*, **11**, 120—128).—A series of experiments shows that the deficiency of nitrogen found in the analysis of guanidine and biguanidine compounds by the method of Will and Varrentrapp is mainly due to the oxidation of some of the ammonia formed (compare Makris, *Annalen*, **184**, 371). The presence of minute traces of cyanic acid in the soda-lime at the close of the operation also accounts for some slight loss of nitrogen.

G. T. M.

Detection of Nitrobenzene. By J. Morpurgo (*Chem. Centr.*, 1890, i, 879; from *Pharm. Post.*, **23**, 258—259).—For the detection of nitrobenzene in bitter almond oil, a specimen is warmed with manganese dioxide and sulphuric acid. Under these circumstances, nitrobenzene does not lose its odour, but after a time it smells of oil of cinnamon; bitter almond oil, on the contrary, develops a disagreeable odour at first, which soon disappears altogether.

In the case of liquors, soaps, &c., calcium hydroxide is added (in the case of a solution, after concentration), warmed, and after allowing to cool, the mass is extracted with ether, the ether distilled off, the residue treated with a little water, two drops of liquid phenol (10 pts. of water : 100 of crystallised phenol) three drops of water, and a piece of potash the size of a pea added, and the mixture warmed carefully. If nitrobenzene is present, a carmine ring forms on the edge of the liquid which becomes green on the addition of bleaching powder.

J. W. L.

Examination and Valuation of Spirituous Liquors. By W. Fresenius (*Zeit. anal. Chem.*, **29**, 283—317).—The problem of discriminating a genuine brandy, rum, or other spirituous beverage from an artificial product by chemical methods is beset with peculiar difficulties, both because no consensus of opinion exists as to a definition of a genuine spirit, and because, in the majority of cases, analysis is incompetent to distinguish between articles admitted on all hands to be genuine and those manufactured wholly from foreign ingredients. The author, being in possession of specimens of known character, has analysed them with the following results (p. 1195).

Of the cognacs, Nos. 2 and 3 were fine sorts 15 years old; 1, 4, and 5 were also fine brands, but somewhat younger; 6 and 7 still younger, and originally less alcoholic; 8 had been slightly coloured with caramel.

The rums were all Jamaica rums, but No. 4 had been mixed with one-sixth of pure spirit of wine.

Nos. 1 and 2 of the arracks were from Batavia, the latter mixed with one-sixth of refined spirit; No. 3 was from Sourabaya. Of the Kirschwasser samples, Nos. 1, 2, 3, 4, and 10 were distilled in 1887;

8 in 1886; 9 in 1885; 11 in 1883; 5 in 1885 and 1886, and mixed; 3, 4, 6, 7 and 11 were from black cherries; 8 partly from red. No. 12 was 1887 faints (last runnings).

The dark colour of rum was doubtless originally due to the spurting over of some of the still residue, but at the present time it is invariably produced by caramel. Since consumers would not accept it without the dark colour, the addition of caramel cannot be regarded as a falsification. The colouring and extractive matters of cognac are supposed to be wholly derived from the casks in which it is stored, and the quality of the wood for casks is of great importance. The best is that from Dantzig, Stettin, and Angoulême, as it contains the smallest quantity of bitter principles, and relatively considerable amounts of quercin and quercitrin, to the presence of which aroma and colour respectively are due. Since the absorption of these substances has come to be regarded as a mark of age, young brandy is now almost always slightly coloured by caramel, and a little sugar (generally under 1 per cent.) is added, such additions seeming to be approved by consumers. The presence of such small amounts of added matters in an otherwise genuine brandy cannot be regarded as sufficient to condemn it. But since at some Custom Houses a sweetened spirit is regarded as a liqueur, the practice has grown up of exporting separately the wine distillate and the sugar for sweetening it.

Another, not uncommon, addition is water, and within certain limits this is unavoidable, as the spirit obtained by distillation is often too strong for use. Since, however, spirits stored in wooden casks undergo a loss of alcohol, water is often added to young spirit to give it the appearance of age. More objectionable is the addition of both water and alcohol, but with the lower qualities of rum and arrack it must be regarded as almost the rule. Since these additions impoverish the aroma, it becomes necessary to intensify this by adding various essences, and from this to the manufacture of a wholly factitious product is but a step. The materials added to confer aroma are very various; on the one hand, cognac oil, obtained by the distillation of wine lees, is used, and on the other, ethereal oils and extracts of vanilla, carob pods, tea, almond shells, &c., some of which increase the extractive matters.

The definitions of genuine cognac by various authorities are not in accord; the author considers small additions of caramel and sugar to the wine distillate, with enough water to produce a drinkable spirit, to be admissible, but all beyond this to constitute falsification. With regard to the detection of these additions, that of *caramel*, when in notable quantity, is possible by Amthor's test with paraldehyde and phenylhydrazine (Abstr., 1885, 604); that of *sugar* is more doubtful, since substances reducing Fehling's solution are extracted from the wood of the casks. When, however, the amount exceeds 0·5 per cent., and the reduction is markedly increased by inversion, the presence of sugar may be assumed. The addition of *water* and *alcohol* can only be indirectly inferred from the enfeebling of the aroma, but genuine wine distillates sometimes possess a very feeble aroma. The comparative or total absence of furfuraldehyde is one of the best indications of the absence of the genuine distillate, since this always contains furfuraldehyde, whilst well distilled spirit does not. Little can be done in the detection of artificial aromas, both because few chemical methods are available, and because the nature of the aromatic substances present in genuine spirits is too little known. The author's opinion is that chemical analysis is not competent to decide as to the genuineness of cognac, rum, or arrack, but that the smell and taste, as judged by experts, are by far the best tests. The test relied on by the Custom House authorities, namely, the estimation of the extractive matters, the amount of which is assumed not to exceed 0·5 per cent. in genuine spirits, is highly fallacious, since in the majority of cases it fails to detect falsifications, whilst at the same time it would condemn the oldest and finest genuine products as adulterated.

The author has repeated his experiments made in 1887 on the increase in volume of chloroform when shaken with cognac, but finds his then conclusions not to be confirmed. The behaviour of different specimens of (so-called) pure spirit of wine is by no means uniform.

M. J. S.

Estimation of Starch in Fodder, &c. By A. Leclerc (*J. Pharm.* [5], 21, 641—645).—Weigh off 2 grams of powdered grain, or 5 grams of straw, hay, fæces, &c., place in a 200 c.c. flask, and add 10 c.c. of water. It is essential that the assay should be thoroughly moistened in every part. To the moistened mass add 180 c.c. of a neutral zinc chloride solution of sp. gr. 1·450, agitate, and heat in a salt-water bath at 108° for 1 to 1½ hours. In the case of grain, the heating can be stopped when the *débris* has been rendered soluble; for straw, the full 1½ hours should be taken. Cool and transfer to a 250 c.c. flask, making up the volume by the addition of zinc chloride solution; in the case of fibrous fodder, the volume is made up to 253 c.c., to compensate for the volume of the residue. Filter, and of the opalescent filtrate take, say, 25 c.c. in a 150 c.c. beaker, add 2 c.c. of hydrochloric acid to retain the zinc in solution, and then 75 c.c. of 90 per cent. alcohol, or 62 c.c. of 95 per cent. alcohol. Filter through a tared filter after 24 hours. The whole of the dextrin and starch are precipitated; the sugars remain in solution. The precipitate is washed, until free from zinc chloride, with a mixture of 1000 c.c. 90 per cent. alcohol and 5 c.c. of hydrochloric acid; the acid is then washed out with alcohol alone. A little mineral matter taken down by the starch is obtained as ash on burning the starch, and is deducted. A little nitrogenous matter is also present in the case of grain, which can be determined by estimation of the nitrogen. Thus in the quantities given, maize would yield about 1·5 to 2 milligrams of nitrogenous matter in the precipitate from 25 c.c. of solution, oats a little less, and straw not more than 0·5 milligram. The formation of a little dextrin is no inconvenience, as it has the same composition as the starch. The zinc chloride solution is prepared by treating hydrochloric acid with excess of zinc. The decanted solution is decolorised by the addition of a little concentrated potassium permanganate solution, boiled, and treated with zinc oxide as long as any dissolves; after cooling and filtering, the solution is ready for use. J. T.

Test for Aldehyde. By L. Crismer (*Zeit. anal. Chem.*, 29, 350—351).—Nessler's reagent is a delicate test for aldehyde and substances of aldehyde function, giving with them a yellowish precipitate, which gradually darkens through reddish-brown to black. It can be distinguished from the precipitate caused by ammonia by the addition of potassium cyanide, which dissolves the ammonia precipitate, but turns the aldehyde precipitate black. Ordinary ether and chloroform are always found to contain aldehyde, but can be completely purified therefrom by treatment with Nessler's reagent and distillation. Hydroxylamine salts also give black precipitates with Nessler's reagent. M. J. S.

Adulteration of Linseed Oil. By A. AIGNAN (*Compt. rend.*, **110**, 1273—1275).—Pure linseed oil has no rotatory power, but if mixed with resin oil it turns the plane of polarisation through an angle proportional to the quantity of the latter. If $[\alpha]_D$ represents the rotation observed with a column of oil 20 cm. long, and h the weight of resin oil in 100 parts of the mixture, then with *refined resin oil*, $[\alpha]_D = + 14/15h$; with *selected white resin oil*, $[\alpha]_D = + 17/15h$, and with *finest rectified resin oil*, $[\alpha]_D = + 21/15h$. The first variety is most commonly met with as an adulterant.

In order to detect resin oil in paint, the latter is extracted with ether, and the rotatory power of the ethereal solution measured in a column 20 cm. long. The proportion of resin oil is given by the formula $h = \frac{[\alpha]_D}{43'}$. A known weight, P_1, of the ethereal solution is heated at 100°, in order to expel the ether, and the residual oil, P_2, is weighed; then $P_1/P_2 \times 100 = h$, the total percentage of oil in the ethereal solution. If $h_1 = h$, only resin oil is present; in any other case, $h/h_1 \times 100$ gives the proportion of resin oil in 100 parts of the mixture (compare this vol., p. 422). C. H. B.

Estimation of Codeïne and Morphine. By E. CLAASSEN (*Chem. Centr.*, 1890, i, 741; from *Pharm. Rundschau*, 1890, 40).—The author utilises the precipitation of morphine by codeïne from solutions of its salts for the quantitative estimation of the former. (1.) The liquid containing free codeine is warmed with an excess of morphine sulphate, the liquid is frequently shaken, and the precipitated morphine collected at the end of 24 hours. Its weight, multiplied by 0·9868, gives the amount of anhydrous codeine; multiplied by 1·0462 gives the amount of codeïne + 1 mol. H_2O. If the codeine is present, either in the free state, or as a salt with or without the presence of morphine or its salts, the solution is evaporated to dryness with excess of magnesium oxide, the residue is stirred with hot water, and shaken in a flask with ether (free from alcohol); the ether is distilled from the extract, the residue extracted with hot water, filtered, and the codeïne determined in the solution as above described. It is well to wet with benzene the sides of the glass vessel in which the precipitation is conducted. (2.) If *only* free codeine is present in the solution, its quantity may be determined by boiling it with an excess of ammonium chloride, and collecting the free ammonia, which may be titrated. The amount of ammonia multiplied by 17·588 gives the amount of anhydrous codeine. (3.) In all other cases where a variety of substances may be present with the codeine and morphine, the solution is acidified with dilute sulphuric acid, evaporated to dryness with excess of magnesium oxide, the residue is extracted with strong alcohol, the latter distilled off, and the residue heated (as in "2") with excess of ammonium chloride. The liquid remaining in the flask is acidified and the morphine precipitated with a slight excess of ammonia. After filtering off the precipitated morphine, the ammonia is entirely evaporated from the filtrate, when a further small quantity of morphine separates. Finally the codeïne, which is in the filtrate as hydrochloride, may be determined according to (1). J. W. L.

Analysis of Urine. By K. Taniguti (*Zeit. physiol. Chem.*, **14**, 471—490).—Salkowski has proposed a method of estimating creatinine in urine which was compared in a series of experiments with the older method of Neubauer. The results are sometimes higher by the one, sometimes by the other method.

Creatinine can be detected in the urine after the ammoniacal fermentation has progressed for 61 days.

A substance is present in normal urine which yields acetone when the urine is distilled with sulphuric acid. At least 10 c.c. of concentrated sulphuric acid should be added to 300 c.c. of urine; if less than this amount of acid is used, all the acetone does not come off on distillation. The total distillate is made alkaline with sodium hydroxide; a solution of iodine in potassium iodide is added; and after 24 hours the precipitated iodoform is collected on a weighed filter, dried, and weighed. From the amount of iodoform so obtained, the quantity of acetone obtainable is calculated; various specimens of urine yielded from 0·01 to 0·02 gram of iodoform.

Further experiments confirmed Salkowski's statement (Abstr., 1889, 431) that volatile fatty acids are formed during the ammoniacal fermentation of urine. Quantitative results show that the fatty acids (chiefly acetic) increase with the intensity of the fermentation and the length of time for which it is allowed to occur.

The source of the acid is considered to be the carbohydrate of normal urine. Humous substances are considered by Udránszky (Abstr., 1888, 180) to have a similar origin, but the amount of humous substances does not increase with putrefaction, that is, as the carbohydrate disappears; moreover, the humous substances of stale urine have a different elementary composition from those of normal urine. Salkowski considers Udránszky to be wrong in this and other points. W. D. H.

Estimation of Albumin in Urine. By T. C. Van Nüys and R. E. Lyons (*Amer. Chem. J.*, **12**, 336—351).—The authors first estimate the total quantity of the nitrogen in the urine by Kjeldahl's method. The albumin is then precipitated by means of Almén's solution of tannin, the solution filtered, and the nitrogen determined in a measured quantity of the filtrate. The tannin should not be used in large excess. For ordinary quantities of albumin in urine, equal volumes of Almén's solution and of urine are sufficient; for small quantities, one volume of Almén's solution and two volumes of urine. If 2 per cent. or more of the albumin is present, the urine should be diluted with from one to two volumes of water before making the determination. To separate the albumin, 10 c.c. of the filtered urine is introduced with 10 c.c. of Almén's solution into a 50 c.c. flask, and, after mixing well, the liquid is filtered through a dry filter-paper into a dry beaker. 5 c.c. of this solution is subjected to the action of 10 c.c. of concentrated sulphuric acid, as in Kjeldahl's original method. To absorb the ammonia, 10 c.c. of

$\frac{1}{5}$ normal potassium hydroxide solution is employed. If the number of c.c. of $\frac{1}{5}$ normal potassium hydroxide solution employed in the two determinations be subtracted, and the difference multiplied by 0·0028 × 40 × 6·37, the product is the percentage of albumin contained in the urine.

The results of a number of analyses are given, and these show that the method is an exact one. It has, moreover, the advantage of giving the total nitrogen contained in the urine, which may be a matter of importance to the pathologist. G. T. M.

Detection of Carbonic Oxide Hæmoglobin. By A. WETZEL (*Chem. Centr.*, 1890, i, 738—739; from *Ver. phys. med. Gess. Wurzburg*, **23**).—The author recommends the following tests for carbonic oxide hæmoglobin:—10 c.c. of the blood, 15 c.c. of 20 per cent. potassium ferrocyanide solution, and 2 c.c. of acetic acid (1 vol. glacial acetic acid : 2 vols. water) are mixed, and shaken gently. Coagulation ensues, the mass gradually becoming solid. If normal blood only is present, it is dark-brown coloured: if it is carbonic oxide blood, the colour is light-red. In the latter case, the colour of the mass becomes gradually dark-brown at the top, this change proceeding gradually to the bottom. If only very little blood is at hand, it is diluted with 4 to 10 vols. of water, and to 10 c.c. of this, 5 c.c. of the potassium ferrocyanide, and 20 drops of the acetic acid are added.

A second test is:—the blood is diluted to 4 vols. with water, to which 3 vols. of 1 per cent. tannin solution is added, and the mixture shaken. At the end of 24 hours, normal blood has a grey colour, whilst carbonic oxide blood becomes carmine-red. This test is very delicate, and 0·0023 per cent. of carbonic oxide in the air was detected by its means.

The author finds that a blood containing 26·5 per cent. of carbonic oxide blood causes a single wide band in the spectrum. In order to apply this to the quantitative determination of carbonic oxide in blood, he dilutes a blood containing more than the above amount of carbonic oxide with normal blood until the band appears singly.

J. W. L.

Reactions of Carbonic Oxide Blood. By E. RICHTER (*Chem. Centr.*, 1890, i, 730; from *Deutsche med. Wochschr.*, **16**, 199).—The following three reactions are recommended by the author, all of which depend on the stability of carbonic oxide blood:—(1) 3 c.c. of this blood and of normal blood are diluted with 100 c.c. of water, and to 10 c.c. of the solution 2 c.c. of 2 per cent. grape-sugar solution is added, then 2 c.c. of lime-water, and the mixture warmed. (2) To the same diluted blood and 2 c.c. of sugar solution, barium carbonate is added, and the mixture warmed. (3) 5 c.c. of each blood is diluted to 200 c.c., 2 drops of yellow ammonium sulphide, and then 6 drops of 50 per cent. formic acid added. In all these tests, the carbonic oxide blood is not changed, whilst normal blood is discoloured. Tartaric, lactic, or phosphoric acid may be substituted for the formic acid in the last reaction. J. W. L.

ozone, or with ozonised water, oil, or air; neither chlorine nor hydrogen peroxide produces the phenomenon, nor do all waters; for instance, a deep well water and sea water did not, whilst river water did; moreover, boiling and filtering the water did not destroy the power of producing the phosphorescence. Some suggest oxidation of organic matter and organisms as the cause. D. A. L.

Electrical Conductivity of Solutions of Cadmium Salts. By F. J. Wershoven (*Zeit. physikal. Chem.*, 5, 481—525).—Solutions of cadmium chloride, bromide, iodide, nitrate, and sulphate, and potassium cadmium oxide were investigated by the author within wide limits of concentration and temperature. The temperature-coefficient of all the salts, except the iodide and double iodide, approximates at extreme dilutions to 2·3 per cent. per degree. In concentrated solutions, the variations of conductivity with the temperature may be expressed by a linear equation in the case of the chloride, iodide, and double iodide; the other salts require an equation of the second degree. Differences of as much as 10 per cent. sometimes appear between Grotrian's numbers and the conductivities found by the author; these the latter attributes to the "not quite perfect purity" of his preparations. A long discussion of the results with respect to molecular conductivity, the rate of transference of the ions, and the supposed complexity of the salt-molecules is entered on. The author concludes with Arrhenius that in cadmium nitrate the inactive molecules are not complex, but that in the other salts they are. Combined with Kohlrausch's values for the speed of migration of the anions Cl, Br, I, and NO_3, the numbers obtained for extreme dilutions give the following speeds of the cadmium ion:—49·2, 50·9, 49·3, 53·7; in the mean, 51. The speeds of other ions (bivalent metals) in the same units are: barium, 51; zinc, 51; magnesium, 53.

In the course of his experiments, the author found that a freshly-platinised platinum electrode, when dipped into a solution of potassium iodide, coloured the solution at first yellow, and, after a few minutes, pink. The coloration is due to platinum tetriodide dissolved in the solution of potassium iodide, and not in any way to iodine, as was proved by the addition of starch solution. The action seems to be $PtCl_4 + 4KI = PtI_4 + 4KCl$. It is not necessary that the electrode should have been previously immersed in a solution of platinum chloride; hydrochloric acid alone effects the reaction, which indeed may be used as a most delicate test for this acid, yielding results when silver nitrate gives no turbidity. For this purpose, the washed platinised electrode is dipped repeatedly into potassium iodide solution until it no longer gives the pink colour; it is then washed thoroughly with alcohol and water, allowed to remain for some time in the solution to be tested for hydrochloric acid, is again washed, and reimmersed in dilute potassium iodide solution. After some time, the pink colour appears. Chlorides, or hydrobromic and other acids, do not give the coloration. J. W.

Electrolysis of Various Substances. By P. L. Aslanoglou (*Chem. News*, 62, 42—43).—The current from six Fuller's mercury dichromate elements was passed through various solutions with the following results:—Water containing calcium, magnesium, barium, strontium, or zinc hydrogen carbonate yielded a deposit of the normal carbonate at the negative electrode, both oxygen and hydrogen being evolved in all cases. Ferrous carbonate remained unaltered under similar treatment, although the evolution of the gases was the same. Silver chloride dissolved in sodium thiosulphate gave a deposit of metallic silver and an odour of hydrogen sulphide with an evolution of hydrogen but no oxygen. Lead sulphate dissolved in ammonium tartrate deposited a black mass, smelling of ammonia, at the negative pole, while the positive pole and the liquid became yellow and both oxygen and hydrogen were evolved. D. A. L.

Amalgams. By M. Le Blanc (*Zeit. physikal. Chem.*, 5, 467—480).—This paper contains an investigation of the magnitude of the polarisation given by various amalgams in a solution of the corresponding chloride against zinc amalgam. The apparatus used included a large tuning-fork, which by its vibrations allowed measurements of the E.M.F. of polarisation to be made while the primary current was practically constantly flowing. The rate of fall of the polarisation after the primary current was interrupted gave a means of estimating the relative stability of the amalgams. Amongst those of the metals of the alkalis and alkaline earths, lithium and magnesium amalgams are the least stable. After the current from eight Leclanché cells had passed for ten minutes, the evolution of gas was in general feeble, but in the case of lithium and magnesium, it was comparatively lively. The author found that in a mixture of zinc chloride and hydrogen chloride solutions, zinc amalgam was formed at the negative pole, which would indicate that *atomic* hydrogen displaces zinc in its salts. The ammonium and alkylammonium amalgams are proved to have an actual existence, for the phenomena observed with solutions of the ammonium chlorides are quite comparable with those obtained when metallic chlorides are employed. These amalgams, however, are much less stable, as is seen by the relatively rapid falling-off of the E.M.F. of polarisation when the primary current ceases to flow. Besides ammonium, the author investigated methyl-, ethyl-, dimethyl-, diethyl-, trimethyl-, triethyl-, and tetramethyl-ammonium amalgams. Triethylammonium amalgam probably does not exist—it is at any rate extremely unstable; trimethyl- and diethyl-ammonium form amalgams scarcely less so. The formation of a mercury froth on electrolysis has hitherto been held as a good indication of the production of an amalgam, but it is pointed out by the author that in the case of ethylammonium there is no froth, and yet the electrical behaviour shows that a comparatively stable amalgam is formed. J. W.

Melting Points of Organic Compounds. By A. Reissert (*Ber.*, 23, 2239—2245).—The author has tried to ascertain under what conditions the melting point of a substance can be determined with constant results; his experiments in this direction were not successful, but it was found that, if in taking the melting point in a capillary tube the following three rules are observed, the errors of observation are considerably diminished.

(1.) The zero point of the thermometer should be determined from time to time, and the proper correction made if necessary.

(2.) The correction for the projecting thread must always be made, otherwise there may be a difference of several degrees between the melting points found by different observers; Rimbach's tables (this vol., p. 205) are convenient for this purpose.

(3.) The temperature at which the substance commences to melt should be noted and not that at which it is completely liquefied.

The corrected melting points of 24 pure substances, ranging from paraxylene (m. p. 13°) to anthraquinone (m. p. 284·65°) are given.

F. S. K.

Deductions from Van't Hoff's Theory. By S. PAGLIANI (*Gazzetta*, 19, 453—478; compare this vol., p. 845).—The author has calculated the value of i from Van't Hoff's equation

$$i = \frac{Q}{2t^2} \div \frac{2d \log C}{dt} \ldots\ldots\ldots (1),$$

for solutions at various temperatures and of different degrees of concentration of the salts K_2SO_4, $NaNO_3$, KCl, NH_4Cl, KNO_3, and NaCl. The figures obtained lead to the conclusion that the above equation is wanting in generality, the values of i diminishing with the increase of concentration contrary to the theory. If (1) were in general true, Q and $\frac{d \log c}{dt}$ would have the same sign; in other words, the solubility of a salt and its heat of dissolution at different temperatures would always vary in the same sense, a generalisation to which there are very numerous exceptions.

These discrepancies are probably due to the dependence of Van't Hoff's equation on the general laws of equilibrium in solutions, the second of which assumes that the transformation of one system into another takes place at constant volume, an assumption which does not hold in solutions of salts.

A comparison of (1) with the equation deduced from the diminution of the vapour tension of the solution of a salt, shows that if salts are considered to be in solution in the anhydrous state, Van't Hoff's equation is either in conflict with experimental results, or with Kirchhoff's theoretical deductions (*Ann. Phys. Chem.*, 1858, 194, and 1885, 24; Abstr., 862, 1885); the discrepancies may, however, be explained by assuming that the salts possess a different degree of hydration at different temperatures. Similarly, on comparing (1) with the equation $i = \frac{1}{18 \cdot 5} \frac{M\Delta}{p}$ (where M is the molecular weight, and Δ the depression of the freezing point produced by a quantity p in solution), it appears that, whereas i always diminishes with increase of concentration when calculated from the former equation, the value of $\frac{\Delta}{p}$ increases or diminishes with the concentration according to the nature of the salt; to reconcile the equations, it is necessary to suppose that M uniformly decreases with increasing concentration to an extent sufficient to render the variation of $\frac{\Delta}{p}$ insignificant.

The absorption of heat which in many cases takes place during dissolution, and which increases with the increase of dilution of the solution and with the diminution of the temperature of the solvent, just as the state of hydration of a salt is supposed to do, is explained by the author by the assumption that the quasi-aëriform condition in which, by Van't Hoff's theory, salts are supposed to exist in dilute solutions, necessitates the absorption of a certain quantity of heat of dilatation. S. B. A. A.

Thermal Behaviour of Cupric Chloride Solutions. By L. T. Reicher and C. M. van Deventer (*Zeit. physikal. Chem.*, 5, 559—565). Le Châtelier and Van't Hoff deduced as a necessary consequence of thermodynamics that when the heat of dissolution of a substance in its almost saturated solution was negative, the solubility would increase with increase of temperature; when positive, the solubility would diminish with rise of temperature. The salt $CuCl_2,2H_2O$ is one of the few which dissolve in much water with development of heat, and its temperature coefficient of solubility is positive. These facts, when taken in conjunction with the above principle, would point to curious behaviour of the salt with respect to the heat of dissolution in liquids of different concentration. The authors have investigated the matter experimentally, and find that in a saturated solution, the heat of dissolution is negative, as theory predicts. From observations of their own, and from data given by Thomsen as to the heat of dilution of cupric chloride solutions, they calculate that the heat of dissolution attains a maximum (at 11°) when the solvent has a strength of about 8 mols. of $CuCl_2,2H_2O$ to 198 mols. of H_2O. At this concentration, therefore, the salt would be dissolved without any thermal effect whatever, and direct experiment confirms this conclusion. The heat of dissolution becomes negative when the concentration is about 18 mols. of salt to 198 mols. of water. J. W.

Heat of Combustion and Constitution of Organic Compounds. By O. Dieffenbach (*Zeit. physikal. Chem.*, 5, 566—588). —The author subjects the heats of combustion of various organic compounds to an arithmetical investigation, and from his results seeks to draw conclusions as to the constitution of the substances in question. As the basis of calculation he assumes that the heat of combustion of a compound is additively made up of certain values which are constant for all compounds. Thus we have the heat of combustion of the "isolated" carbon-atom, of the hydrogen-atom attached to carbon, and of the various forms of linking between the carbon-atoms. All these constants may, from the experimental data, be expressed in terms of any one: the fatty single bond is chosen as the standard by the author. Reckoning in this way, he finds that what is left over for carbon linking in the benzene nucleus is equal to the thermal value of nine single bonds, and bears no simple relation to three single and three double bonds: he thus considers it highly probable that the six carbon-atoms in the benzene ring are connected by nine single bonds, and that Kekulé's formula is erroneous. Similarly, the heat of combustion of naphthalene would point to its ten carbon-atoms being connected by sixteen single bonds. The six carbon bonds in hexamethylene (hexahydrobenzene) appear to be ordinary fatty bonds; but the three in trimethylene are not so.

By making sundry more or less probable assumptions, the author endeavours to fix limits between which the value of his standard must lie, and comes to the conclusion that the value for the single bond must be greater than 15000 cal. and less than 48000 cal. Further, the relations between the various kinds of linking are found to be—

$$\begin{aligned} \text{double} &= 2 \text{ single} - 15193 \text{ cal.} \\ \text{triple} &= 3 \text{ single} - 3 \times 14952 \text{ cal.} \\ 2 \text{ trimethylene} &= 2 \text{ single} - 15286 \text{ cal.} \end{aligned}$$

The numerical terms in these equations are approximately multiples of 15000, so that the author thus thinks it probable that the absolute values of the constants are also multiples of such a number. That being the case, the only values which satisfy the limits he found above are—

$$\begin{aligned} \text{single} &= 30300 \text{ cal.} \\ \text{double} &= 45450 \text{ cal.} = \tfrac{3}{2} \text{ single} \\ \text{triple} &= 45450 \text{ cal.} = \tfrac{3}{2} \text{ single} \\ \text{trimethylene} &= 22725 \text{ cal.} = \tfrac{3}{4} \text{ single.} \end{aligned}$$

The thermal value of the double bond would thus be equal to that of the triple bond. Further, the heat of combustion of the "isolated" carbon-atom would be 166573 cal., and of the hydrogen-atom attached to carbon, 11039 cals. By the help of these values, the author calculates the heat of combustion of several compounds not used in obtaining the numbers, and finds a satisfactory agreement with direct experiment. J. W.

The "Dead Space" in Chemical Reactions. By O. LIEBREICH (*Zeit. physikal. Chem.*, 5, 529—558).—In a communication to the Royal Prussian Academy, the author pointed out that certain parts of the liquid in which a slow chemical transformation is going on exhibit either no reaction, or a diminished or delayed reaction. This peculiar region he terms the dead space, and in the present paper seeks to ascertain the cause of the phenomenon. For the purposes of experiment, the most useful reactions are the transformation in dilute aqueous solution of chloral into chloroform by means of sodium carbonate, and the reaction between iodic acid and sulphurous acid. In the first case, the extent of the reaction is rendered visible by the separation of chloroform; in the second case, by the liberation of iodine.

The dead space appears at the free surface of the liquid, and is easily visible to the naked eye; and in narrow spaces, capillary tubes for example, there is either retardation or entire prevention of the reaction, as may be seen when iodic and sulphurous acids are used along with starch solution. In somewhat wider tubes, a thin thread of blue appears in the last case along the axis. Some 40 figures are given in the paper to show the form of the dead space in vessels of various shapes.

The author proves conclusively that the dead space at the free surface is not due to evaporation, and is inclined to attribute the phenomenon to the physical influence of the walls and to the surface tension, there being a certain viscosity to hinder the reaction in these regions. This view receives support from the fact that the dead space diminishes in extent with rise of temperature. J. W.

Influence of Glass Surfaces on Velocity of Reaction. By Speranski (*Zeit. physikal. Chem.*, 5, 607—608).—The observation of Liebreich (preceding abstract), that the reaction between iodic and sulphurous acids did not take place when the mixture was poured into a vessel filled with glass beads, points to a possible source of error in the determination of many velocities of reaction. The author studied the influence of glass wool and glass beads on the rate of inversion of cane-sugar by hydrochloric acid. Glass wool produced a continuous diminution of the velocity-constant, but this was proved to proceed from interaction between the glass and the acid, the titre falling to about half its initial value in three days. Beads previously boiled in acid exerted not the slightest influence on the rate of inversion. J. W.

Isomorphism. Part II. By J. W. Retgers (*Zeit. physikal. Chem.*, 5, 436—466).—In a former paper (this vol., p. 328), the author studied the nitrates of the alkali metals and of silver. He now takes up and investigates in detail the corresponding chlorates, the method employed being, as before, a study of the specific gravities of the mixed crystals.

In the isodimorphous series [$AgClO_3 : NaClO_3$], crystals containing up to 18·2 per cent. of silver chlorate are regular; a break in the series then follows, after which crystals containing more than 71·5 per cent. of the silver salt are quadratic. Potassium and silver chlorates crystallise very sparingly with each other, the monoclinic potassium salt taking up only a small fraction of a per cent. of silver salt, which in its turn behaves similarly towards the former. A quadratic double salt, $KClO_3.AgClO_3$, is, however, formed when the simple salts are allowed to crystallise in molecular proportions. Sodium and potassium chlorates neither form a double salt, nor do they take up more than traces of each other when they crystallise from mixed solutions. The chlorates of ammonium, rubidium, cæsium, and thallium are all considered by the author to be monoclinic and isomorphous with potassium chlorate. Lithium chlorate is probably rhombic. A table is given comparing the nitrates, chlorates, bromates, and iodates of the above metals.

The author, in conclusion, criticises the value of identity of angle, parallel growth, &c., as criteria of isomorphism; and is of opinion that only a study of the capability in any given case to form mixed crystals can lead to definite and trustworthy results. J. W.

Freezing Point of Isomorphous Mixtures. By F. W. KÜSTER (*Zeit. physikal. Chem.*, 5, 601—606).—It is well known that Van't Hoff's law for the depression of the freezing point holds true only when the solvent separates out as such. If some of the dissolved substance crystallises along with the solvent on freezing, then the law is no longer applicable (Van't Hoff, this vol., p. 1044), but must be suitably altered. The author investigates a combination of substances which crystallise together in all proportions, namely, hexachlor-α-keto-γ-pentylene, C_5Cl_6O, and pentachlormonobrom-α-keto-γ-pentylene, C_5Cl_5BrO. Here the crystals which separate have the same composition as the liquid, and the freezing point may be calculated from the simple formula of mixing, that is, the curve of the freezing point tabulated against percentage composition of the mixture is a straight line joining the freezing points of the two pure substances. J. W.

Affinity-constants of Organic Acids. By H. G. BETHMANN (*Zeit. physikal. Chem.*, 5, 385—422).—In this paper we have a further contribution to the determination of the constants of affinity which have been shown by Ostwald (Abstr.. 1889, 818) to be so characteristic for the various organic acids. The author has measured the constants of over 40 additional substances. including substituted benzoic acids, the polycarboxylic acids of benzene, naphthoic and hydronaphthoic acids, many bibasic acids of the oxalic series, and one or two derivatives of pyridine and thiazole.

The alkyl substitution-products of succinic and glutaric acids are the subject of a special discussion from the point of view of the Van't Hoff-Wislicenus theory. The substitution of a hydrogen-atom by a methyl-group usually lowers the constant, but in succinic acid, &c., the opposite is the case. From a consideration of the numbers obtained by him for the different derivatives, the author is disposed to believe that the raising of the constant in such instances is due to approximation of the two carboxyl-groups, brought about by the introduction of the compound radicle. J. W.

Inorganic Chemistry.

Ammonia in Burnt Magnesium. By P. L. ASLANOGLOU (*Chem. News*, 62, 99).—Ammonia was observed in the magnesium hydroxide left behind after burning magnesium wire or dust in the air.

D. A. L.

Water of Crystallisation. By L. SCHNEIDER (*Monatsh.*, 11, 166—178).—In his investigations, the author considers, as water of crystallisation, only that water which is directly taken up by the anhydrous salt, and which can be driven off on heating the compound. Supposing the density of the anhydrous salt to remain constant when in combination, it appears that water, existing as water of crystallisation, has a constant density of either $\frac{6}{5}$ or $\frac{4}{3}$. The former number obtains in the case of the following compounds:—$NaBr,2H_2O$; $BaCl_2,2H_2O$; $SrCl_2,6H_2O$; $Na_2CO_3,10H_2O$; $2NaOH,7H_2O$; $CaSO_4,2H_2O$; $Al_2(SO_4)_3,18H_2O$; $Na_2B_4O_7,5H_2O$; $Ca(NO_3)_2,4H_2O$; $K_2Al_2(SO_4)_4,24H_2O$; $(NH_4)_2Al_2(SO_4)_4,24H_2O$; $Na_2Al_2(SO_4)_4,24H_2O$; $HBr,5H_2O$; $KClO_3,2H_2O$; $BaCl_2,4H_2O$, and others; the latter in that of ferrous, copper, zinc, magnesium, and manganese sulphates. In the case of the monohydrate of sulphuric acid, H_2SO_4,H_2O, the molecule of water has a density of $\frac{4}{3}$; the second molecule existing in the hydrate $H_2SO_4,2H_2O$ has a density of $\frac{6}{5}$.

The density of an aqueous solution of a salt is dependent on the following factors:—(1) the quantity of anhydrous salt in solution; (2) the quantity of the combined water; (3) the quantity of uncombined water having a density 1. Knowing the density of the anhydrous salt, and which of the expressions $\frac{6}{5}$ and $\frac{4}{3}$ represents the density of the combined water, the density of an aqueous solution of any strength can be readily calculated. The paper contains a series of tables, which show how very closely the numbers obtained by such calculations agree with those found by observation. G. T. M.

Action of Arseniuretted Hydrogen on Potassium Permanganate. By D. TIVOLI (*Gazzetta*, 19, 630—632).—When a current of pure arseniuretted hydrogen is passed into a dilute solution of potassium permanganate, a brown precipitate is formed, the liquid after a time becoming clear and colourless. The following reactions take place:—(1) $AsH_3 + 2KMnO_4 = K_2HAsO_4 + Mn_2O_3 + H_2O$; (2) $AsH_3 + 2KMnO_4 = K_2HAsO_3 + 2MnO_2 + H_2O$. The first reaction is the principal one, the solution containing potassium arsenate and only small quantities of arsenite; part of the arsenate is mechanically retained by the precipitate. The latter consists of hydrated sesquioxide of manganese mixed with small and variable quantities of the hydrated peroxide. S. B. A. A.

Note on the Diamond. By A. KRAUSE (*Ber.*, 23, 2409—2412).—Diamond splinters were burnt in a current of oxygen, the products of combustion absorbed by ammonia, and the ammoniacal solution decomposed with pure sodium hydroxide. A comparison of the crystals obtained on evaporation with those of pure sodium carbonate, showed that they had the same percentage of water of crystallisation, and that they were identical in crystalline form, optical properties, melting point, electrical conductivity, and solubility in water. The author concludes that the diamond must be chemically identical with carbon, since not only is the atomic weight the same, but on oxidation they both yield exactly the same product. J. B. T.

Potassium Tetrathionate and Pentathionate. By A. FOCK and K. KLÜSS (*Ber.*, 23, 2428—2432).—The authors have examined the crystals to which Rammelsberg gave the formula $K_2S_5O_6$, and find them to be really potassium tetrathionate, $K_2S_4O_6$, and they suggest that the analysis which Rammelsberg published was made with a different and impure preparation. The compounds described by Lewis (Trans., 1881, 68, and 1882, 300) and Shaw (Trans., 1883,

357) are really potassium pentathionate, $2K_2S_5O_6 + 3H_2O$, not $K_2S_5O_6 + H_2O$, as the latter states; there is therefore only *one* potassium pentathionate. Potassium tetrathionate crystallises in peculiar hemimorphous or hemihedral forms belonging to the monosymmetric system, not to the rhombic system as stated in Shaw's paper. Potassium pentathionate crystallises in thick prisms and in flat plates, both forms belonging to the rhombic system. J. B. T.

Copper Oxysulphides. By T. Cliche (*Arch. Pharm.*, **228**, 374—414).—The action of ammoniacal copper oxide solution on cupric sulphide when hot, as in the volumetric estimation of copper by (standard) sodium sulphide solution, does not add oxygen to the sulphide, but removes sulphur; the sulphide is partially or completely converted into cuprous sulphide, and the conversion is the more complete the higher the temperature and the more concentrated the oxide solution; both temperature and state of concentration affect the result in a marked manner. The cuprous sulphide is not further attacked. The sulphur removed is oxidised to sulphuric acid, whilst the cupric oxide in solution is reduced to cuprous oxide; the filtrate consequently always contains sulphuric acid when the cupric oxide solution has been prepared either from chloride, nitrate, or acetate. In neutral or acid solutions, the same reaction takes place, but the oxide does not yield up oxygen; the copper solution only acts as a carrier of oxygen from the air. The products of the action of the oxide solution on the sulphide are not oxysulphides, but compounds or mixtures of cupric and cuprous sulphide, and sulphate is always present, due to the easy oxidation of the cupric sulphide, except in the case when cuprous sulphide alone is formed. The water of crystallisation and the combined oxygen of the sulphate are reckoned as oxygen; the compound is considered to be an oxysulphide. The action of concentrated sulphuric acid on metallic copper yields sulphurous anhydride and cupric sulphate, but does not produce oxysulphide, but only cuprous sulphide, so long as any metallic copper is present. This sulphide first appears brown, and then black; it does not oxidise in the air, or only very slightly. When the whole of the metallic copper has dissolved, cupric sulphide is produced by the action of sulphuric acid on the cuprous sulphide, and the newly formed compound is attacked in turn with the separation of free sulphur, the two reactions proceeding simultaneously. The sulphur thus set free is insoluble in carbon bisulphide, and can reproduce cupric sulphide on heating cuprous sulphide with it. J. T.

New Ammoniacal Mercury Compounds, and a New Reaction for Mercurammonium Compounds. By L. Pesci (*Gazzetta*, **19**, 509—526).—On adding ammonia to a solution of mercuric bromide, a flocculent, light-yellow precipitate is slowly formed; this substance is probably analogous to "infusible white precipitate," Hg_2NCl,NH_4Cl, but its composition cannot be definitely ascertained, as it continually loses ammonium bromide when washed with cold water. By treatment with boiling water, it becomes orange-yellow, loses bromine, and its composition gradually approximates to Hg_2NBr.

When an aqueous solution of mercuric bromide is treated with excess of ammonium carbonate, a heavy, white precipitate of needles is formed which readily loses ammonium bromide when treated with water, being converted into the preceding yellow compound. When treated with warm potash or soda, it loses ammonia, and is transformed into mercurammonium bromide, Hg_2NBr. After purification by washing with a dilute solution of ammonium carbonate and drying over sulphuric acid, its composition was $4Hg_2NBr,5NH_4Br$. It is readily soluble in cold hydrochloric acid, but is insoluble in nitric acid; it dissolves in warm, dilute, sulphuric acid (10 per cent), but mercuric bromide crystallises out on cooling; it also dissolves in ammonium chloride, bromide, or iodide with evolution of ammonia. At an elevated temperature, it decomposes without melting.

Mercurammonium bromide, Hg_2NBr, obtained by the decomposition of the preceding compound with potash or soda, or by treating Millon's base with dilute hydrobromic acid, is a pale, orange-yellow, anhydrous powder readily soluble in dilute hydrochloric acid, but insoluble in water and in nitric or sulphuric acids. It behaves like the preceding compound with ammonium chloride, bromide, or iodide. It decomposes on heating without previous fusion, giving off small quantities of ammonia, and forming a sublimate consisting principally of metallic mercury.

When either mercurammonium bromide or the compound $4Hg_2NBr,5NH_4Br$ is treated with a boiling solution of ammonium bromide and filtered after a short contact, the filtrate deposits, on cooling, colourless, microscopic crystals of the composition $Hg_2NBr,3NH_4Br$. The same compound is obtained on adding dilute ammonia to a solution of mercuric bromide in ammonium bromide, or by mixing alcoholic solutions of mercuric bromide and ammonia; in the latter case, however, the product is amorphous. It is decomposed by water, but not by alcohol. It melts at 180° with evolution of ammonia, whilst at a higher temperature a white powder and drops of a yellow liquid are sublimed. It is readily soluble in hydrochloric acid; it also dissolves in hot dilute sulphuric acid, but mercuric bromide separates on cooling; it slowly dissolves in ammonium chloride, bromide, or iodide with evolution of ammonia. It is decomposed by potash or soda with the formation of mercurammonium bromide and ammonia.

The presence of the mercurammonium radicle, Hg_2N, may generally be ascertained by the resistance of its salts to the action of potash or soda and by their decomposition by sodium sulphide; in double salts of mercurammonium and ammonium, the ammonium salt is split off and decomposed by alkalis, and the mercurammonium salt may then be detected by sodium sulphide. As, however, some double salts of mercury and ammonium (for example, $HgCl_2,NH_4Cl$, $HgCl_2,2NH_4Cl$. $HgCl_2,2NH_4I$, &c.) are converted into mercurammonium compounds by treatment with alkalis, the presence of the radicle in the original compound cannot always be determined by this method.

The evolution of ammonia by mercurammonium compounds when treated with ammonium bromide affords a ready means of detecting the radicle; the ammonia may be quantitatively determined by allowing the reaction to proceed for about 48 hours in a closed bell-jar in presence of a definite quantity of oxalic acid. When neutral mercurammonium salts are treated in this way, one-fourth of the evolved ammonia proceeds from the radicle, the reaction which takes place being represented by the equation $Hg_2NX + 3NH_4X = 2HgX_2 + 4NH_3$. The residual solution contains a double salt of mercury and ammonia, which is reconverted into a mercurammonium salt on the addition of ammonia. S. B. A. A.

Cobalt and Nickel Oxides. By G. SCHRODER (*Chem. Centr.*, 1890, i, 931—932, *Inaugural Dissertation*).—The author finds that if the cobalt oxide, Co_3O_5, obtained by treating a solution of a cobalt salt with potassium hypochlorite or hypobromite, is heated to boiling in the liquid, oxides varying in composition from Co_3O_5 to Co_2O_3 are formed, and that the same oxides are produced if the solution of the cobalt salt is first treated with bromine and then with potassium hydroxide.

Since the higher oxide, Co_3O_5, is more readily washed than the cobaltic oxide, Co_2O_3, it is recommended to precipitate cobalt as the higher oxide for the purpose of quantitative analysis. If solutions of salts of nickel are treated in the manner described above, nickel oxide, Ni_2O_3, is the only product. If, on the other hand, potassium hydroxide and, afterwards, bromine are added to the nickel solution, a lower oxide, Ni_5O_7, having a formula between Ni_2O_3 and NiO, is formed. The oxides Ni_5O_7, Ni_2O_3 lose oxygen when boiled in potash solution, and form oxides of an indefinite constitution. J. W. L.

Constitution of the Cobalt, Chromium, and Rhodium Bases. By S. M. JÖRGENSEN (*J. pr. Chem.* [2], **42**, 206—221).—The compound described by Fremy and Cleve as chlorotetraminechromic chloride, $(Cr,4NH_3)Cl_3,H_2O$, is best prepared in the manner previously described by the author (Abstr., 1880, 10). To the mixed solution of chlorotetramine- and chloropurpureo-chromic chloride obtained as there stated, ammonium sulphate is added, the precipitated chlorotetraminechromic sulphate washed with water, and reconverted into the chloride by mixing with moderately concentrated hydrochloric acid. To free this compound from sulphuric acid, it is dissolved in water and filtered, and the filtrate allowed to fall into moderately concentrated hydrochloric acid. Its molecular weight, found by Raoult's method, agrees, as previously stated (this vol., p. 953), with the simple empirical formula given above. In its general behaviour, it strongly resembles the purpureo-compounds, and it is therefore probable that, as in these compounds, one of the chlorine-atoms is combined with the metal. That this is really the case is shown by the fact that only two-thirds of the chlorine is immediately precipitated by silver nitrate in candle light. The composition of the salts described below is also in agreement with this supposition, as is also the fact that the platinochloride contains only one atom of platinum for every chlorine-atom in the molecule.

Chlorotetraminechromic nitrate, $Cl(Cr,4NH_3)2NO_3,H_2O$, is prepared by the addition of nitric acid to a solution of the chloride. It is a beautiful, almost carmine-red salt, and at 100° undergoes a remarkable change, assuming a deep-black colour, and dissolving in water forming a bluish-black solution. In this it differs from the otherwise similar chloropurpureochromic nitrate. The corresponding *bromide*, $Cl(Cr,4NH_3)Br_2,H_2O$, is a violet-red precipitate.

A cobaltammonium chloride of similar composition has been also obtained by Vortmann (Abstr., 1883, 25, this vol., p. 14), and a careful comparison of both compounds has shown that they closely correspond with one another in all their properties, and the author, therefore, terms Vortmann's compound *chlorotetraminecobalt chloride*, $Cl(Co,4NH_3,H_2O)Cl_2$. It was prepared according to the method given by Vortmann, and purified in a manner similar to that given for the chromium salt. It forms a violet, crystalline powder, scarcely distinguishable from chloropurpureocobalt chloride, and soluble in 40 parts of water at the ordinary temperature. Its molecular weight, as found by Raoult's method, agrees with the formula given above. Silver nitrate only precipitates two-thirds of the chlorine in the cold, and sulphuric acid drives off two-thirds of the chlorine as hydrogen chloride, forming the *sulphate* $Cl(Co,4NH_3,H_2O)SO_4$, which crystallises in rhombic tablets, and is isomorphous with the corresponding chromium salt. The *platinochloride*, $Cl(Co,4NH_3,H_2O)PtCl_6,2H_2O$, only contains one atom of platinum for every atom of chlorine present, and crystallises in brown needles which have a silky lustre, and lose their water of crystallisation at 100° or over sulphuric acid. The *bromide*, $Cl(Co,4NH_3,H_2O)Br_2$, is a bluish-violet, crystalline precipitate more soluble than the chloride. The *chromate*, $Cl(Co,4NH_3,H_2O)CrO_4$, forms a greenish-brown precipitate, soluble in cold water with an olive-green colour.

The foregoing description shows that these two chlorotetramine-salts correspond in their composition and general properties with the chloropurpureo-salts, but differ from them in containing $1H_2O$ in place of $1 NH_3$.

$$\begin{array}{ll} Cl(Cr,4NH_3,H_2O)Cl_2. & Cl(Co,4NH_3,H_2O)Cl_2. \\ Cl(Cr,4NH_3,NH_3)Cl_2. & Cl(Co,4NH_3,NH_3)Cl_2. \end{array}$$

The chlorides of both series are isomorphous, and appear to have approximately the same molecular volume. The characteristic fluosilicates of these compounds also form crystals, the difference in the angles of which is very slight. There can, therefore, be no doubt that the first series contain a bivalent radicle isomeric with water in place of NH_3. In confirmation of this it is found that when chlorotetraminecobalt chloride is heated on the water-bath, first with ammonia and then with an excess of hydrochloric acid, it is converted into chloropurpureocobalt chloride. On the other hand, the latter compound, when treated with silver carbonate, yields the roseochloride, the solution of which is converted, on evaporation on the water-bath, into chlorotetraminecobalt chloride. Vortmann has shown that the latter readily passes into the praseochloride, and *vice versâ*.

For the tetramine salts, the author proposes the constitutional formula 
$$R'''\left\langle\begin{matrix}Cl\\ OH_2\cdot Cl\\ NH_3\cdot NH_3\cdot NH_3\cdot NH_3\cdot Cl\end{matrix}\right.$$

, corresponding with those already given for the chloropurpureo- and chloropraseo-salts (*J. pr. Chem.* [2], **41**, 437). The formation of these salts also emphasises the author's previous statement that one of the NH_3-groups in the purpureo-salts is less firmly combined than the remaining four.

H. G. C.

Cryoscopic Investigations of Colloïds. By A. SABANÉEFF (*J. Russ. Chem. Soc.*, **21**, 515—525).—The author has studied the application to some colloïdal substances of Raoult's method of determining the molecular weight from the depression of the freezing point.

Colloïdal tungstic acid was prepared by Graham's method by dialysing a weak hydrochloric acid solution of sodium tungstate. On evaporating the dialysed solution on the water-bath or in a vacuum over sulphuric acid, an amorphous, transparent substance was obtained, the composition of which, after drying at 200°, corresponded with the formula $3WO_3,H_2O$. The depression was identical for both kinds of preparations. The numbers obtained with solutions containing 1·2—100 parts of the acid in 100 parts of water varied from 0·035—1·910°, from which the value 679—995 was calculated as the molecular weight, that of $3WO_3,H_2O$ being = 714. Colloïdal tungstic acid is therefore tritungstic acid.

Colloïdal molybdic acid was prepared in the same manner as the foregoing. After evaporation of the dialysed solution in a vacuum over sulphuric acid, it is left as transparent, hygroscopic, gum-like crusts, soluble in water without change, but on heating the solution a white precipitate separates, and on evaporating to dryness an insoluble residue is left. Immediately after preparation, the salt contains 11·2 per cent. of water; after drying for several weeks over sulphuric acid, only 6·92 per cent. With the time of drying, the solubility of molybdic acid in water is found to decrease, and after some time it becomes insoluble. The depression of the freezing point for solutions containing 1·6—5·1 parts in 100 parts of water gives M = 608—631, the number calculated for $(MO_3)_4$ being 576.

Glycogen.—A very pure preparation was used. For solutions containing 4·06—8·29 parts in 100 parts of water, a depression of 0·050—0·095 was found, giving M = 1545—1625. The molecular weight $(C_6H_{10}O_5)_{10}$ = 1620. The effect of fermentation of glycogen shows that the molecule must be double, $C_6H_{10}O_5$, whilst the action of dilute sulphuric acid (Shtcherbakoff) shows that its true formula is five times larger than the empirical one. On heating at 115°, glycogen loses 3·58 per cent. of its weight, and on dissolving the residue in water and determining the depression of the freezing point, values were obtained for the molecular formula which are 1½ times smaller than the above, pointing probably to the existence of several modifications.

Silicic Acid.—On dialysing a weak solution of hydrochloric acid to which one of pure sodium silicate was added, solutions containing up to 37 per cent. of silicic acid were obtained by boiling down the solution in a flask, whereas the solution of maximum concentration obtained or Graham's method, containing 14 per cent., was found to be very unstable. The depression of the freezing point of solutions, purified by repeated addition of hydrochloric acid and dialysis, was found to be about 0·002°, that is, smaller than the possible experimental error. It shows that the molecular weight of silica is extremely high. Assuming that the depression lies between 0·005° and 0·0025°, and that silica is a polymeride, $(SiO_2)_n$, the value of n will lie between 800 and 1600.

Colloidal Ferric Hydrate.—On dialysing a solution of pure ferric hydroxide in a small quantity of hydrochloric acid, a solution is obtained, containing, even after weeks, some hydrochloric acid. The purest preparations obtained in this way were found to correspond with the composition $Fe_2Cl_6,116Fe_2(OH)_6$. The freezing-point depression of solutions containing $16Fe_2(OH)_6$ for $1Fe_2Cl_6$ was found to be 0·065°. and with increasing number of molecules of hydroxide, the depression was found to diminish, as shown in a tabular arrangement, down to the proportion $Fe_2Cl_6,116Fe_2(OH)_6$, when it was found to be inappreciable. From this it follows, that the hydroxide alone causes no depression, but that the effect is due to the chloride only, and that the molecular weight of the hydroxide in solution is extremely large. On assuming, therefore, that the depression is due only to the presence of the chloride, and recalculating the values accordingly, values were obtained for the molecular weight of the chloride varying between 270 and 342. The molecular weight of Fe_2Cl_6 = 325. The depression of 1 gram of substance in 100 parts of water for ferric chloride is, according to Raoult, = 0·356°, therefore six times larger than the normal value, 0·0584°, obtained by the author. Raoult's large value is due to a dissociation of ferric chloride in aqueous solution, and in the above case, in the presence of a large amount of ferric hydroxide, that is, one of the products of dissociation, scarcely any dissociation takes place. It is interesting to note that the electrical conductivity decreases with the decreasing amount of ferric chloride present, so that the author concludes that pure ferric hydroxide in aqueous solution does not conduct.

Egg albumin, purified by Michailoff's method, shows, in aqueous solution, an appreciable lowering of temperature. A solution of 15·6 parts in 100 parts of water shows a depression of 0·02°, from which it follows that the molecular weight is about 15,000.

Referring to Lubavin's experiments (this vol., p. 685), the author has subjected his solutions to the temperature of −20° for at least one hour, until they became perfectly solid. No coagulation of tungstic or molybdic acid, of glycogen, or albumin occurred, and complete solution took place after fusion. A solution of silica treated in the same manner yielded the greater part of the silica in the insoluble state. The author concludes by remarking that his experiments were carried out before the publication of the interesting researches of Morris and Brown. B. B.

Composition of Some Metallic Sulphides obtained in the Wet Way, and Reactions of the Sulphide of Gold, Au_2S_3. By W. Antony and A. Lucchesi (*Gazzetta*, **19**, 545—562).—To decide whether lead, copper, bismuth, antimony, and gold are precipitated from their solutions by sulphuretted hydrogen as sulphides, or as hydrosulphides, a series of experiments were made, the filtration being conducted under a bell jar, through which a current of hydrogen sulphide was continually passing; boiled water saturated with the gas was used for washing, and was brought on to the precipitate by means of a tube passing through the stopper of the bell jar. The washed precipitate was quickly pressed between filter paper and dried in a current of perfectly pure nitrogen, the temperature being gradually raised to 120—130°, and the issuing gas led through a solution of silver nitrate; the dried sulphide was then analysed. Under these circumstances, the lead precipitate has the composition PbS, the bismuth precipitate, Bi_2S_3; the precipitate from tartar emetic is Sb_2S_3, and that obtained by adding excess of hydrochloric acid to a freshly prepared solution of sodium thioantimonate is Sb_2S_5; the copper precipitate obtained at the ordinary temperature could not be properly washed in the apparatus, but when prepared at 0°, and washed by decantation with sulphuretted hydrogen water at 0° until the precipitate was sufficiently compact for treatment, its composition was found to be CuS.

Dilute solutions of gold (1 per cent.) treated at 90—100° with a current of hydrogen sulphide give a precipitate of pure gold; dilute solutions (1—3 per cent.) treated in the same way at the ordinary temperature (about 8°) yield a black precipitate of Au_2S_2. The temperature of the solution continually rises during the precipitation proportionately to the strength of the solution, and if at any time the temperature approaches 40°, metallic gold is precipitated along with the sulphide. If the solution is not fully precipitated, and the sulphide is allowed to remain in contact with the solution of auric chloride, these salts react according to the equation $4AuCl_3 + 2Au_2S_3 + 8H_2O = 6Au + 12HCl + 2H_2SO_4$, metallic gold being formed. From solutions of aurous sodium thiosulphate, hydrogen sulphide precipitates mixtures of gold, sulphur, and aurous sulphide, which always vary in composition; the action of auric chloride on these solutions is as described by Fordos and Gélis (*Ann. Chim. Pharm.* [3], **13**, 394), the liquid being at first coloured reddish-brown, owing to the formation of a soluble compound rich in gold; but after adding a few drops of the reagent, a precipitate of Au_2S_3 is formed; this is again decomposed by an excess of auric chloride, in accordance with the equation given. When auric chloride is added to potassium or sodium hydrosulphides, Au_2S_2 is formed, and dissolves in excess of the reagent; with ammonium hydrosulphide, however, the precipitate of Au_2S_2 at first formed is immediately deprived of its sulphur and reduced to metallic gold. When aurous sulphide is left in contact with either colourless or yellow ammonium sulphide, it is similarly reduced. S. B. A. A.

A New Anhydrous Double Chloride of Gold and Potassium.

By A. LAINER (*Monatsh.*, **11**, 220—223).—The author has obtained a compound having the formula $AuCl_3,KCl$, by dissolving gold in aqua-regia, and adding the molecular proportion of potassium chloride dissolved in a little water. After sufficient concentration of the solution over quick-lime and over sulphuric acid, crystallisation commenced, and a deposit of glistening, yellow needles was obtained, which remained unchanged on exposure to the air. The crystallographic measurements of these needles correspond exactly with those of crystals obtained by Topsöe (*Monatsh.*, 1874, 265), and to which he attributed the formula $2(AuCl_3,KCl) + H_2O$. G. T. M.

Platososemiamine Chloride, an Isomeride of Magnus' Salt. By A. Cossa (*Ber.*, 23, 2503—2509).—By the action of a boiling solution of ammonium nitrate on Magnus' salt a mixture is obtained, consisting of platosamine chloride, platinodiamine chloronitrate (Gros), and a compound isomeric with Magnus' salt. It is insoluble in alcohol; 100 parts of water dissolve 0·34 part at 17°, and 1·82 parts at 100°; it crystallises from water in yellow, lustrous plates, of sp. gr. 3·61. On boiling with excess of ammonia, platosodiamine chloride is formed, whilst with oxidising agents it yields platinodiamine chloride. The author regards the substance as a compound of 1 mol. of platosodiamine chloride and 2 mols. of the chloride of a new base (platinosemiamine) $PtCl·NH_3Cl$. The *potassiochloride* of this base, $Pt(NH_3)Cl_2,KCl,H_2O$, is readily soluble in water, and yields the isomeride of Magnus' salt on treatment with platosodiamine chloride. The isomeride is also formed by the addition of ammonia to platinous chloride, and by its elimination from platososemiamine chloride. J. B. T.

Organic Chemistry.

Geometrical Isomerism of the Bromo-derivatives of Pseudobutylene. By A. Favorsky and C. Debout (*J. pr. Chem.* [2], 42, 149—155).—In this paper the authors show that Wislicenus and Hölz, in their work on the brominated derivatives of pseudobutylene (Abstr., 1889, 576), were dealing with a mixture of butylenes, and therefore with a mixture of derivatives, not with geometrical isomerides. Their theoretical conclusions, consequently, are unsound. A. G. B.

Hexadecylene Bromide Derivatives. By F. Krafft and L. Grosjean (*Ber.*, 23, 2352—2356).—Pure hexadecylene bromide is prepared by treating a carbon bisulphide solution of pure hexadecylene with the calculated quantity of bromine dissolved in the same medium; the partially purified hydrocarbon from spermaceti may also be emyloyed. The bromide boils at 225—227° at 15 mm. without decomposition. *Diacetylhexadecylene*, $C_{16}H_{32}(OAc)_2$, is obtained by boiling pure hexadecylene bromide with glacial acetic acid for 5—6 hours, the excess of acid is evaporated under reduced pressure, the residue dissolved in alcohol, and precipitated with water; it crystallises in colourless plates, melting at 55—56°. *Hexadecylene glycol*, $C_{16}H_{31}(OH)_2$, is prepared by boiling the diacetyl-derivative with alcoholic potash; the product is poured into cold water, and the precipitated glycol purified by recrystallisation from alcohol; it melts at 72—73°, and, in small quantities, boils unchanged at 210—211° under a pressure of 9 mm., and 220—221° at 15 mm. *Hexadecylenedicarboxylic anhydride*, $C_{18}H_{32}O_3$, is formed by treating hexadecylene bromide with potassium cyanide, and hydrolysing the product with alcoholic potash; it melts at 73—75°, and boils at 245—248° at 15 mm. *Hexadecylenedicarboxylic acid*, $C_{16}H_{31}(CO{\cdot}OH)_2$, is obtained by dissolving the anhydride in dilute ammonia, and precipitating with dilute hydrochloric acid; it melts at 121°, and is converted into the anhydride. The *silver salt* is crystalline.

J. B. T.

The Two Diiodides of Acetylene. By E. PATERNÒ and A. PERATONER (*Gazzetta* 19, 580—601).—The existence of two isomeric symmetrical diiodoethylenes, CHI:CHI, is a point of some importance in the theory of isomerism in space, and has hitherto been taken as established by Sabanéeff's experiments (*Annalen*, **178**, 122): the authors have now re-investigated the subject. By passing acetylene over iodine in presence of absolute alcohol with frequent agitation, Sabanéeff obtained a solid iodide crystallising in needles, melting at 73°, and boiling at 192°, a liquid compound solidifying below 0°, and a small quantity of another very volatile iodide. On repeating these experiments, the authors obtained a large quantity of the solid iodide together with a very small quantity of an impure liquid product. When the reaction takes place in an acetic acid solution (instead of in alcohol), nothing but the solid iodide is formed; on the other hand, in presence of an excess of iodic acid, the product consists mainly of the liquid iodide, a small quantity of moniodacetylene, C_2HI, being also formed; the latter is also obtained in minute quantities in the other methods of preparing the iodides. The iodide is a heavy liquid with a pleasant, ethereal odour, boils at 29—32°, and does not solidify in a mixture of ice and salt. On heating it in a closed vessel above its boiling point, it decomposes with a slight explosion into carbon and hydrogen iodide. It combines with cuprous chloride forming a red, flocculent compound analogous to copper acetylide. In an acetic acid solution, it readily combines with hydriodic acid to form the solid diiodide; this crystallises in large colourless needles which cannot be powdered on account of their ductility. It melts at 71° and volatilises in a current of steam, but, contrary to Plimpton's statement (Trans., 1882, 392), it is largely decomposed when distilled under the ordinary pressure.

The liquid iodide cannot be obtained pure on account of its instability; the analyses are very discrepant but point towards a formula $C_4H_4I_2$; the crude product is always discoloured by iodine, and when decolorised by washing with potash it soon turns yellow or reddish-brown again. It has a pleasant odour recalling that of violets; it is insoluble in water, but dissolves in alcohol, ether, benzene, and acetic acid; it is an excellent solvent for the solid iodide. It undergoes some change when merely heated on the water-bath; it boils with decomposition at 160—165°, and is converted into the solid iodide by distillation in a current of steam under reduced pressure; when heated for several hours with water in a reflux apparatus, the products consist of the solid iodide, iodine, and hydriodic acid. It does not solidify at a few degrees below 0° as affirmed by Sabanéeff, but remains liquid even at —18°. Sabanéeff's liquid iodide appears to have been a solution of the solid in the liquid iodide.

When the solid iodide is heated with mercuric chloride (2 parts) and alcohol at 180—190° for 8—10 hours, and the product is steam-distilled, acetylene chloriodide, CH_2ICl, passes over; mercuric chloride acts much more readily on the liquid iodide, the same product being formed; a portion of the iodide is, however, decomposed during the reaction. Iodine chloride acts similarly on both the iodides forming the same chloriodide, $CHCl{:}CHI$. By treatment with benzene and aluminium chloride, anthracene is formed together with a hydrocarbon which distils between 250° and 290°, yields benzoic acid on oxidation with potassium permanganate, and probably has the composition $C_2H_4Ph_2$.

The analogies between the above results and those obtained by Demole (Abstr , 1880, 158), Anschütz (Abstr., 1887, 150) and Heppe (Abstr., 1875, 361) render the formula $CHI{:}CHI$ a more probable one for the iodides than $CH_2{:}CI_2$. Silver acetate has no action on the solid iodide, but forms a monacetate with the liquid compound. Both iodides deposit iodine when heated with alcohol and iodic acid, although no moniodacetylene appears to be formed. From the foregoing experiments it would seem that the first product of the action of acetylene on iodine is the liquid iodide, of which the products of decomposition (C_2HI and HI) combine to form the symmetrical solid iodide, $CHI{:}CHI$; a portion of the iodine, however, acts directly on acetylene forming the moniodo-derivative. Although the liquid iodide behaves as a symmetrical diiodide of acetylene, and is capable of almost complete transformation into the solid compound, it appears to have the composition $C_2H_2I_2 + C_2H_2$. The existence of two different isomeric symmetrical diiodoethylenes is therefore still unproved.

Dimethylacetylene and its Tetrabromides. By A. Favorsky (*J. pr. Chem.* [2], **42**, 143—149).—The author has already shown (*J. pr. Chem.* [2], **37**, 383, 430) that by the action of alcoholic potash on monosubstituted ethylacetylene, a hydrocarbon, C_4H_6, is obtained, having the properties of dimethylacetylene and yielding hexamethylbenzene on treatment with sulphuric acid.

A dibromide, $C_4H_6Br_2$, is obtained as a yellow oil by brominating an ethereal solution of this hydrocarbon at a low temperature. By further bromination (equal mols.) at the ordinary temperature, a crystalline tetrabromide is obtained; when this is recrystallised at the ordinary temperature, the crystals retain their transparency and lustre for some time, whereas when it is recrystalised at a low temperature, the crystals quickly become opaque and milky, especially when touched with one of the first mentioned crystals. Both kinds melt at 230° with some decomposition; their crystallography is fully given.

None of the hydrocarbons of the formula C_4H_6, except Henninger's erythrene, identical with Ciamician and Magnanini's pyrrolylene, have been isolated, being only known as their tetrabromides. The proximity of the melting points of these tetrabomides to that of erythrene tetrabromide indicates the probability of their identity with it. A. G. B.

γ-Chlorobutyronitrile. By S. GABRIEL (*Ber.*, **23**, 2489—2493; compare preceding abstract).—With the hope of throwing light on some of the reactions of orthocyanobenzyl chloride, the analogous fatty compound, γ-chlorobutyronitrile, $CN{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2Cl$, has been investigated. *γ-Thiocyanobutyronitrile*, $CN{\cdot}[CH_2]_3{\cdot}SCN$, is prepared by boiling γ-chlorobutyronitrile with alcoholic potassium thiocyanate for two hours in a reflux apparatus; the alcohol is evaporated, the residue treated with water, and the oily portion separated. It is a pale-yellow, almost odourless liquid, boiling at 195° under a pressure of 30—40 mm., and 220° at 110—120 mm.; it undergoes slight decomposition on distillation at the ordinary pressure. *γ-Dithiodibutyramide*, $NH_2{\cdot}CO{\cdot}[CH_2]_3{\cdot}S{\cdot}S{\cdot}[CH_2]_3{\cdot}CO{\cdot}NH_2$, is obtained by treating the previous compound with concentrated sulphuric acid in the cold; the reaction is violent, a considerable evolution of carbonic and sulphurous anhydrides taking place. After remaining over night, the liquid is poured into cold water, treated with a slight excess of ammonia, and evaporated; on recrystallisation from water, it is deposited in flat needles which melt at 166—167°.

The reaction probably proceeds in two stages; by the elimination of ammonia and carbonic anhydride, an intermediate mercaptan-derivative, $NH_2{\cdot}CO{\cdot}[CH_2]_3{\cdot}SH$, is probably formed, from which hydrogen is eliminated by the action of sulphuric anhydride. *γ-Dithiodibutyric acid*, $COOH{\cdot}[CH_2]_3{\cdot}S_2{\cdot}[CH_2]_3{\cdot}COOH$, is obtained on boiling the amide with concentrated hydrochloric acid; it crystallises from water in plates melting at 108—109°, and is readily soluble in ammonia and alkalis. On heating γ-chlorobutyronitrile with excess of alcoholic hydrogen potassium sulphide for ½—1 hour, crystals are formed; after washing these with alcohol and water, vermilion-red needles are obtained melting at 113—114°. The compound is soluble in alcohol and benzene, but insoluble in water; it has the formula $C_8H_{10}S_3$, and is the analogue of the compound $C_{16}H_{10}S_3$, from orthocyanobenzyl chloride (*loc. cit.*). The *methiodide*, $C_8H_{10}S_3,MeI$, is prepared by dissolving the compound in methyl iodide: on recrystallisation from alcohol, it melts at 103—104°. The formation of this iodide appears to indicate that the red compound is a sulphide of the series R_3S, and its constitution may, perhaps, therefore be represented by the formula $S(C_4H_5S)_2$.

γ-Thiodibutyronitrile, $S(C_3H_6{\cdot}CN)_2$, is obtained on warming γ-chlorobutyronitrile with alcoholic potassium sulphide; it is a colourless, oily liquid boiling above 300°, and is almost odourless at ordinary temperatures. With concentrated hydrochloric acid, it yields *γ-thiodibutyric acid*, $S(C_3H_6{\cdot}COOH)_2$, which is deposited from water in long, flat crystals melting at 99°. It is readily soluble in ammonia and fixed alkalis. J. B. T.

Constitution of the Derivatives of Cyanamide. By A. Smolka (*Monatsh.*, 11, 179—219; compare Abstr., 1888, 42 and 830; 1889, 114 and 951).—The author has fully and carefully reviewed the syntheses and reactions of substituted cyano-compounds, with the object of proving their derivation and constitution. Tables are appended showing the constitution of the possible compounds which may be regarded as being derived (1) from cyanamide, $CN{\cdot}NH_2$, dicyanodiamide, $CN{\cdot}NH{\cdot}C(NH){\cdot}NH_2$, carbamidocyanamide, $CN{\cdot}NH{\cdot}CO{\cdot}NH_2$, and thiocarbamidocyanamide, $CN{\cdot}NH{\cdot}CS{\cdot}NH_2$, by the addition of the elements of ammonia, water, and hydrogen sulphide respectively; (2) from cyanamide, by the addition of another molecule of cyanamide, cyanic and thiocyanic acids respectively; (3) from cyanamide or guanidine, cyanic acid or carbamide, thiocyanic acid or thiocarbamide, by combination with guanidine, carbamide and thiocarbamide respectively; and (4) from dicyanodiamide or biguanide, amidodicyanic acid or dicyanodiamidine (guanyl carbamide), thiocarbamincyamide or thiodicyanodiamidine, biuret, thiobiuret, and dithiobiuret, by combination with cyanamide or guanidine, cyanic acid or carbamide, thiocyanic acid or thiocarbamide respectively. It would be possible to synthesise all the compounds appearing on the tables, if the uret, biuret, triuret, and dicyanodiamide compounds known have the constitutions there attributed to them. Many of the syntheses have been actually brought about; others. however, are impracticable, owing to the compounds being themselves unstable under the conditions necessary to induce combination between their generators.

G. T. M.

Crystallisation of Sodium Hydroxide from Isobutyl Alcohol. By C. Göttig (*Ber.*, 23, 2246—2247).—A compound of the composition $NaOH,6C_4H_{10}O$, is deposited in well-defined crystals, when an almost saturated solution of sodium hydroxide in isobutyl alcohol is evaporated over sulphuric acid; when placed on water, it behaves like other compounds of the same nature, and moves about the surface very quickly during solution. The crystals lose 5 mols. of the alcohol over sulphuric acid. F. S. K.

Oxidation of ε-Methylethylethylene Glycol. By H. v. Pechmann (*Ber.*, 23, 2427—2428).—ε-Methylethylethylene glycol, $OH{\cdot}CHMe{\cdot}CHEt{\cdot}OH$, is treated with bromine-water (4 atomic proportions) and exposed to direct sunlight for a day; the solution is decolorised with sulphurous anhydride, sodium chloride is added, and the solution distilled. The distillate contains acetylpropionyl, and on treatment with phenylhydrazine, the osazone (m. p. 166—167°) is obtained. Certain other compounds, such as hydrobenzoin and tartaric acid, which contain a secondary glycol-group, may be oxidised in the same manner, but diisopropyl glycol is not converted into the corresponding diketone in this way. J. B. T.

Syntheses in the Sugar Group. By E. Fischer (*Ber.*, 23, 2114—2141).—The present paper is a brief survey of the results which have been obtained by the author and others in their investigations of the sugar group.

A few years ago (1886), dextrose, levulose, galactose, and sorbinose were the simplest known members of the sugar group, arabinose, which was at one time thought to be an isomeride of grape-sugar, having been shown by Kiliani (Abstr., 1887, 465) to have the molecular formula $C_5H_{10}O_5$.

The constitution of dextrose and galactose is, at the present time, expressed by the formula $CH_2(OH)\cdot[CH(OH)]_4\cdot COH$, and that of levulose by the formula $CH_2(OH)\cdot[CH(OH)]_3\cdot CO\cdot CH_2\cdot OH$, these formulæ being based on the following facts:—On reduction with sodium amalgam, dextrose and levulose yield mannitol, and galactose yields dulcitol, both of which compounds were proved to be hexahydric derivatives of normal hexane. On oxidation with chlorine- or bromine-water, dextrose and galactose are converted into monocarboxylic acids, gluconic acid and galactonic acid, and on further oxidation into dicarboxylic acids, saccharic acid, and mucic acid; they contain, therefore, the aldehyde-group. Levulose, on the other hand, is only very slowly acted on by cold bromine-water, and is destroyed by more powerful oxidising agents. All three sugars combine with hydrogen cyanide; on hydrolysis, the cyanhydrin obtained from dextrose and galactose yields normal heptylic acid, whilst that obtained from levulose gives methylbutylacetic acid. Both dextrose and galactose combine with phenylhydrazine and with hydroxylamine just like simple aldehydes.

The one argument which is still brought against the aldehyde formula, namely, that dextrose and galactose do not give the characteristic reaction of aldehydes with a sulphurous acid solution of rosaniline, cannot be regarded as of much importance, because no simple fatty hydroxy-aldehyde has yet been tested with this reagent.

The great want of a suitable method for the isolation of sugars was supplied by the discovery of the phenylhydrazine reaction (Abstr., 1885, 53). When a warm 10 per cent. aqueous solution of dextrose is warmed for 10—15 minutes with a solution of phenylhydrazine in dilute acetic acid, glucosazone, $C_{18}H_{22}N_4O_4$, is deposited in crystals. The formation of this substance takes place in two phases (Abstr., 1887, 567); the sugar first combines with the base (1 mol.) like an ordinary aldehyde, forming a readily soluble hydrazone, but in presence of excess of phenylhydrazine the hydrazone undergoes a peculiar oxidation, one $CH_2\cdot OH$-group being converted into the carbonyl-group, which then reacts with the base (1 mol.) in the usual way.

The fact that the osazone obtained from dextrose is identical with that formed from levulose proves, not only that this explanation of the reaction is correct, but also that both compounds have the constitution $CH_2(OH)\cdot[CH(OH)]_3\cdot C(N_2HPh)\cdot CH{:}N_2HPh$.

All natural sugars which reduce Fehling's solution, including lactose and maltose, behave in this way with phenylhydrazine, as do also all aldehydes and ketones which contain a $CH_2\cdot OH$- or $CH\cdot OH$-

group adjacent to the aldehyde- or carbonyl-radicle. The hydrazones of most of the naturally occurring sugars are readily soluble in water, but mannose and its optical isomerides, and the various artificial sugars containing 7, 8, and 9 carbon-atoms (comp. this vol., p. 1230), form hydrazones, which are only sparingly soluble, and which can therefore be most conveniently employed for the identification or isolation of these sugars, into which they can be reconverted by decomposition with hydrochloric acid. When a hydrazone is vigorously shaken with hydrochloric acid of sp. gr. 1·19 at the ordinary temperature, a brown solution of the hydrochloride is obtained, but after one to two minutes the separation of phenylhydrazine hydrochloride commences, and in 10 to 15 minutes decomposition is complete; the sugar can be easily isolated from the filtered solution.

Of far more value for the identification of sugars are the almost insoluble, crystalline osazones, which differ from one another in solubility, melting point, and optical behaviour. On reduction with zinc-dust and glacial acetic acid, they are converted into basic compounds. Glucosazone, for example, yields the compound

$$CH_2(OH)\cdot[CH(OH)]_3\cdot CO\cdot CH_2\cdot NH_2,$$

one hydrazine-group being displaced by oxygen, the other being converted into an amido-group, with elimination of aniline; when this base is treated with nitrous acid in the cold, it is converted into levulose (Abstr., 1888, 39). As the other bases obtained in like manner do not crystallise well, the reconversion of the osazones into the sugars is best effected by decomposing them with fuming hydrochloric acid (Abstr., 1888, 1267). When finely divided glucosazone is quickly heated to 40° with fuming hydrochloric acid, the solution kept at this temperature for one minute, and then cooled to 25°, phenylhydrazine hydrochloride separates in crystals, and in 10 minutes the reaction is at an end; the filtered solution contains glucosone, which can be isolated in the form of its insoluble lead compound.

Glucosone has not yet been obtained in crystals; its reactions show that it is the aldehyde of levulose, $CH_2(OH)\cdot[CH(OH)]_3\cdot CO\cdot COH$, and its formation is expressed by the equation—

$$C_6H_{10}O_4(N_2HPh)_2 + 2H_2O = C_6H_{10}O_6 + 2N_2H_3Ph.$$

It combines with phenylhydrazine, yielding glucosazone; it gives crystalline quinoxaline-derivatives with aromatic orthodiamines, and on reduction with zinc-dust and acetic acid, it is completely converted into levulose.

It seems probable that other, as yet unknown, ketone-sugars can be obtained from the aldehyde-sugars by the same method as that employed in the transformation of dextrose into levulose. The inverse process, namely, the conversion of a ketone- into an aldehyde-sugar, has already been carried out as follows:—Levulose can be reduced to mannitol, which, on oxidation with nitric acid, gives the aldehyde mannose, and from the latter dextrose can be obtained in the manner described below.

The osazones may also be employed for ascertaining the molecular formula of a sugar, as was done in the case of arabinose, sorbinose, and xylose; also for determining its constitution, as exemplified by the case of rhamnose and lactose.

The hydrazones and osazones are also particularly valuable for the detection of new sugars and sugar-like substances, witness the case of mannose, the true aldehyde of mannitol, a sugar which, first prepared artificially by the oxidation of the alcohol, was soon afterwards detected in the vegetable kingdom by Tollens and Gans, and by R. Reiss (Abstr., 1889, 687), who named it seminose. Erythrose and glycerose, two sugar-like substances, obtained by the oxidation of erythrol and glycerol respectively (Abstr., 1888, 1264), were also isolated by means of their osazones.

Glycerose, which is most conveniently obtained by the oxidation of glycerol with bromine and sodium carbonate, was proved to have the molecular formula $C_3H_6O_3$ by the analysis of the osazone, but it is probably a mixture of glyceraldehyde and dihydroxyacetone; when treated with dilute alkalis, it gives α-acrose (Abstr., 1888, 358), for the formation of which glyceraldehyde is necessary, and it combines with hydrogen cyanide, yielding a cyanhydrin, which on hydrolysis is converted into trihydroxyisobutyric acid (Abstr., 1889, 478), a compound that can only be formed from dihydroxyacetone.

The first step in the synthesis of sugars was made by Butlerow (*Annalen*, **120**, 295), the discoverer of methylenitan, a yellowish, sweet syrup, obtained by treating a hot solution of trioxymethylene with calcium hydroxide; this substance shows the usual reactions of sugars, but is optically inactive, and seems not to ferment with yeast. The method of preparing formaldehyde having been greatly improved by Loew (Abstr., 1886, 609), it became possible to examine the condensation of this substance more fully, which soon led to the discovery of formose (*ibid.*, 610). This compound, which was obtained by Loew by the condensation of formaldehyde with calcium hydroxide, was thought by him to be different from methylenitan, and to have the composition $C_6H_{12}O_6$; the author proved, however (Abstr., 1888, 590), that both substances consist of various sugar-like compounds, and are practically identical, the principal constituent of both being a sugar (formose) of the composition $C_6H_{12}O_6$, another sugar, α-acrose, being also present in the two mixtures. A little later Loew (Abstr., 1889, 581) obtained a sugar, which he named methose, by the condensation of formaldehyde by the action of lead and magnesium oxides, but this product was proved by the author to be identical with α-acrose. In the meantime (Abstr., 1887, 651, and 1888, 39), it was found that two isomeric sugars, α- and β-acrose, are formed when acraldehyde bromide is treated with a cold solution of barium hydroxide; these two substances, which can be most conveniently prepared by treating glycerose with cold dilute alkalis, can be isolated from various other sugar-like substances, which are produced at the same time, by means of their osazones, the latter being reconverted into the sugars by treatment with hydrochloric acid, in the manner described above.

α-Acrose, which is only obtained in small quantities, seems to be formed by a sort of aldol condensation of equal molecules of glyceraldehyde and dihydroxyacetone, in accordance with the equation—

$$CH_2(OH)\cdot CH(OH)\cdot CHO + CH_2(OH)\cdot CO\cdot CH_2\cdot OH = CH_2(OH)\cdot[CH(OH)]_3\cdot CO\cdot CH_2\cdot OH;$$

its formation from glycerose and from formaldehyde takes place under conditions which exist in the vegetable kingdom, and is, therefore, of far greater interest than its preparation from acraldehyde bromide.

The remarkable resemblance of α-acrosazone to glucosazone, from which it differs principally in being optically inactive, at once led the author to suppose that α-acrose was the optically inactive form of dextrose or levulose. On decomposition with hydrochloric acid, α-acrosazone yields a sweet syrup which ferments with yeast, gives levulinic acid with hydrochloric acid, and, on reduction with sodium amalgam, is converted into a crystalline hexahydric alcohol, α-acritol (Abstr., 1889, 484), the resemblance of which to mannitol is so close that it was thought to be simply the inactive form of this naturally occurring alcohol. But for the fortunate discovery that α-acritol can be prepared from mannose, it would have been a task of considerable difficulty to prove its relationship to mannitol, as only 0·2 gram of α-acritol is obtained from 1 kilo. of glycerol.

When mannose, the aldehyde of mannitol, is oxidised with bromine-water, it is converted into a monocarboxylic acid, mannonic acid, $C_6H_{12}O_7$, which can be purified by means of the hydrazide by the method previously described (this vol., p. 152). On evaporating an aqueous solution of the acid, a crystalline lactone, which differs from the lactone of arabinosecarboxylic acid only in possessing an opposite rotatory power, is obtained; when these two lactones are mixed together in aqueous solution, they combine to form an optically inactive lactone. On reduction with sodium amalgam in the manner already described (this vol., p. 1149), the three lactones are converted into a dextro-rotatory, levo-rotatory, and inactive mannose respectively; these sugars, on further reduction, yield the corresponding active and inactive mannitols, the inactive modification being identical with synthetical α acritol.

The relationship between all the known members of the mannitol series is shown in the table on the following page, the letters *d*, *l*, and *i* (from dexter, lævus, and inactive) serving to distinguish the various isomerides; the compounds marked with an asterisk are new, and will be described in a future paper.

Now since i-mannitol is identical with the α-acritol obtained synthetically, and α-acrose, obtained from α-acrosazone, is identical with i-fructose (this vol., p. 466), all that remains to complete the synthesis of a natural sugar is to convert a member of the inactive into a member of the active series. This can be accomplished in the case of the sugars themselves, through the agency of yeast. When an aqueous solution of synthetical α-acrose (i-fructose) is fermented with yeast, the solution, which was previously inactive, becomes strongly dextro-rotatory, and yields a glucosazone which is dextro-rotatory; this solution contains a sugar which is named

MANNITOL SERIES.

l-Fructose.	i-Fructose. (α-Acrose).	d-Fructose. (Fruit-sugar).
	i-Glucosone.	d-Glucosone.

Mannose Group.

l-Mannonic acid. (Arabinosecarboxylic acid).	i-Mannonic acid.	d-Mannonic acid.

l-Mannitol.	i-Mannitol. (α-Acritol).	d-Mannitol.
l-Mannosaccharic acid. (Metasaccharic acid).	*i-Mannosaccharic acid.	*d-Mannosaccharic acid.

Glucose Group.

*l-Gluconic acid.	*i-Gluconic acid.	d-Gluconic acid.
*l-Glucose.	*i-Glucose.	d-Glucose. (Grape-sugar).

Alcohols wanting.

*l-Saccharic acid.	*i-Saccharic acid.	d-Saccharic acid.

l-fructose, in spite of the fact that it is dextro-rotatory, because the letters *d* and *l* do not denote in every case the irregularly changing rotatory power, but express rather the chemical relationship between the compounds; the letter *d* was chosen for the group of natural sugars, because most of them are dextro-rotatory, and although levulose is levo-rotatory, it belongs to the same geometrical series as d-mannose.

i-Mannose ferments with yeast just like i-fructose, the dextro-rotatory modification being destroyed, and the levo-rotatory modification remaining unchanged (this vol., p. 446), so that in both cases the yeast uses that part of the sugar to which it has been accustomed in the past.

As fermentation gives the less interesting compounds of the *l*-series only, chemical methods have to be employed for obtaining the natural sugars. i-Mannitol, on careful oxidation with nitric acid, yields i-mannose, which is converted into i-mannonic acid by treatment with bromine-water; by means of its strychnine or morphine salt, this acid can be separated into d- and l-mannonic acids, which, on reduction, give the optically active mannoses and mannitols. The d-mannose obtained in this way can be transformed into d-fructose (levulose) by means of its glucosazone, which is identical with that of dextrose and of levulose. The conversion of dextrose into mannose, and *vice versâ*, can be accomplished by means of the acids. When gluconic acid is heated with quinine at 140°, it is partially converted into d-mannonic acid; the latter, under the same conditions, gives considerable quantities of d-gluconic acid, which on reduction yields d-glucose (dextrose), the synthesis of this natural sugar being thus completed.

l-Mannonic acid, in like manner, can be converted into the optical isomeride, l-gluconic acid, but the process is difficult to carry out, and the yield is small.

l-Gluconic acid can be more conveniently obtained, together with arabinosecarboxylic acid (l-mannonic acid), by treating arabinose with hydrocyanic acid and hydrolysing the product; this is the first instance of the formation of two stereochemical isomerides by the combination of an aldehyde with hydrogen cyanide.

The two active gluconic acids are very similar in appearance, and combine in aqueous solution yielding an inactive acid which forms salts and other inactive derivatives; on reduction, they are converted into the corresponding optically active isomerides of dextrose, namely, l- and i-glucose, and on oxidation they yield l- and i-saccharic acid.

The isomerism of all the compounds included in the above table can be explained in accordance with Le Bel and Van't Hoff's hypothesis, but the views at present held on the combination of isomeric compounds containing asymmetrical carbon-atoms will probably have to be modified.

Since all the members of the mannitol series can be prepared from their elements, the most important natural sugars have now been synthesised; but it is possible to prepare artificially sugars containing 7, 8, 9, &c., carbon-atoms by converting one containing 6 carbon-atoms into the acid containing 7, by means of hydrogen cyanide, and then reducing the lactone of this acid with sodium amalgam. The sugar containing 7 carbon-atoms produced in this way can then be employed for continuing the process up the series; mannoheptose,* mannooctose, and mannononose have already been prepared (compare this vol., p. 1230).

Many of these new synthetical sugars will certainly be found in the vegetable kingdom, and, even already, it has been proved that the heptahydric alcohol, formed by the reduction of mannoheptose, is identical with perseitol, $C_7H_{16}O_7$, a compound which occurs in the fruit of *Laurus persea*.

The most interesting result of these investigations is, however, the synthesis of dextrose and levulose, which throws some light on one of the most important and most wonderful physiological processes, namely, the formation of carbohydrates in green plants. As far as is known, these two sugars are not only the first products of assimilation, but they are also the material from which all other organic constituents of plants are prepared. Since it has not yet been proved that formaldehyde occurs in plants in any appreciable quantity, it seems probable that a search for other intermediate products, such as glycerose, might be attended with success. The fact that the active sugars only are formed in plants, whilst inactive acrose is alone produced by chemical synthesis, is still more interesting, as the question arises whether the formation of optically-active substances is a prerogative of plants—the result it may be of a kind of vital force? The answer to this question is probably in the negative, and it is, doubtless, but incomplete knowledge that gives an appearance of the wonderful to the process. No facts are known which directly negative the view that plants first prepare inactive sugars, and then split them up, making use of the members of the d-mannitol series for the production of starch, cellulose, inulin, &c., the optical isomerides serving to fulfil other functions.

---

* The system of nomenclature suggested for the sugars has been already explained (this vol. p. 598).

Another interesting problem is, what would be the effect if some of the artificial sugars were supplied to animals, instead of the natural products? Mannose, which is so nearly related to dextrose, would probably serve as nutriment, even to the more highly organised animals, and the slight change in food might produce corresponding changes in assimilation. The liver, for example, might secrete a new glycogen, the mammæ a substitute for lactose. The consequence of substituting a pentose or a heptose, or, more especially, the fermentable nonose, for ordinary sugar might be far more important, and it would not be surprising if, under such circumstances, the functions of the blood and the tissues were modified; the pig, for example, secreting a different fat, the bee a different wax. As, moreover, with the help of fungi, plants prepare not only the more complex carbohydrates and fats, but albuminoïds as well, they might be forced to form different albuminoïds if supplied with some new sugar; a change of architecture, under chemical influence, might in this way be brought about, which would lead to the most remarkable results, and produce changes of form more fundamental than it has yet been found possible to do by crossing and selection. Although in the past hundreds of organic substances have been supplied to animals in order to determine what changes they undergo in the system, the materials used had invariably no resemblance whatever to natural food-stuffs; in the possession of new sugars, the physiologist will have a fruitful field of research, his labours in which are likely to lead to remarkable results.

For the chemist there remains work enough, even in the group of the carbohydrates; in accordance with present theories sixteen hexoses, of the same structure as dextrose, without counting the inactive forms, can exist in the dulcitol series, and, probably, all these compounds are actually capable of existence. It may even be said, with some assurance, that their preparation by the methods employed in the mannitol series will not be exceptionally difficult, as soon as it has been found possible to convert the various tartaric acids into the optically isomeric trihydroxybutyric acids.
